Alternative routes of access may further expand the patient population who are not transfemoral or transapical candidates. The routes frequently require some form of surgical exposure with modification of existing THV delivery platforms. The subclavian artery, via a right or left subclavian artery cutdown and/or conduit, and direct aortic access, via a parasternal incision or hemisternotomy, are the two most common routes described, both of which require surgical exposure. Current device sizes do not permit a fully percutaneous access from an alternative arterial site, such as the brachial artery, though this may be possible in the future.

**Adjunctive Technology**

Accessory technology in the THV field may revolutionize the deployment of THV, imaging of the aortic valve, hemostasis of surgical sites, and safety profile of the procedure. New balloon technology may prevent valve slippage or minimize PVL, while reducing the delivery system profile. A number of percutaneous transapical systems may provide a safe and bloodless entry site to the left ventricle. Cerebral protection devices, such as SMT (Herzliya, Israel), Embrella (Edwards Lifesciences), and Claret Medical (Santa Rosa, CA) may reduce stroke rates for transfemoral and transapical approaches by the use of deflectors and filters. Finally, advanced imaging techniques may offer increased aortic annulus resolution and anatomy that improves sizing, while positioning software programs automate valve positioning based on individual anatomy. These telemanipulation ideas offer tremendous potential for application in the field of THV.

**Conclusions**

TAVR has become a safe, effective, and appropriate first-line therapy for the treatment of symptomatic severe AS in patients with prohibitive surgical risk. Both the transfemoral and transapical approaches are available, depending on patient anatomy and characteristics. The Edwards SAPIEN and Medtronic CoreValve THV systems are under study in the United States, but an explosion of new technology and innovation is on the forefront in the field of THV. Results from the PARTNER study have established THV as a superior treatment when compared with medical therapy for severe AS, and further study of lower risk patient populations is underway.

**SUGGESTED READINGS**

Dr. Williams and colleagues at Columbia University have the leading experience and expertise in the United States regarding transcatheter aortic valves. This chapter is outstanding and provides us a detailed approach to this complexed intervention. The chapter descriptions are clear and they give us a terrific approach to this important new technology.

The important concepts include that of a heart team (cardiologist and surgeons), hybrid lab, and appropriate selection of candidates. I cannot overstate the importance of the selection criteria. There is no doubt that when used properly, this technology has outstanding results in high-risk patients. However, there are many patients who are just too high risks for any procedure let alone a valve operation. Despite the fact that the approach can be completely percutaneous, as an aortic valve surgery this cannot be ignored. Though we had outstanding results in the PARTNER trial, our commercial results lagged in the beginning because of issues with selection. Often the patient comorbidities are more important than their aortic valve disease.

There are still some issues that need to be learned and dealt with. In the initial experiences, vascular complications were the major cause of morbidity and mortality. I think things have gotten better with appropriate imaging and use of transapical and transaortic routes for deployment. An ongoing issue is aortic insufficiency which occurs in some fashion in the majority of patients. This relates to evolving technology and limited valve sizes. However, we will need to understand better what this means to overall survival, both short and long term.

Coronary Artery Disease

Coronary Artery Bypass Grafting using Cardiopulmonary Bypass
Ahmet Kilic, Chittor Sai-Sudakar, Juan Crestanello, and Robert S.D. Higgins

INTRODUCTION
Atherosclerotic heart disease continues to be the leading cause of death in the United States. While coronary artery bypass surgery has enjoyed a storied evolution since the 1960s to be among the most spectacular advances in medicine, the field of cardiothoracic surgery is undergoing a significant evolution with the advent of more effective medical therapies, alternative percutaneous and hybrid revascularization techniques, and percutaneous valve procedures. Ironically as these alternative strategies evolve, the need for effective surgical myocardial revascularization techniques using cardiopulmonary bypass is becoming even more critical in patients with advanced atherosclerotic heart disease and left ventricular dysfunction. Central to this expanding need is the refinement of indications for coronary artery bypass procedures in critically ill patients. Older patients with advanced disease, left ventricular dysfunction, and multiple comorbidities create even greater challenges for the practicing cardiac surgeon.

In this chapter, we will review the evolving assessments of coronary artery anatomy using innovation imaging techniques. A full understanding of assessments of myocardial viability and suitability for revascularization continues to be of critical importance in this discussion. We will also review the impact of left ventricular dysfunction on surgical revascularization outcomes in patients with low ejection fraction. The importance of surgical risk reduction in complicated coronary revascularization particularly in patients on platelet inhibitor therapies, that is, clopidogrel as well as evolving perioperative management techniques, has significantly reduced the morbidity and perioperative complications of coronary revascularization. The indications for hybrid and multivessel disease management as well as left main coronary revascularization will also be reviewed.

No discussion of the management of coronary artery disease (CAD) by conventional revascularization techniques can ignore the importance of the development of appropriateness criteria for the management of multivessel disease and left main coronary disease. Evidence highlighting the benefits of coronary artery bypass grafting (CABG) continues to demonstrate significant survival advantage in patients with multivessel disease compared with percutaneous coronary intervention (PCI). In these recent contributions to the literature, critical evidence from randomized clinical trials and case-matched patient studies, CABG was associated with lower risk of death than stenting underscoring the comparative effectiveness of CABG in these patients. As we appreciate the comparative benefits of CABG versus PCI, we also have to be mindful of the challenges in the current reimbursement environment to manage preventable complications, so as to reduce the financial impact of readmissions in the current healthcare economy. Only if the surgical profession can minimize the risk in appropriately selected patients, enhance patient outcomes, reduce perioperative complications, and readmission rates after CABG, will we be able to continue to demonstrate the comparative benefits of CABG.

ASSESSMENT OF CORONARY ANATOMY

Coronary Angiography
Coronary angiography remains the gold standard in defining coronary anatomy and graft patency. It is an invasive procedure and is associated with procedural risks including stroke, native vessel dissection, acute myocardial infarction (MI), ventricular arrhythmias, and puncture site morbidities such as hematomas and pseudoaneurysm formation. In addition, its deficiency in three-dimensional definition has led to the investigation of other noninvasive imaging techniques to define the overall coronary pathoanatomy. Initial attempts to utilize electron beam tomography and helical scan computed tomography (CT) were not encouraging due to motion artifacts, the need for prolonged breath holding, and image distortion due to metallic clips. Newer imaging techniques such as multidetector computed tomography (MDCT) have begun to revolutionize the diagnostic field.

Multidetector Computed Tomography
MDCT allows for fast data acquisition in a single breath hold of 25 to 30 seconds with varying slice thickness collimation, and Gantry rotation speeds following intravenous administration of 80 to 100 ml of nonionic contrast agent and a predetermined delay period to allow the contrast to reach the arterial circulation. Preprocedure beta-blockade allows for a heart rate of <60 beats per minute since faster hearts along with atrial fibrillation and...
can dictate the type of surgery offered to the patients. Coronary calcification is obscured by the dye used in angiography. In an open procedure, such areas can be palpated and anastomosis can be performed in the noncalcified segments of the coronary vessels. However, tactile feedback is absent in the minimally invasive procedures. Regions of coronary vessels burdened by calcification as evidenced by MDCT can be avoided for anastomosis.

**Evaluation of Native Coronary Anatomy**

Martuscelli and coworkers investigated the accuracy of MDCT in detection of significant (>50%) stenosis using a scanner equipped for 16 × 0.625 mm collimation and compared it with coronary angiography in 64 patients with suspected CAD. Eighty-four percent of the angiographic segments were evaluable. Severe calcification, cardiac motion artifacts, poor opacification, and blending of the segments with veins hindered the evaluation of the remaining segments. In the segments that were evaluable, namely, vessels >1.5 mm in diameter, MDCT had a sensitivity, specificity, positive predictive value, and negative predictive value of 89%, 98%, 90%, and 98%, respectively; MDCT had a 100% specificity and sensitivity in detecting total occlusion. Overall, MDCT detected 78% of stenoses detected by angiography. Cury et al. demonstrated an excellent correlation between 16-slice MDCT and angiography in quantifying the degree of stenosis. However, MDCT tended to overestimate the stenosis. The evaluation of the coronary anatomy and the results were significantly better than those obtained with the 4-slice MDCT. With the advent of 64-slice MDCT, Rubinshtein et al. analyzed its efficacy in the emergency room in evaluating patients with chest pain. They observed that emergency room MDCT had a high positive predictive value for diagnosis of acute coronary syndrome and a negative study predicted a low rate of major adverse cardiovascular event. In this study, only 4.6% of the coronary segments were of low image quality testifying to improvements in MDCT technology and also aided by the low calcium burden. These diagnostic tests have also been helpful in planning for minimally invasive revascularization procedures. During the procedures of minimally invasive direct coronary artery bypass (MIDCAB) or totally endoscopic coronary artery bypass (TECAB), the visualization of the target vessels is often limited and it is critical to identify the target vessel correctly and bypass it at the correct site. A common source of error is the bypassing of a large diagonal instead of the left anterior descending (LAD) artery during minimally invasive surgery. In addition, the target vessels could be buried under epicardial fat, covered by a myocardial bridge, run an intramural course, or heavily calcified. Newer generation MDCT scanners have been shown to identify these variations in coronary anatomy better than coronary angiography. These findings can be buried under epicardial fat, covered by a myocardial bridge, run an intramural course, or heavily calcified. Newer generation MDCT scanners have been shown to identify these variations in coronary anatomy better than coronary angiography. These findings...
the outer diameter. Inside the lumen of the stent, there is an increase in the attenuation that can be minimized by utilizing submillimeter collimation and a sharp reconstruction kernel. With improving technological areas, the larger diameter stents in the left main coronary artery and the proximal coronary vasculature can be analyzed for evidence of decreased luminal diameter due to intimal hyperplasia. The native coronary vasculature in the immediate vicinity of the stent is difficult to evaluate for stenosis due to beaming artifacts. In addition, beam hardening produces dark areas adjacent to the clips stimulating stenosis especially at the anastomotic points.

MDCT can be effectively used as a one-stop test to evaluate the different causes of chest pain following CABG. Dual source and 256-slice scanning allow for fast data acquisition, may further simplify the test, improve diagnostic accuracy, and eliminate the current limitations imposed by rapid hearts rates. MR coronary angiography is being evaluated to analyze its potential as a noninvasive diagnostic tool. The summary statement released by the American Heart Association in collaboration with other councils has recommended that neither coronary artery CTA nor MRA should be used to screen for CAD in patients who have no signs or symptoms of CAD (Class III, level of evidence C). The potential benefit of noninvasive coronary angiography is likely to be greatest and is reasonable for symptomatic patients who are at intermediate risk for CAD after initial risk stratification including patients with equivocal stress-test results (Class IIa, level of evidence B). Concerns regarding radiation dose limit the use of coronary CTA in high-risk patients who have a very low pretest likelihood of coronary stenoses; they are likely to require intervention and invasive catheter angiography for definitive evaluation; thus, CTA is not recommended for those individuals (Class III, level of evidence C). Pronounced coronary calcification may negatively impact interpretability and accuracy of coronary CTA and thus, the usefulness of CTA is uncertain in these individuals (Class IIb, level of evidence B).²

**ASSESSMENT OF MYOCARDIAL ISCHEMIA AND VIABILITY**

Total or sub-total occlusion of any portion of the coronary vasculature leads to varying spectra of myocardial viability including infarction, myocardial stunning, and hibernating myocardium. Reestablishment of the coronary perfusion by fibrinolytic therapy or percutaneous interventions is the cornerstone of the ST elevation myocardial infarction (STEMI) protocols adopted by nearly all the hospitals across the country. In less emergent cases or patients presenting in outpatient settings with symptoms of angina or congestive heart failure and documented evidence of critical CAD and depressed systolic function, there is considerable debate about the utility of further assessment for myocardial viability prior to any intervention.

**Nuclear Imaging**

Nuclear imaging utilizes technetium-labeled radioisotopes or positron emission tomography (PET) tracers under rest and stress conditions to detect the extent and severity of myocardial ischemia (Table 51.2), and single-photon-emission computed tomography (SPECT) myocardial perfusion imaging is considered a useful tool for risk assessment for CAD. Following the injection of the thallium or technetium-labeled tracers (sesta­mibi or tetrofosmin), their uptake by the myocyte is dependent on the regional myocardial blood flow. The subsequent washout of these radiopharmaceuticals is faster from normal myocardium compared with the ischemic myocardium. The images obtained at this time point are usually considered the resting images. Subsequently, stress images are obtained using exercise stress protocols (Fig. 51.1). In patients who are unable to exercise or who have other pathologies such as an abnormal EKG, left bundle-branch block, paced rhythm, chronic obstructive pulmonary disease, or asthma pharmacological stress is induced utilizing several agents (vasodilator therapy, adenosine, dipyridamole, or dobutamine). The images obtained at rest and stress are compared and myocardial perfusion defects are graded as myocardial ischemia, reversible or fixed perfusion defects. Myocardial perfusion imaging utilizing SPECT has been validated in several studies as a useful screening tool for CAD in patients with risk factors and in addition for the detection of extent and degree of myocardial ischemia. Glucose metabolism substitutes fatty acid metabolism as the main energy source in ischemic but viable myocardium. ¹⁸F fluorodeoxyglucose (FDG), a glucose analog combined with a tracer (Rubidium-82), is used to evaluate the glucose metabolism in the myocyte. Following the detection of a fixed perfusion defect on perfusion imaging, preservation of ¹⁸F-FDG uptake in that region by a PET scan is suggestive of hibernating myocardium and indicative of the beneficial effect of revascularization in patients with ventricular dysfunction.

Disturbances in fatty acid metabolism in the myocyte persist for up to 30 hours following the cessation of symptoms from a transient coronary event. This pathway has been investigated as a potential diagnostic tool for a recent coronary event by using radioiodine-labeled branched chain fatty acid β-methyl-p-[123I]-iodophenyl pentadecenoic acid (BMIPP) SPECT scans to detect acute coronary syndromes in the emergency room with a sensitivity, specificity, and negative predictive value of 81%, 61%, and 83%, respectively.

**Cardiovascular Magnetic Resonance**

Over the last decade, cardiovascular magnetic resonance (CMR) has gained in popularity as a reliable diagnostic modality for cardiac structure and function and myocardial ischemia to the extent that clinical utility pathways are being developed to utilize this technology for patients presenting with acute coronary syndromes (Fig. 51.2).

---

**Fig. 51.1.** Exercise/pharmacological stress ⁹⁹mTc myocardial perfusion imaging protocol. (From Yoshinaga K, Manabe O, Tamaki N. Physiological assessment of myocardial perfusion using nuclear cardiology would enhance coronary artery disease patient care: which imaging modality is best for evaluation of myocardial ischemia? (SPECT-side). Circ J 2011;75(3):713-722.)

**Fig. 51.2.** Algorithm for potential usage of cardiovascular magnetic resonance imaging in patients with suspected ST elevation myocardial infarction. From Kim HW, Farzaneh-Far A, Kim RJ. Cardiovascular magnetic resonance in patients with myocardial infarction: current and emerging applications. J Am Coll Cardiol 2009;55(1):1-16, with permission.
Cardiovascular Magnetic Resonance Techniques

The powerful magnetic field exerted by CMR scanner with a field strength of 1.5 to T (30,000 times stronger than the earth’s magnetic field) aligns the hydrogen atoms in the human body. Subsequently, radiofrequency pulses delivered by the scanner excite the hydrogen nuclei and receiver coils detect the signals as the hydrogen nuclei relax. The strength of the signal is dependent on the density of the protons in any given tissue and accounts for the contrast in the MR images. In addition, the images are also dependent on two distinct relaxation patterns of the protons. T1 is the longitudinal relaxation time and is the time required for a substance to be magnetized after being placed in a magnetic field, whereas T2, the transverse relaxation time is a measure of how long the resonating protons remain in phase following a radiofrequency pulse.

- **Spin Echo Imaging:** Blood is black and tissues are bright.
- **Gradient Echo Imaging:** Blood is bright and cardiac tissue is dark.
- **Cine CMR:** Provides important information regarding segmental and global ventricular function, wall thickness at different time points of the cardiac cycle, and structural heart defects including aneurysms, septal defects, and valve pathologies.
- **Perfusion Imaging:** For the assessment of myocardial perfusion and used in conjunction with vasodilators. Vasodilation with adenosine or dipyridamole following a bolus contrast injection causes a three- to five-fold increase in blood flow in myocardial regions supplied by normal coronary arteries resulting in bright areas in contrast to the areas supplied by stenotic coronary arteries, which appear as dark regions on imaging.
- **Delayed Contrast Imaging:** For the assessment of the ability of myocardium to clear the contrast (gadolinium diethylenetriamine penta-acetic acid). Normal myocardium clears the contrast quickly and appears dark. Ischemic or scar tissue appears bright due to delayed clearance of contrast.

**ASSESSMENT OF MYOCARDIAL VIABILITY**

In canine models of acute and chronic MI, contrast MRI was used to distinguish between reversible and irreversible ischemic injury independent of wall motion and infarct age. Kim et al. observed that contrast MRI in combination with cine MRI could identify acute MI (hyperenhanced with contractile dysfunction), injured but viable myocardium (not hyperenhanced but with contractile dysfunction and normal myocardium (not hyperenhanced and with normal function). Subsequently, the same group investigated the use of contrast-enhanced MRI to predict improvements following revascularization in regions of abnormal ventricular contraction. Gadolinium-enhanced MRI was performed in 50 patients with ventricular dysfunction before either surgical or percutaneous revascularization to assess the transmural extent of the hyperenhanced myocardium postulated to represent nonviable myocardium. In addition, cine MRI was performed to assess the regional contractility at the same locations before and after revascularization. Following analysis of the data, the authors demonstrated that the likelihood of improvement in regional contractility after revascularization decreased progressively as the transmural extent of the hyperenhancement before revascularization increased. The amount of left ventricular mass that was dysfunctional and not hyperenhanced before revascularization strongly related to the degree of improvement in the wall motion score and ejection fraction after revascularization. The investigators clearly demonstrated that reversible myocardial dysfunction can be identified by contrast-enhanced MRI before coronary revascularization (Fig. 51.3). Further confirmatory studies established the value of delayed enhancement MRI as a powerful predictor of myocardial viability after surgery.

**HYBRID CORONARY REvascularization**

While conventional revascularization is routine in patients with triple-vessel CAD, hybrid coronary revascularization (HCR) has evolved to combine (a) surgical revascularization to the LAD coronary artery with the LIMA through a minimally invasive approach and (b) percutaneous coronary revascularization (PCI) to the circumflex and right coronary artery (RCA) territories. HCR is an alternative revascularization strategy for patients with triple-vessel CAD. HCR achieves complete revascularization and combines the advantages of bypass surgery and PCI (Fig. 51.4).

![Fig. 51.3.](image-url) Relationship between the transmural extent of hyperenhancement before revascularization and the likelihood of increased contractility after revascularization. (From Kim RJ, et al. The use of contrast-enhanced magnetic resonance imaging to identify reversible myocardial dysfunction. N Engl J Med 2000;343(20):1445-1453.)
Although traditional CABG is highly effective in improving symptoms and increasing survival, it is associated with morbidity and mortality mostly related to the invasiveness of the procedure. Revascularization of the LAD coronary artery with the LIMA provides the major clinical advantage of CABG and provides the majority of the survival advantage provided by CABG with the best long-term patency rate. Compared with PCI, LIMA bypass for isolated lesions of the LAD results in better angina relief, and lower incidence of major adverse cardiovascular and cerebrovascular events and need for repeat revascularization. Long-term patency of saphenous vein bypass grafts (SVG) is inferior to that of arterial grafts. It is unknown how the patency of SVG compares to the patency of DES in the same position.

Table 51.3 summarizes the potential advantages of HCR and compares them with PCI and CABG. HCR achieves complete revascularization potentially combining the advantages of both revascularization strategies: low procedural morbidity and mortality, low restenosis rate, and low repeated revascularization rates.

HCR builds on the concept of “heart team” approach for the management of coronary revascularization. The heart team, integrated by cardiac surgeons, interventional cardiologists, clinical cardiologists, and primary physicians, evaluate the patient’s clinical and angiographic characteristics and offer the patients a revascularization strategy based on best evidence and clinical guidelines. For HCR, interventional cardiologist and surgeons should agree that the patients are candidates for both (a) PCI to the non-LAD territories and (b) minimally invasive bypass to the LAD using the LIMA.

Theoretically, all patients with triple-vessel CAD can be considered for HCR. However, until the results of randomized prospective trials exploring the safety and efficacy of HCR compared with conventional CABG are available, HCR should be reserved for:

(a) Patients with proximal LAD stenosis or chronic total occlusion of the LAD and focal lesions in the RCA or circumflex artery amenable to PCI. Patients with multisegment and diffuse disease of the RCA or circumflex artery, which would require complex PCI with multiple stents, are better candidates for conventional CABG. The SYNTAX score is helpful to select these patients. Patients with a high SYNTAX score because of complex lesions in the RCA and circumflex territory may benefit from conventional CABG rather than PCI to those targets. The LAD target should be adequate for bypass.

(b) Patients with limited or absent venous conduits.

(c) Patients with severe calcification of the ascending aorta.

(d) Patients at high risk for conventional surgery secondary to multiple comorbidities or who would tolerate a median sternotomy poorly (elderly, disabled or deconditioned patients, immunosuppressed).

Patients with double-vessel CAD may also benefit from HCR. These indications are reflected in the European Society of Cardiology and ACCF-AHA guidelines (Table 51.4).

HCR is contraindicated in patients who are hemodynamically unstable or in cardiogenic shock, or who have malignant arrhythmias. Patency of the LIMA should be evaluated preoperatively either by conventional angiogram or by CT angiography. Patients unable to tolerate single-lung ventilation due to underlying poor pulmonary function (severe COPD with FEV1 <50% predicted, baseline hypercarbia or hypoxia on ABG, severe pulmonary hypertension) are not candidates for HCR.

Patients with contraindications to PCI are also not candidates for HCR. Those include patients with:

(a) In stent stenosis in a non-LAD territory.

(b) Intolerance to clopidogrel or inability to take double antiplatelet therapy for more than a year.

(c) Nonresponders to antiplatelet therapy.

(d) Severe renal dysfunction.

Relative contraindications include:

- (e) EF <20%.
- (f) Inability to tolerate CO₂ insufflation.
- (g) Intramyocardial LAD.

Relative contraindications include:

- (a) Previous left-sided thoracic surgery or adhesions on left pleural space.
- (b) Previous cardiac surgery.
- (c) Severe PVD that preclude angiographic access.
- (d) Lesion at high risk of restenosis (bifurcation, trifurcation lesions).
- (e) Lack of suitable graft conduits.
- (f) Morbid obesity (BMI >40).
- (g) Small left chest cavity with large cardiac silhouette and a thick chest wall due to obesity. This combination makes the trocar placement dangerous. It also compromised the movements of the robotics arms and requires a larger thoracotomy to perform the anastomosis.
- (h) Unfavorable LAD artery for PCI (i.e., excessive vessel tortuosity or chronic total occlusion).
- (i) Previous left-sided thoracic surgery or adhesions on left pleural space.
- (j) Lack of suitable graft conduits.
- (k) Previous cardiac surgery.

Hybrid procedure consisting of ITA to LAD and PCI of other territories appears reasonable when PCI of the LAD is not an option or unlikely to portend good results. Indications should be selected by the Heart Team and potential opportunities for using a hybrid approach are listed here (recommendation class I, level of evidence B):

1. Primary PCI for posterior or inferior STEMI and severe CAD in nonculprit vessel(s), better suited for CABG.
2. Emergent PCI prior to surgery in patients with combined valvular and coronary disease, if the patient cannot be transferred for surgery, or in the presence of acute ischemia.
3. Patients who had previous CABG and now require valve surgery and who have at least one important patent graft (e.g., ITA to LAD) and one or two occluded grafts with a native vessel suitable for PCI.
4. Combination of revascularization with nonsternotomy valve intervention (e.g., PCI and minimally invasive mitral valve repair, or PCI and transapical aortic valve implantation).
5. In patients with conditions likely to prevent healing after sternotomy, surgery can be restricted to the LAD territory using minimally invasive direct coronary artery bypass (MIDCAB) excluded patients left ITA grafting. Remaining lesions in other vessels are treated by PCI.

There is no retraction of the ribs as it is in the traditional MIDCAB approach.

Robotics ports are placed on the third, fifth, and seventh intercostal space slightly anterior to the left anterior axillary line (Figs 51.5 and 51.6A). CO₂ insufflation is established via a trocar side port. We prefer high flow at low pressure to avoid hemo-dynamic compromise (20 L/min at 6 to 8 mmHg). Patient hemodynamics should be carefully monitored during the time the chest is insufflated. The intrathoracic pressure may need to be adjusted and vasoco-strictors may be necessary to maintain blood pressure and cardiac output during the procedure. Excessive volume infusion should be avoided to prevent right ventricular dilatation that may compromise the performance of a totally endoscopic procedure.

The internal mammary artery is taken down in a skeletonized manner using the electrocautery and bipolar forceps. Side branches are cauterized or clipped. After heparin is administered to achieve an ACT >300 seconds, the distal end of the mammary is divided between clips. The left phrenic nerve should be identified and avoided. A pericardium window is performed robotically as a trapdoor incision with the base on the diaphragm. One incision is placed anterior and parallel to the left phrenic nerve and another in the midline. Both pericardial incisions are connected at the base of the heart. The LIMA, the target area, and its relationship to the chest wall are identified after careful release of the left chest insufflation. This reestablishes the normal anatomic relation between the heart and the chest wall and allows for identification of the intercostal space closer to the target area minimizing the size of the thoracotomy incision. The robotic instruments and ports are then removed. There is a learning curve associated with the procedure with decrease in robotic time, rate of injury to the LIMA, and conversion rate as operators became more experienced.

TECAB can also be performed. The mammary is taken down as previously described with the DaVinci system. A robotic endostabilizer, placed through an additional port under the xiphoid, is used to immobilize the target vessel. The anastomosis is performed with the robotic instruments either with sutures or with U clips (Medtronic, Minneapolis, MN). It is a more
Section II: Adult Cardiac Surgery

Fig. 51.5. Positioning and port location for robotic left internal mammary artery takedown. Note left shoulder retracted inferiorly to avoid conflicts with the right robotic arm. Ports are located in the third, fifth, and seventh intercostal spaces anterior to the anterior axillary line (dotted line). The fifth intercostal port incision is conversed to a left anterior minithoracotomy.

technically demanding and time-consuming procedure that has been mastered only by a few centers of excellence. TECAB can be performed on cardiopulmonary bypass either in the arrested heart or on a beating heart. Cardiopulmonary support can be instituted through the groin with cannulation of the left common femoral artery and vein. On-pump beating heart bypass can be used to avoid the hemodynamic and pulmonary disturbances associated with single-lung ventilation, chest insufflation, hypercarbia, cardiac manipulation, and coronary occlusion. Decompression of the heart also increases the intrathoracic space, which is especially important for TECAB procedures. TECAB can also be performed with an arrested heart occluding the aorta with an EndoClamp aortic occlusion catheter (Edwards Lifesciences, Irvine, CA). Additional bypasses to the diagonal, ramus intermedius, and obtuse marginal coronary arteries can also be performed with the MIDCAB or TECAB approach.

Revascularization of the non-LAD vessels can be staged (PCI followed by CABG or CABG followed by PCI) or performed concomitantly in the same setting as the minimally invasive CABG. There are advantages and disadvantages associated with each approach:

(a) **PCI first followed by CABG:** This approach minimizes the risk of ischemia during minimally invasive bypass to the LAD by providing collateral circulation through the PCI revascularized targets. If PCI is unsuccessful or the result is not satisfactory, the revascularization strategy can be converted to conventional CABG. This approach can also be used in the setting of and acute MI where the culprit vessel is not the LAD. PCI is initially performed to the non-LAD culprit lesion and it is later followed by minimally invasive CABG to the LAD. The disadvantages include the risk of stent thrombosis during discontinuation of antiplatelet therapy during the staged CABG. If antiplatelet therapy is not discontinued, there is an increased risk of bleeding during the staged CABG.

(b) **CABG followed by PCI:** It is the most common approach used for HCR. In our practice, we perform PCI 48 hours after the minimally invasive CABG when the chest tube has been removed. Since minimally invasive CABG can be associated with a lower early patency rate than CABG performed through a median sternotomy, this approach allows for routine angiography of the LIMA to LAD bypass. It provides quality control and confirms the patency of the graft. Dual antiplatelet therapy can be instituted once the risk of surgical bleeding has subsided and continued indefinitely. The presence of a patent LIMA to LAD

Fig. 51.6. Minimally invasive coronary artery bypass. (A) The left internal mammary artery is harvested robotically using the DaVinci System. (B) Then a left anterior minithoracotomy is performed in the fifth or fourth intercostal space and a direct hand sewn left internal mammary artery to left anterior descending anastomosis is performed. Note the use of endostabilizer that is placed through the seventh intercostal space port site (C). End result with closed incision and chest tube placed through the seventh intercostal space port site. Note exiting from the third space port site the OnQ pump catheters. They are placed in the subpleural space for postoperative pain control.
The main theoretical advantages of HCR are considered to be shorter hospital stay, rapid rehabilitation, shorter time to return to work, and improved quality of life. To date, no randomized trial comparing HCR with either CABG or PCI has been published. The reported experience with HCR has been reviewed by Bonaros et al. It included 29 studies with a total of 774 patients. Operative mortality was 1.2%. The stenosis of the LIMA to LAD graft was 2.9% and the rate of PCI reinterventions was 14.5% (Table 51.5).

Halkos et al. compared by propensity matching 147 patients with triple-vessel CAD treated with HCR patients with 588 patients who were treated with off-pump CABG. The incidence of in-hospital major adverse cardiac and cerebrovascular events (MACCE: death, stroke, and MI) was similar between groups. Length of ICU and hospital stay were similar between the groups. At a mean follow up of 3.2 years, the need for repeated revascularization was higher in the HCR group than in the off-pump CABG group (12.2% versus 3.7%; \( P < 0.001 \)). There was also an increased need for target vessel revascularization in the HCR group (8.8% vs. 3.1%; \( P < 0.002 \)) driven by both lesions in the LIMA to LAD graft and in-stent restenosis. Lesions in the LIMA to LAD graft were more common in the HCR that in the off-pump group (4.8% vs. 1.0%; \( P < 0.001 \)). The 5-year survival was similar between the groups. There were no data reported on angina symptoms or acute coronary events at follow up.

A multicenter NIH observational study is being conducted to evaluate the incidence of death, stroke, MI, and repeat revascularization after HCR or PCI. In addition, to explore the effectiveness and safety of HCR, this study will establish the foundation for a randomized multicenter trial that will help to determine the role of HCR in the treatment of CAD.

**OUTCOMES OF CORONARY ARTERY BYPASS GRAFTING**

Advancements in percutaneous treatment strategies for CAD including angioplasty and drug-eluting stents combined with more minimally invasive open techniques for revascularization such as off-pump CABG and robotic CABG have selected a different profile of patients to undergo the traditional on-pump CABG. The landscape has shifted toward a patient population that is older and sicker with greater risk for morbidity and mortality. As an outgrowth of the changing patient demographics,
major improvements in patient risk stratification and quality improvement have taken place. Giant strides in understanding patient-specific risks can be attributed to the development of the European System for Cardiac Operative Risk Evaluation (EuroSCORE), the Society of Thoracic Surgeons (STS) online risk calculator, and the Veterans Administration risk score. These combined with institutional quality improvement programs have contributed to improve our understanding of CAD and have been invaluable in discussing patient-specific expectations and risks in the perioperative setting. Indeed, despite the increased scrutiny of CABG procedures and the more challenging patient profile, on-pump CABG continues to have improving patient outcomes with a mortality rate below 2% for isolated revascularization procedures.

**ON-PUMP CORONARY ARTERY BYPASS GRAFTING VS MEDICAL THERAPY**

The indications for surgical revascularization over optimized medical therapy were shaped in the 1970s and 1980s by three major randomized studies. The most recent AHA/ACC guidelines for surgical revascularization are patients with left main disease, left main equivalent (>70% stenosis of proximal LAD and LCx), significant left ventricular dysfunction, intractable angina pectoris despite maximal nonsurgical therapy, and significant three-vessel disease.

More recent randomized studies show that CABG yields up to 44% decrease in total mortality, Q-wave MI, or refractory angina requiring revascularization at a 5-year follow-up in patients with multivessel CAD. A survival advantage for early coronary intervention over medical therapy has also been shown in patients ranging from single vessel to multivessel coronary arterial disease. Undoubtedly, the optimal outcome for patients suffering from coronary arterial disease is the amelioration of ischemia with revascularization combined with both medical and risk factor optimization.

**ON-PUMP VS OFF-PUMP CORONARY ARTERY BYPASS GRAFTING**

The theoretical advantages of off-pump CABG (OPCAB) versus on-pump CABG is all related to the avoidance of the cardiopulmonary bypass circuit. There should be a decreased systemic inflammatory response, a lower degree of myocardial ischemia, and a lower risk of end-organ damage. This theoretical advantage should be seen highest in patients who are at greatest risk (i.e., older, diabetic, chronic renal insufficiency, porcelain aorta). However, there is great controversy and debate in the literature over the two techniques with no clear cut advantage. Initial review of the multitude of prospective, retrospective, and meta-analyses studies conducted on the merits of off-pump (OPCAB) versus on-pump coronary arterial bypass showed no advantage to off-pump revascularization. Subsequently, the proponents of OPCAB have argued that there is a less inflammatory response, myocardial injury, neurologic morbidity, renal insult, equal graft patency, and economic advantage of using off-pump techniques. The ROOBY trial aimed at answering the controversy was conducted as a randomized study of over 2,200 patients receiving either an elective or urgent CABG in the Veterans Affairs population. The primary long-term end point was death from any cause, a repeat revascularization procedure, or a nonfatal MI within 1 year of surgery with secondary end points of completeness of revascularization, graft patency and neurological outcomes. The conclusions of the study showed no differences in survival, use of resources or neurological outcomes. It did, however, report a decreased graft patency rate and worse composite outcome (death or major adverse event) in the OPCAB group. The shortcomings of the trial were quickly pointed out, however, by those prominent in the surgical community (surgeon inexperience with the OPCAB technique, selection bias of low-risk male patients, condition of the aorta—among others) thus adding further fuel to the debate. Despite the evergrowing amount of literature on the topic, the controversy continues to exist. Traditional on-pump CABG continues to have excellent results, but the technique of OPCAB is a tool that all cardiac surgeons should have in their armamentarium.

**TIMING OF CORONARY ARTERY BYPASS GRAFTING AFTER AN ACUTE MYOCARDIAL INFARCTION**

Although early PCI after an acute MI remains the goal for patients with coronary ischemia, the timing of surgical revascularization after an MI remains controversial. Patients who undergo early (<48 hours) CABG after an acute MI have a higher mortality. This is undoubtedly a direct result of the higher acuity and hemodynamic decompensation of patients in this group. For patients with stable CAD who have had an acute MI, it is commonplace to perform CABG in an elective, outpatient setting. The subset of patients for which the timing of CABG after an MI is debatable is the patients with a high grade lesion not amenable to PCI, the ever increasing population of patients who have been loaded with an irreversible antiplatelet medication prior to a cardiac catheterization, patients with unstable angina, and lastly patients with poor ventricular function. Although there is no consensus statement to timing of CABG after an MI, it is common practice to wait...
at least 5 days when possible after a loading dose of irreversible, antithrombotic therapy to reduce the chance of postoperative bleeding. An argument has been made for the use of on-pump but beating-heart CABG strategy to reduce the morbidity and mortality associated with cardiopulmonary arrest of the myocardium in the acute infarction period.

**CHOICE OF BYPASS CONDUITS**

There is little doubt about the benefits of using the left internal mammary in situ as a bypass conduit to the LAD artery whenever possible. The use of the right internal mammary artery and the use of both internal mammary arteries in improving long-term survival, especially in the young, nondiabetic patient population have been extensively highlighted. The benefits of total arterial revascularization using the radial artery as the third bypass conduit have been shown to have excellent 4-year patency, above 90% in target-specific arteries and in the experienced surgeons’ hands. The availability, resistance to spasm, and relative ease of handling the saphenous vein graft have kept it as the most commonly used conduit following the LIMA. Groups have reported that no difference exists between the 1-year patency of radial arterial grafts and grafts using the saphenous vein. In addition to the above-named conduits, the gastroepiploic arteries, the lesser saphenous vein, and the inferior epigastric artery and others have been described with some success.

**CORONARY ARTERY BYPASS GRAFTING IN PATIENTS WITH ISCHEMIC HEART FAILURE**

Patients who are often the sickest with the poorest left ventricular function are often the ones with the most to gain from surgical revascularization. The assessment of left ventricular dysfunction and myocardial viability in the previous discussion has identified advanced diagnostic modalities to evaluate these patients.

The STICH trial was conducted as a randomized trial comparing optimal medical therapy alone with medical therapy with the addition of CABG in patients with significant left ventricular dysfunction (ejection fraction < 35%). Accruing more than 600 patients in each arm, the results showed that the addition of CABG decreased rates of death from cardiovascular causes as well as rate of hospitalization for cardiovascular causes. Specifically, the medical therapy group had a 68% occurrence of the above compared with a 58% occurrence in the CABG group (hazard ratio of 0.81, confidence interval 0.66 to 1.00; P = 0.05) in a median follow-up period of 56 months. This may be an underestimation of the true effect, given the 17% crossover rate from those assigned to the medical therapy alone group into the CABG group.

**COMPLICATIONS**

According to the STS risk adjustment database, the mortality rate for all isolated CABG is 1.9% with the risk of a major complication at 15%. The risk of bleeding requiring reoperation is 1.8%, the risk of a perioperative MI is 0.9%, chance of any neurologic outcome (including coma, stroke, paralysis, transient ischemic attack) is 1.6% with a 1.1% risk of a permanent stroke. A chance of any infection is 1.1%, deep sternal wound infection is 0.2%, and a leg infection is 0.3%. The possibility of renal failure is 3.8% and the possibility of any need for reintervention (operation for valvular dysfunction, graft occlusion, bleeding, and other cardiac/noncardiac operations) is 4.2%. Finally, the chance of postoperative atrial fibrillation is 23%.

**FUTURE DIRECTIONS**

As surgeons continue to push the borders of technology and minimally invasive surgery with both hybrid procedures (minimally invasive CABG combined with PCI) and totally robotic coronary arterial revascularization, the landscape of patients undergoing on-pump CABG will continue to evolve. Increasingly, patients are being referred for surgery with multiple previous stents and failed angioplasties allowing for minimal room for error in the perioperative period to maintain superb results. In a period of heavy scrutiny on outcomes and large databases with surgeon-specific data available, it is incumbent on the cardiac surgeon to plan out a safe, expeditious, and efficacious operation in a patient-specific manner.

Kim HW, Farzaneh-Far A, Kim RJ. Cardiovascular magnetic resonance in patients with myocardial

This chapter by Kilic and his colleagues at Ohio State University is a outstanding chapter and discusses multiple controversial areas in cardiac surgery. The section on imaging is comprehensive and certainly demonstrates how coronary disease imaging will change in the future. There are three controversial areas that are mentioned in the chapter that are worth discussing. The first relates to viability. We are stuck as surgeons operating on patients with very poor ventricular function. This is certainly a major change in the last two decades. The big issue is deciding to whom to operate on. Our basic rule here is with ischemic cardiomyopathy is there needs to be evidences of viability and the arteries must be graft-able. One can operate on very diffuse disease in patients with decent function but in those patients with major dysfunction one must have excellent distal targets.

The second area that is discussed is hybrid revascularization. This is an important area and certainly is being practiced in multiple institutions. There is now a trial being worked out for the CTSN sponsored by NHLBI related to hybrid revascularization. I think we are going to have to learn a great deal more about this area and determine which patients will benefit from these technologies. Finally, the area of off-pump versus on-pump is a continuing area of controversy. If one can get outstanding graft patency with off-pump technology, then that is an appropriate technique. If one cannot guarantee it, then their on-pump technology has certainly compared favorably the off-pump approach. Certainly off-pump has less bleeding and perhaps a shorter hospital stay but there are really no other major safety differences in most of the randomized trials. I should mention these areas, latter cases will be highlighted by the authors.

ILK
INTRODUCTION

Over the past decade, there has been increasing interest in performing coronary artery bypass grafting (CABG) without the use of cardiopulmonary bypass. The growth in off-pump coronary artery bypass surgery (OPCAB) has been largely driven by increasing recognition of the deleterious effects of cardiopulmonary bypass and the desire to avoid the diffuse inflammatory response, multiorgan dysfunction, and neurocognitive complications that may follow. Increasing clinical experience with OPCAB has allowed analysis of outcomes following the procedure and demonstrated improved clinical outcomes in both prospective and large, risk-adjusted, retrospective comparisons among various patient populations.

Approximately 20% of CABG cases performed annually in the United States are performed off-pump and some centers report a significantly higher percentage of OPCAB cases. Increasing technical proficiency has been facilitated in large part by continued improvements in exposure and retraction techniques and the development of specialized stabilizers and positioners, which allow experienced off-pump surgeons to conduct complex multivessel coronary revascularizations that were not previously feasible without the use of cardiopulmonary bypass. With current positioners and stabilizers, OPCAB can be performed in the vast majority of patients needing coronary revascularization.

Even among cardiovascular surgeons not routinely performing coronary revascularization off-pump, there are newly recognized clinical scenarios, such as patients with severe atherosclerosis of the ascending aorta, for whom the use of OPCAB techniques may be particularly beneficial. OPCAB continues to be a facilitating technology for surgeons developing and promoting minimally invasive approaches to coronary revascularization. OPCAB has, therefore, evolved into a component of the armamentarium of the modern cardiovascular surgeon.

PREOPERATIVE CONSIDERATIONS

Although OPCAB is now performed routinely in some clinical practices, the tendency to automatically or blindly assign patients to OPCAB should be resisted. Preoperative factors favoring OPCAB must be weighed carefully against relative or absolute contraindications for the procedure. Rational and systematic consideration of these factors maximizes the likelihood of a technically successful procedure while limiting the chance for adverse events.

SURGEON

The individual surgeon’s training, experience, and attitudes toward OPCAB are the starting point from which any preoperative decision making should begin. OPCAB presents a unique set of technical challenges to the cardiovascular surgeon, who otherwise would be operating in a motionless and bloodless field. It has been estimated that OPCAB is feasible in up to 95% of patients presenting for primary CABG.

Individual surgeon experience in OPCAB is an important determinant in patient selection for OPCAB. The unique technical challenges of OPCAB grafting and its relative unfamiliarity have raised concern that adoption of OPCAB may lead to poorer outcomes during each surgeon’s “learning curve.” With careful patient selection, OPCAB surgery can be gradually assimilated into clinical practice while preserving and ultimately improving clinical outcomes. Very early in a surgeon’s experience, it is reasonable to exclude patients with depressed left ventricular function, left main disease, and those requiring multiple lateral wall grafts. With experience, more complex and technically challenging cases can be performed safely off-pump. Over time, OPCAB can be applied to a broad spectrum of clinical settings, including patients with advanced age, multivessel disease, depressed left ventricular function, left main disease, and complete arterial revascularization. Gradual assimilation of OPCAB thereby develops surgeon familiarity and comfort with the technique, allowing its broader application to an increasing pool of patients who derive benefit from avoiding cardiopulmonary bypass.

Patient

Patients for whom OPCAB is inappropriate are those in cardiogenic shock, those suffering from recurrent ischemic arrhythmias, and those with thoracic anatomy that severely limits the ability to rotate the heart, for instance, those with pectus excavatum or previous left pneumonectomy (see Table 52.1). Relative contraindications include intramyocardial coronary arteries, and small or diffusely calcified distal target vessels. These targets may be safely bypassed off-pump only with the benefit of considerable experience. On the other hand, patients with left main coronary lesions and recent myocardial infarction can safely have coronary revascularization performed off-pump and should be considered candidates for the procedure.

The preoperative evaluation of the patient proceeds with a complete history and physical exam. If radial artery harvest is contemplated, patients with inconclusive Allen’s tests undergo radial and ulnar artery duplex examinations. Criteria for preoperative carotid duplex examination include left main disease, peripheral vascular disease, carotid bruises, history of CVA, history of heavy tobacco use, and age >65 years. If significant carotid disease is detected, further work-up is pursued and staged or concomitant carotid endarterectomy is performed.

The role of atherosclerotic lesions of the ascending aorta in perioperative stroke has become increasingly evident over the past decade, and it is in this group of patients where OPCAB may be of greatest benefit. OPCAB surgery combined with clampless proximal anastomosis techniques is a uniquely valuable alternative for patients with severe atherosclerosis of the ascending aorta.

Aorta in which aortic clamping may pose a significant risk for atheroembolic stroke. Routine intraoperative use of epiaortic ultrasound is an invaluable tool for identifying patients with severe atherosclerosis of the ascending aorta so that their stroke risk can be effectively managed.

**INTRAOPERATIVE MANAGEMENT**

The planned conduct of OPCAB introduces a number of new patient care issues to the staff of an operating room. An important underlying concept to ensuring patient safety and the smooth conduct of the procedure is communication between the surgeon, operating room staff, and anesthesiologists. Excellent communication between the surgeon and the anesthesia provider is paramount in order to ensure intraoperative hemodynamic stability and to coordinate any departure from the planned order of distal or proximal anastomoses.

**ANESTHESIA**

Several aspects of anesthetic management of patients during OPCAB are common to the management of patients having conventional CABG. All patients undergoing OPCAB require invasive monitoring. At a minimum, an arterial line and central venous line are required. Pulmonary artery catheters are used routinely. Monitoring of pulmonary artery pressures can be particularly useful during retraction of the heart for the construction of distal anastomoses, as pulmonary artery pressure elevations are frequently the first sign of hemodynamic compromise prior to ischemic arrhythmias or cardiovascular collapse. Transesophageal echocardiogram is utilized sparingly but may be of use in order to identify areas of hypokinesis or significant mitral regurgitation following periods of regional myocardial ischemia.

In addition to the routine monitoring and safe anesthetic induction desired in all CABG procedures, there are a number of anesthesia management issues that are specific to OPCAB. In contrast to conventional CABG procedures, maintenance of normothermia is critically important throughout the case, as the ability to actively rewarm the patient by cardiopulmonary bypass is forfeited. Significant hypothermia adversely affects coagulation, is arrhythmogenic, and delays postoperative extubation. Efforts to maintain normothermia should therefore begin prior to induction. At our institution, a convective air system cycles warm air continuously to warm the patient throughout the procedure (Bair Hugger; Arizant Healthcare, Eden Prairie, MN).

The major challenge in the intraoperative anesthetic management of patients undergoing OPCAB is maintenance of hemodynamic stability during the elevation and retraction of the heart necessary to obtain exposure of coronary targets. Significant alterations in blood pressure and cardiac output may occur if preparatory steps are not taken. This can occur with rightward retraction of the heart for lateral wall exposure. Acutely, this is typically related to decreases in preload and left ventricular filling that occur as the vena cavae, right atrium, right ventricular outflow tract, and pulmonary veins may be compressed with this maneuver. An effective first-line treatment for this response is the administration of intravenous fluids. An assessment of the patient’s intravascular volume status is made prior to manipulation of the heart and preload is subsequently optimized. In order to compensate for the acute changes in preload that occur during cardiac manipulation, placement of the patient in steep Trendelenburg and reverse Trendelenburg positions can rapidly alter preload conditions to favor different hemodynamic states. Patient positioning is particularly useful when moment-to-moment changes in blood pressure are desired, for instance when rightward displacement of the heart is anticipated (Trendelenburg position) or when moderate hypotension is desired prior to placement of a partial occluding vascular clamp on the ascending aorta (reverse Trendelenburg position). Often, significant pharmacologic manipulation of systemic blood pressure can be avoided with bed positioning alone. Releasing the right-sided pericardial traction sutures and elevating the right limb of the sternal retractor on rolled towels are routine and valuable maneuvers to facilitate exposure and hemodynamic stability. Opening the right pleural cavity or releasing pericardial attachments along the diaphragm can also prove useful during rightward displacement of the heart.

As experience with OPCAB continues to evolve, the use of inotropes and vasopressors to maintain hemodynamic stability has been liberalized. Early in our experience, adjustment of preload conditions with intravenous fluid was the primary means by which stable blood pressures were maintained. In order to limit the intravenous fluid load given to patients intraoperatively, low-to-moderate doses of alpha agents such as norepinephrine are now routinely used. This practice has led to more favorable volume status in the postoperative period and has not had untoward effects on myocardial protection. It is unusual for patients to have a significant inotropic or vasopressor requirement beyond the immediate perioperative period.

Familiarity with the OPCAB procedure on the part of the anesthesia team is critical to the safe conduct of the operation. Patient care issues specific to OPCAB are thereby anticipated and addressed before they adversely affect the outcome of the procedure. Communication between the anesthesia team and the surgeon prior to and during the operation is important, particularly when changes in the surgeon’s operative plan occur.

**SURGERY**

The surgeon should come to the operating room with an operative plan that optimizes the likelihood for a successful outcome but also should remain flexible enough to change the operation as intraoperative findings and events dictate. This is one area where OPCAB and conventional CABG procedures differ significantly. OPCAB procedures frequently require significant intraoperative decision making that may result in departure from the routine. The following describes how a typical OPCAB case is performed in a patient requiring multivessel bypass.

**Preparation**

All patients for whom OPCAB is planned receive an aspirin suppository following
induction of anesthesia and prior to being prepped for surgery. In our practice, we administer aspirin perioperatively and dual antiplatelet therapy (aspirin and clopidogrel) in the postoperative period for platelet inhibition. Clopidogrel is administered within 4 hours after surgery if chest tube output is <100 cm³/hour for 4 hours.

The chest is opened in the usual manner through a midline sternotomy incision. Left and/or right internal mammary arteries (LIMA/RIMA) are harvested with the use of an upward-lifting retractor. Other radial artery or saphenous vein conduits are harvested simultaneously by endoscopic techniques as needed. Prior to vein or radial artery harvest, patients receive 5,000 units of heparin; this is important to avoid fibrin strands in endoscopically harvested conduits. Prior to division of IMA conduits from the chest wall, heparin is given (180 units/kg) to achieve a target activated clotting time of >350 seconds. Heparin is re-dosed every 30 minutes to maintain this level of anticoagulation. A sternal retractor (OctoBase; Medtronic, Inc., Minneapolis, MN) designed to act as a platform for OPCAB stabilizers and positioners (Octopus Evolution AS and Starfish EVO, Medtronic, Inc.; ACROBAT and EXPOSE, Maquet, Inc., Wayne, NJ) is placed in the chest. A wide inverted “T”-shaped pericardiotomy is performed, dividing the pericardium along the diaphragm. The phrenic nerves should be identified and protected during pericardiotomy. It is important to divide the pericardium to the apex to facilitate cardiac displacement. The left pleural space is opened widely; opening the right pleural space will facilitate cardiac displacement, but has been less necessary since the introduction of cardiac positioning devices and is infrequently performed in the absence of RIMA harvest. Care is taken during the dissection to clip any large vessels encountered and to avoid the phrenic nerves. It is also important to divide the diaphragmatic muscle slips, which insert on the right side of the xiphoid in order to allow elevation of the right sternal border, creating space for rightward cardiac displacement. Placement of two rolled towels under the right limb of the retractor elevates the right sternal edge, allowing the heart to be positioned toward the right without compression against the sternum or retractor.

The most important traction suture is a deep posterior pericardial suture placed approximately two-thirds of the way between the inferior vena cava and left pulmonary vein at the point where the pericardium reflects over the left atrium. Care should be taken with superficial placement of this suture to avoid the underlying descending thoracic aorta, esophagus, left lung, and pulmonary veins. The suture is covered with a soft rubber catheter to prevent laceration of the epicardial surface of the heart. The purpose of this deep traction suture is to elevate the heart up and out of the pericardial well to facilitate exposure of the coronary targets. When this suture is retracted toward the patient’s left hip, it elevates the base of the heart toward the ceiling and points the apex vertically with remarkably little change in hemodynamics. When the deep pericardial traction suture is retracted toward the left shoulder, the heart rotates from left to right. This exposure can occasionally be obtained without the deep stitch by placing a warm laparotomy pad under­neath the heart.

Epiaortic ultrasound is performed on all patients prior to manipulation of the aorta. This procedure adds only 1 to 2 minutes to the operative time and is the most sensitive means to detect atherosclerotic lesions of the ascending aorta intraoperatively. More importantly, it allows the surgeon to individualize placement of aortic clamps and proximal anastomosis devices to minimize the risk of atheroembolism. Its use has led to the reduction of postoperative stroke in patients at high risk for atheroembolism. A finding of grade IV or grade V atherosclerosis precludes application of a clamp to the ascending aorta (Table 52.2). The use of a clampless facilitating device that allows construction of a handsewn proximal anastomosis (Heartstring; Guidant Corporation, Indianapolis, IN) is possible when relatively uninvolved areas of the ascending aorta are detected by epiaortic ultrasound. When atherosclerotic involvement is very diffuse, a “no-touch” technique is employed with the innominate artery, LIMA, or RIMA utilized for proximal bypass graft in-flow. It is often necessary in these circumstances to construct a “Y” or “T” graft off either IMA for the purposes of arterial inflow, thus obviating aortic manipulation (Fig. 52.1).

The heart is allowed to roll with gravity into the left or right chest, facilitated by table rotation or tension on traction sutures. With proper exposure and retraction, the heart should never be compressed against the sternum or pericardium. Right pericardial traction sutures are released when exposing the left side of the heart, and similarly left pericardial traction sutures are released when exposing the right coronary artery. Pericardial sutures on both the right and left sides are never under tension simultaneously when displacing the heart to expose coronary targets. Gentle application of these techniques maintains stable hemodynamics while providing excellent exposure.

When grafting of the lateral wall or inferior wall is planned, a cardiac positioning device (Starfish EVO; Medtronic, Inc.; ACROBAT and EXPOSE, Maquet, Inc.) is also used (Figs. 52.2 and 52.3). This device uses suction to attach to the epicardial surface of the heart and elevates and displaces the heart to provide exposure of coronary targets with little hemodynamic compromise. Its hemodynamic advantage comes from the fact that it rotates the heart along the axis of the vena cavae while elevating it out of the pericardial well, thereby avoiding compression or kinking of the atria, vena cavae, and pulmonary veins. This device aids in exposure and presenta­tion, especially in cases of cardiomegaly and depressed left ventricular function.

Fig. 52.1. Construction of a “Y” arterial graft using the “no touch” technique for arterial inflow.
Fig. 52.2. Cardiac displacement and presentation of diagonal branches of the left anterior descending artery. The cardiac positioner is applied to the apex or left lateral wall of the heart and lifts the heart out of the pericardial well and rolls it to the right allowing the heart to roll under the right sternal border. Left-sided pericardial traction sutures and the deep stitch are placed under tension. The coronary stabilizer reaches across the heart from the right side of the sternal retractor, aiding in both the presentation and stabilization of the lateral wall and diagonal coronary targets.

It may be applied anywhere on the epicardial surface of the heart and is frequently moved away from the apex to facilitate exposure of various coronary artery targets.

On rare occasions when bradycardia and cardiomegaly coexist, ventricular distension hinders effective cardiac displacement. In this situation, temporary epicardial atrial pacing may significantly reduce cardiac size by decreasing diastolic filling time and improving target vessel exposure.

Section II: Adult Cardiac Surgery

Sequence of Grafting

In OPCAB surgery, the chosen sequence of grafting to maintain hemodynamic stability and avoid critical ischemia is one of the most important factors in the success of the operation. As a general rule, the collateralized vessel or vessels are grafted first and then reperfusion by performing the proximal anastomoses or releasing flow through the IMA. The last coronary target grafted is the collateralizing vessel(s). This strategy avoids interrupting vital flow from the collateralizing vessel to the collateralized territory until after the collateralized vessel has been grafted.

At times, the proximal anastomoses may be performed early in the operative sequence to aid in early reperfusion of a collateralized vessel. Performing the proximal anastomoses first may make estimation of graft length more difficult. The anticipated length is measured with a silk tie so that conduit can be appropriately cut in this circumstance. If the LIMA to left anterior descending (LAD) artery graft must be performed first, it is necessary to leave a long mammary pedicle to avoid tension on the LIMA anastomosis during subsequent displacement of the heart to expose other target vessels.

A preferred sequence of grafting is as follows:

1. Perform the anastomosis to the completely occluded or most collateralized vessel first. The collateralizing vessel can then be safely grafted, thus minimizing myocardial ischemia.
2. The LIMA to LAD artery anastomosis should be performed first if the LAD is collateralized or in cases of tight left main stenosis. This anastomosis is performed last when the LAD is the collateralizing vessel.
3. The proximal anastomosis can be performed first or early after the distal anastomosis if the target is a critical, collateralized vessel. This allows simultaneous perfusion during subsequent occlusion of the collateralizing vessel and minimizes overall myocardial ischemia.
4. Beware of a large right coronary artery with moderate stenosis. The right coronary artery, particularly if large and dominant, can cause significant problems when occluded during OPCAB. Acute occlusion of a moderately stenotic right coronary artery may lead to severe hemodynamic compromise secondary to bradycardia. The surgeon must be prepared to use an intracoronary shunt or epicardial pacing promptly to correct bradycardia and interrupt events leading to cardiovascular collapse.
5. Beware of mitral regurgitation during OPCAB. Prolonged displacement of the heart especially when grafting lateral wall vessels in the setting of mild-to-moderate mitral regurgitation can lead to severe hemodynamic compromise. Attempts should be made to address acute ischemic mitral regurgitation early in the operative sequence by grafting and perfusing the culprit vessel responsible for presumed papillary muscle dysfunction or utilizing intracoronary shunts to allow for continuous distal perfusion.
6. Most importantly, graft sequence should be individualized, depending on anatomic patterns of coronary occlusion and collateralization, myocardial contractility, atherosclerosis of the ascending aorta, conduit availability, and graft geometry.

Cardiac Displacement and Presentation of Coronary Targets

It is important to understand that the cardiac displacement techniques for exposure of the inferior and lateral coronary arteries are different. The lateral wall vessels are approached by rolling the apex of the heart toward/under the right sternal border. As previously described, the traction sutures on the right pericardium are released and the right pleural cavity can be opened. The left-sided traction sutures are pulled up taut on the sternal retractor and the table is rotated sharply to the right to assist in rolling the heart under the right sternal border. The deep stitch is pulled toward the patient’s left shoulder and secured to the sternal retractor. The coronary stabilizer is mounted on the right side of the sternal retractor and its arm reaches across the heart, aiding in both the presentation and stabilization of the obtuse marginal coronary arteries (Fig. 52.2). The cardiac positioner may be applied to the left lateral wall of the heart rather than the apex, as needed.

For the inferior wall vessels, such as the posterior descending artery, left ventricular branch of the right coronary artery, or posterolateral obtuse marginal branch, the deep traction stitch is pulled toward the patient’s left hip or directly caudad and clamped to the drapes (Fig. 52.3). The coronary stabilizer is attached to the left limb of the sternal retractor. The patient is placed in Trendelenburg position with the bed tilted to the patient’s right. The base of the
heart is elevated and the apex is oriented vertically toward the ceiling. The positioner may be applied to the apex of the heart and helps to elevate the heart.

In contrast to targets on the lateral and inferior walls, the anterior wall vessels (LAD and diagonals) are exposed with very little manipulation of the heart. The deep traction stitch is secured to the drapes on the patient’s left side, and the coronary stabilizer is brought over the anterior wall from the caudal or left side of the sternal retractor. An apical positioner is usually not necessary for grafting of the anterior wall. Care is taken to divide the pericardium to allow the LIMA pedicle to fall posteriorly into the left chest, medial and posterior to the apex of the left lung.

**Coronary Stabilization and Grafting**

The current generation of coronary stabilization devices rely on suction rather than compression to maintain epicardial tissue capture. This characteristic allows the device to achieve coronary stabilization at the mechanical median of the cardiac cycle, rather than compressing the cardiac chambers excessively. Thus, stabilization is maintained while mechanical interference with ventricular function is minimized. Once the device is applied, a few seconds may be needed to ensure hemodynamic stability. If hemodynamics are compromised, the degree of compression should be reduced and the mechanical median of the cardiac cycle should be more clearly identified by allowing the stabilizer arm to become flexible while still maintaining suction. The suction is maintained to avoid losing tissue capture. After the appropriate position for the stabilizer arm is determined, it is tightened once more. The malleable pods of the stabilizer allow the surgeon to spread the epicardium adjacent to the coronary targets, significantly improving visualization of the coronary artery. Epicardial fat retractors are rarely necessary.

After optimal exposure is obtained, a soft silastic vessel loop (Quest Medical, Allen, TX) is placed proximally around the target vessel for occlusion (Fig. 52.4). Care should be taken when the vessel loop is placed to avoid entering the ventricle or damaging epicardial veins. When this occurs, a superficial epicardial suture generally stops bleeding. The vessel loop may be directed out of the surgeon’s field of view with the aid of a loose pericardial suture acting as a pulley (Fig. 52.5).

When the target vessel is poorly collateralized, an interval of test occlusion lasting 2 to 5 minutes followed by reperfusion for a similar interval can be used to determine how regional myocardial ischemia will be tolerated once the anastomosis is underway. This gives the surgeon some measure of assurance prior to creating an arteriotomy. Once the distal anastomosis is underway, it is critical for the anesthesia team to continuously communicate with the surgeon. Changes in hemodynamics should be quickly addressed and arrhythmias promptly treated with epicardial pacing or an intracoronary shunt.

The target vessel is occluded by applying the minimum necessary tension on the vessel loop. This tension is directed in such a manner that the vessel is lifted out of surrounding epicardial fat, further improving exposure of the target. The target vessel is opened with a coronary knife and the arteriotomy is extended with coronary scissors. The field is kept free of blood by dispersing retrograde bleeding from the distal end of the arteriotomy with a humidified CO₂ blower (ClearView Blower/Mister; Medtronic, Inc.). It is important that the surgeon’s assistant blow on the target only when the surgeon is placing the needle through the tissue of the conduit or target vessel so as to minimize the potential trauma to the intima of the target vessel that can occur with excessive use of the blower. Excellent visualization is critical for a precise anastomosis. Magnification of 3.5X, a headlight, and Castroviejo needle drivers are used for all anastomoses. 8-0 monofilament suture is used for all distal anastomoses to optimize precision, unless severe calcification or thickened conduit mandates use of a heavier needle.

**Myocardial Protection**

Myocardial protection during OPCAB has evolved as techniques for performing the procedure have been refined. Early on, before the development of suction-based stabilizers, intermittent pharmacologic arrest and profound bradycardia were induced during the procedure with adenosine and short-acting β-blockers. In addition to reducing the motion of the target vessel, this strategy achieved some degree of myocardial protection by reducing myocardial oxygen demand. These maneuvers have largely passed from clinical practice with the widespread application of modern suction-based coronary stabilizers and positioning devices.

A number of other myocardial protection strategies developed early in the experience of OPCAB remain in routine use. Maintenance of systemic blood pressure by optimizing preload conditions and the use of vasopressors are part of careful anesthetic management. During target vessel occlusion, however, this practice is an important component of myocardial protection as perfusion to ischemic myocardium via collaterals is dependent on this perfusion pressure. Another myocardial protection strategy that may be taken for granted is the careful use of traction sutures, apical heart positioners, and coronary stabilizers that provide adequate exposure of the target vessel without excessively compressing the cardiac chambers and causing undue hemodynamic compromise. When ideally placed, these devices do not interfere with the cardiac cycle, vasopressor requirements are minimized, and overall myocardial oxygen demand is minimized. This careful positioning of the heart should be considered a routine strategy for myocardial protection. Finally, selection of the order in which distal anastomoses are constructed during a multivessel OPCAB procedure is another strategy by which the surgeon can limit the degree of regional ischemia to which the heart is subjected. Occlusion of a collateralized target vessel

![Fig. 52.4. Dissected coronary artery with the silastic stitch and coronary stabilizer in position.](image)

![Fig. 52.5. Loose pericardial suture that allows for displacement and correct tension for retraction on the silastic stitch.](image)
first in the operative sequence allows this territory to be perfused via collaterals during construction of the anastomosis. Subsequently, occluded territories can then be perfused via reversed flow in the collaterals from completed grafts.

Construction of one or more proximal anastomoses early in the operative sequence is an adjunct to the thoughtful selection of the order in which distal anastomoses are constructed. Construction of a proximal anastomosis prior to the first distal anastomosis allows immediate reperfusion of the ischemic territory following target vessel occlusion and construction of the distal anastomosis. If this target vessel is collateralized, then a subsequently constructed distal anastomosis to the collaterализing target vessel can be performed with the benefit of reversed collateral flow originating from the first bypass graft. An advantage of grafting the LAD with an in situ LIMA pedicle first in the operative sequence is that this anastomosis requires minimal lifting of the heart, and subsequent target vessels can be exposed and grafted with the benefit of collateral flow from the LIMA to LAD anastomosis without interrupting the operative sequence to perform a proximal anastomosis.

An intracoronary shunt may be placed if significant hemodynamic compromise occurs following target vessel occlusion despite the use of the routine measures described above. The shunts (ClearView Intracoronary Shunts; Medtronic, Inc.) range in size from 1.0 to 3.0 mm. When appropriately sized for the target vessel, they are easily placed and removed and provide significant flow and a reasonably bloodless field. Intracoronary shunts may be particularly useful with large right coronary arteries and bradyarrhythmias, intramyocardial vessels where the placement of an occlusive vessel loop may be hazardous, and with critical anatomy where occlusion of an important collateralizing vessel may lead to global myocardial ischemia and hemodynamic collapse. The shunt is removed and the coronary artery is de-aired prior to tying the suture on the distal anastomosis and flow is re-established.

Proximal Anastomoses

Proximal anastomoses to the disease-free aorta are routinely performed with an aortic partial occlusion clamp. The systolic blood pressure is lowered to <95 mmHg prior to application of the clamp. Once the clamp is applied, aortotomies are made with a 4.0-mm aortic punch. Vein graft anastomoses are created with 6-0 monofilament suture and arterial grafts with 7-0 monofilament suture. Any graft taken as a "T" off an IMA is anastomosed with 8-0 monofilament. The aortic root is de-aired through the most anterior anastomosis after the clamp is removed, prior to tying this suture. The vein grafts are kept occluded until they are de-aired with a 25-gauge needle. Arterial grafts are not punctured but are allowed to backbleed prior to clamp removal.

As described previously, placement of the partial occluding aortic clamp is guided by the results of routine epiaortic ultrasound scanning. Clamping is not performed in the presence of diffuse grade III or any grade IV or V atherosclerotic involvement of the ascending aorta. When an uninvolved segment of the ascending aorta can be identified that would yield acceptable graft geometry, we typically use a clamping proximal aortotomy system (Heartstring: Maquet, Inc.) that allows creation of a beveled, hand-sewn anastomosis. If atherosclerotic involvement of the ascending aorta is diffuse, precluding use of the Heartstring device, the proximal anastomosis is taken off of an IMA pedicle. Alternatively, a proximal device system can be utilized but many current iterations requires creation of the proximal anastomosis prior to the distal anastomosis, so graft length must be judged accordingly.

After completion and reperfusion of all grafts, protamine is administered (0.75 to 1.0 mg/kg) to partially correct the activated clotting time to approximately 150 seconds. As hemostasis is being achieved, chest drains are placed, one in each open pleural space and one in the mediastinum. Temporary epicardial pacing wires are placed only if the patient requires epicardial pacing immediately prior to chest closure and are rarely used. The chest is closed in the standard manner with sternal wires and running absorbable sutures in the fascia, subcutaneous, and subcuticular layers.

 Patients who have undergone OPCAB surgery have a decreased need for inotropic support in the postoperative period, most likely because of avoidance of global ischemia and reduced myocardial stunning. Postoperative hemorrhage and transfusion requirements are reduced in OPCAB patients because of reduced fibrinolytic pathway activation and coagulation factor and platelet consumption. Patients who have undergone OPCAB surgery are in a relatively hypercoagulable state compared with the coagulopathy that is typical following cardiopulmonary bypass. This state has the potential to adversely affect graft patency in the postoperative period. As described earlier, we address this preoperatively with the administration of aspirin following induction of anesthesia. Following surgery, we continue aspirin administration daily as with patients undergoing conventional CABG surgery. Dual antiplatelet therapy is continued for 6 months (albeit in the absence of a strong evidence base for this practice); aspirin therapy is continued for life, as per guidelines.

OPCAB patients have a decreased need for mechanical ventilation postoperatively. To realize this benefit for the patient and the health system, caregivers should be immediately prepared to wean and extubate patients as their need for mechanical assistance is diminished. With appropriate anesthesia planning and staffing, patients can generally be extubated in the operating room following an OPCAB procedure or within 30 to 90 minutes of arrival in the intensive care unit. When this is not feasible, clinical pathways that set objective criteria and goals facilitate the timely progression of ventilator weaning and extubation that minimizes patient exposure to ventilator-related complications and maximizes efficiency and cost-effectiveness.

CLINICAL OUTCOMES FOLLOWING OFF-PUMP CORONARY ARTERY BYPASS SURGERY

The postoperative care of patients who have undergone OPCAB surgery is similar in many respects to that of patients undergoing conventional CABG surgery. The requirement for close monitoring of patient cardiopulmonary status, renal function, and chest tube drainage is similar. However, there are a number of important differences that caregivers must be aware of in order to take advantage of the opportunity for expedited care that OPCAB surgery can offer.

POSTOPERATIVE MANAGEMENT

The postoperative care of patients who have undergone OPCAB surgery is similar in many respects to that of patients undergoing conventional CABG surgery. The requirement for close monitoring of patient cardiopulmonary status, renal function, and chest tube drainage is similar. However, there are a number of important differences that caregivers must be aware of in order to take advantage of the opportunity for expedited care that OPCAB surgery can offer.

Patients who have undergone OPCAB surgery have a decreased need for inotropic support in the postoperative period, most likely because of avoidance of global ischemia and reduced myocardial stunning. Postoperative hemorrhage and transfusion requirements are reduced in OPCAB patients because of reduced fibrinolytic pathway activation and coagulation factor and platelet consumption. Patients who have undergone OPCAB surgery are in a relatively hypercoagulable state compared with the coagulopathy that is typical following cardiopulmonary bypass. This state has the potential to adversely affect graft patency in the postoperative period. As described earlier, we address this preoperatively with the administration of aspirin following induction of anesthesia. To realize this benefit for the patient and the health system, caregivers should be immediately prepared to wean and extubate patients as their need for mechanical assistance is diminished. With appropriate anesthesia planning and staffing, patients can generally be extubated in the operating room following an OPCAB procedure or within 30 to 90 minutes of arrival in the intensive care unit. When this is not feasible, clinical pathways that set objective criteria and goals facilitate the timely progression of ventilator weaning and extubation that minimizes patient exposure to ventilator-related complications and maximizes efficiency and cost-effectiveness.

CLINICAL OUTCOMES FOLLOWING OFF-PUMP CORONARY ARTERY BYPASS SURGERY

Patient outcomes following OPCAB have been studied by several prospective randomized studies. A consistent finding among most of these studies has been that OPCAB in experienced hands is a safe and efficacious method to perform coronary revascularization. The magnitude of the overall clinical benefit to the patient from avoiding cardiopulmonary bypass remains a point of contention.

Exposure of circulating blood to the large foreign surface of a cardiopulmonary
bypass circuit leads to the broad activation of plasma protein systems and cellular blood components, which triggers a whole body inflammatory response, coagulation cascade activation, and fibrinolytic activity. As expected, avoidance of cardio-pulmonary bypass by OPCAB is associated with a decreased inflammatory response following surgery as measured by neutrophil activity, cytokine levels, and complement activation.

OPCAB presents unique technical challenges to the surgeon who must master the exposure and stabilization techniques that make beating heart surgery possible. Because of this, graft patency in patients undergoing OPCAB has been an area of concern throughout the development of the field. In the largest single-center randomized study in which graft patency was systematically studied, there were no differences in patency rates in any coronary distribution for patients undergoing OPCAB or conventional CABG. A smaller study subsequently demonstrated reduced patency rates for patients undergoing OPCAB 3 months following surgery. More recent data from a multi-institutional trial showed decreased patency rates for patients who underwent OPCAB at 1-year follow-up. Individual operator variability may explain the differences between these studies, as surgeon experience and expertise with off-pump techniques have been questioned in the latter trial. Though there is a significant learning curve for OPCAB, through careful patient selection, this period can be managed and safely traversed while maintaining excellent clinical outcomes.

OPCAB offers certain benefits in postoperative outcomes, specifically shorter hospitalizations and periods of mechanical ventilation and potentially fewer blood transfusions without compromising long-term survival. Accordingly, outcomes following OPCAB for high-risk subpopulations have demonstrated the greatest improvement over on-pump surgery. For example, OPCAB patients with poor left ventricular function have been observed in several large observational studies to have lower morbidity and mortality. Patients with advanced age comprise another high-risk subgroup, which has increasingly been found to benefit from off-pump coronary revascularization. Other high-risk patients potentially benefiting from OPCAB include female patients and patients with obesity, low body mass index, diabetes mellitus, and renal insufficiency.

**FUTURE DIRECTIONS FOR OFF-PUMP CORONARY ARTERY BYPASS SURGERY**

At its inception, OPCAB surgery was performed rarely and only by a few surgeons and only on patients with certain limited coronary anatomies. Since that time, OPCAB has evolved into a routinely performed operation that can be applied to virtually the entire spectrum of patients requiring coronary revascularization. OPCAB surgery is now well accepted to have specific advantages to the patient compared with conventional CABG and is becoming the gold standard of care for certain clinical situations, such as patients with heavy atherosclerotic disease of the ascending aorta. For many surgeons, OPCAB surgery has become an important component of the armamentarium with which to manage a wide array of clinical challenges.

OPCAB surgery has matured and been accepted by the clinical community to the extent that it has itself become a facilitating technology for further advancements in cardiovascular surgery. Minimally invasive approaches to surgical coronary revascularization are now by definition OPCAB procedures. These evolving procedures will continue to be dependent on OPCAB techniques to construct anastomoses. At our institution, robotic techniques for LIMA harvesting are being combined with nonrib spreading mini-thoracotomies through which minimally invasive coronary revascularization is performed to the anterior wall. This procedure is potentially extending the benefits of LIMA to LAD grafting to patients who would otherwise not be referred for CABG.

Application of OPCAB to patients with multivessel disease is also performed in combination with percutaneous coronary intervention (PCI) of other territories by combining minimally invasive LIMA-LAD grafting with PCI of non-LAD vessels. Hybrid procedures are being evaluated rigorously to determine what subpopulation of patients with multivessel disease may benefit from this approach. Patients with multivessel disease currently being treated with percutaneous techniques alone represent a group for whom hybrid procedures may increasingly be used.

Off-pump coronary artery bypass is a useful strategy for coronary revascularization for the modern cardiothoracic surgeon. Certain at-risk groups of patients demonstrate improved short-term and equivalent long-term outcomes following OPCAB. OPCAB is a requisite tool for the practitioner wishing to pursue hybrid or minimally invasive coronary revascularization.

**SUGGESTED READINGS**

Dr. Puskas and colleagues at Emory University have developed a thoughtful approach for off-pump coronary artery bypass surgery. I would like to compliment Dr. Puskas for doing coronary angiography on his initial cases to determine the technique was worthwhile. The description by these authors on techniques and indications are critical to the safe use of this modality. At our institution, we do not perform off-pump as routine. However, as the authors have stated it must be part of every surgeon's armamentarium. There certainly are cases from which the patient would benefit by using off-pump approach. These include calcified aortas, minimally invasive coronary artery bypass grafting, and in some patients where one must truly limit the amount of blood utilized. Therefore, I think this chapter is a primer for these situations. I do not think the question is whether one should do off-pump versus on-pump but rather in which cases one modality is more suitable than the other. Dr. Puskas and colleagues have stated some true and relative contraindications and I think these should be followed. By the same token, there are some specific indications for off-pump surgery and I believe we now have a better understanding when that should be done.
INTRODUCTION
Coronary artery bypass grafting (CABG) surgery and percutaneous coronary intervention (PCI) are established treatment for coronary artery disease (CAD). Both have been shown to be effective in both alleviating symptoms and increasing long-term survival.

CABG surgery has been shown to have superior outcomes in the high-risk patient cohorts (diabetics, left main disease, three vessel disease, high SYNTAX scores, and patients with reduced cardiac function). The extent of benefit in low and intermediate risk patients is not as well defined. The main advantage of CABG arises from the use of the left internal mammary artery (LIMA) to left anterior descending (LAD) artery graft, which has an unparalleled long-term patency. Saphenous vein graft (SVG) failure remains one of the weaknesses of CABG with early failure rates, ranging from 6.2% to 30%.

Conversely, multivessel PCI with drug-eluting stents (DES) has the distinct advantage of being a less invasive form of therapy, with faster recovery and lower stroke rates, compared with CABG. DES have lower failure rates at 12 to 18 months compared with SVG (defined as stent restenosis and thrombosis compared with SVG occlusion). One of the main disadvantages of PCI is the higher rates of target vessel reintervention when compared with CABG, especially with respect to PCI in the LAD territory.

The potential of hybrid coronary revascularization (HCR) strategy is the ability to offer patients a tailored approach to the treatment of CAD, while minimizing the risks of the operation. The LIMA to LAD graft is performed in tandem with PCI to non-LAD vessels, combining the superior patency of the LIMA to LAD graft with that of DES to non-LAD vessels. As less surgical grafts will be required with HCR, this provides the additional advantage of enabling the LIMA to LAD graft to be performed through a nonsternotomy approach. Several observational studies have shown that HCR is a feasible and safe technique with short-term outcomes that are noninferior to standard CABG.

TIMING
Hybrid revascularization can be performed as either a “one-” or “two-staged” procedure. HCR performed in a single setting requires a specially designed hybrid operating room combining the facilities of the cardiovascular surgery operating room with that of a catheterization laboratory (Fig. 53.1).

The “one-stage” approach has the distinct advantages of allowing for completion angiography to assess graft patency, allows for more aggressive multivessel PCI, and facilitates completion of the procedure during a single operation while entailing a single technical fee (Table 53.1). The main disadvantage is the increased risk of bleeding given that the surgery must be performed under the influence of the potent antiplatelet agents used for PCI (Table 53.1).

On the other hand, for the “two-staged” approach, PCI and CABG are performed in their respective procedural environments separated by hours or days, although they are routinely performed during the same admission. When PCI is performed prior to CABG, lesions that cannot be successfully addressed by PCI can later be grafted at the time of CABG (Table 53.2).

The disadvantage to this strategy is that CABG will have to be performed under the effect of dual anti-platelet therapy such as aspirin and Clopidogrel, thereby increasing the rate of major bleeding and bleeding-related complications. Also, especially when minimally invasive approaches are utilized, completion angiogram to ensure LIMA to LAD integrity requires the performance of an additional procedure. Performing the LIMA to LAD graft prior to PCI allows for more aggressive interventions to be performed with the LAD territory revascularized (Table 53.3). The integrity of the LIMA to LAD can be assessed at the time of PCI in this approach.

Performance of CABG prior to PCI provides the benefits of a LIMA to LAD graft prior to intervention on the subsequent vessels, which avoid the risks associated with anti-platelet agents. This approach also allows for evaluation of the LIMA to LAD patency during PCI via angiography. The disadvantage of this approach is that CABG will be performed with incomplete revascularization due to residual coronary artery stenosis that could, potentially, increase perioperative morbidity. Additionally, in the event of unsuccessful PCI or procedure-related coronary complications, a repeat and higher risk CABG procedure may be required.

SURGICAL TECHNIQUES
Revascularization of non-LAD vessels is performed during the PCI portion of the HCR procedure. The femoral or radial approaches are utilized and the procedure is performed as per the standard routine protocols for stent implantation.

The CABG component of HCR constitutes the surgical revascularization of the LAD utilizing the LIMA to LAD graft. Multiple techniques exist to perform this surgical portion of the procedure and are discussed below.

Minimally Invasive Direct Coronary Artery Bypass (MIDCAB) or Minimally Invasive Cardiac Surgery (MICS) refers to the technique in which the LIMA mobilization is performed through a limited anterior or left thoracotomy through the fourth or fifth intercostal space utilizing a special retractor. A hand-sewn LIMA to LAD anastomosis is then performed on the beating heart using specialized stabilizers, retractors, and a coronary shunt. Single-lung ventilation with a double-lumen...

CABG, coronary artery bypass grafting; PCI, percutaneous coronary intervention; LAD, left anterior descending; LIMA, left internal mammary artery.

Thoracoscopic Endoscopic Atraumatic Coronary Artery Bypass (Endo-ACAB) refers to the technique in which the LIMA mobilization is performed via thoracoscopy through port access incisions. The LIMA to LAD anastomosis is then performed on the beating heart similar to the MIDCAB. Dissection of the LIMA is facilitated in this technique with single-lung ventilation and the insufflation of CO₂ at pressures of 8 to 15 mmHg creating a controlled pneumothorax.

Robotically Assisted Coronary Artery Bypass Graft refers to a technique in which robotic assistance is utilized for the LIMA takedown. This is followed by a hand-sewn LIMA to LAD anastomosis on the beating heart utilizing a 4 to 5 cm anterior thoracotomy while an endoscopic stabilizer, placed through a separate port incision, stabilizes the LAD.

Beating Heart Totally Endoscopic Coronary Artery Bypass Graft (TECAB) refers to a technique in which robotic assistance is utilized for the LIMA takedown and the anastomosis is performed endoscopically utilizing a robot. The LIMA to LAD anastomosis can be performed on the beating heart or on an arrested heart using cardiopulmonary bypass (CPB).

Trans-sternal approach refers to the classic approach in which the LIMA mobilization and anastomosis are performed endotracheal tube is preferred to facilitate optimal anatomical exposure.

Thoracoscopy is performed via port access incisions, and the LIMA is mobilized using a robotic-assisted or conventional technique. The LIMA-LAD bypass is then performed on the beating heart or on an arrested heart using CPB.

Dissolution of the LIMA is facilitated in this technique with single-lung ventilation and the insufflation of CO₂ at pressures of 8 to 15 mmHg creating a controlled pneumothorax.
that a minimally invasive approach could with lesions amenable to PCI, a repeat cardiac intervention may be desirable. These include lack of pulmonary conditions that prohibit single-artery territories. There are other scenarios in which minimizing the extent of surgical intervention may be desirable. These include lack of conduits, the inability to graft a vessel but with lesions amenable to PCI, a repeat cardiac operation, or high-risk patients with concomitant pre-existing organ dysfunction, recent history of myocardial infarction, and severe atherosclerotic aortic disease (Table 53.4).

Several important contraindications must be considered. The presence of concomitant valve disease, an intramyocardial LAD, pulmonary conditions that prohibit single-lung ventilation, and subclavian artery stenosis are absolute contraindications to MIDCAB and TECAB. Morbid obesity and prior chest irradiation are relative contraindications to MIDCAB. Any conditions that preclude peripheral cannulation for CPB are contraindications to TECAB with CPB.

### PATIENT SELECTION

The ideal candidates for HCR are patients with multivessel CAD comprising a high-grade lesion in the LAD and lesions amenable to PCI in the left circumflex and right coronary artery territories. There are other scenarios in which minimizing the extent of surgical intervention may be desirable. These include lack of conduits, the inability to graft a vessel but with lesions amenable to PCI, a repeat cardiac operation, or high-risk patients with concomitant pre-existing organ dysfunction, recent history of myocardial infarction, and severe atherosclerotic aortic disease (Table 53.4).

### CURRENT DATA

The current data on HCR are based on single-institutional experience. At present, there are no randomized clinical trials on HCR. The National Heart, Lung, and Blood Institute (NHLBI) have initiated the first observational trial to attempt to define the ideal patient population for HCR.

Several retrospective studies have published their results on HCR since its initial implementation in 1996. Since then, approximately 918 patients have undergone HCR. The data from these studies have shown low 30-day mortality (0% to 2%) and in-hospital morbidity (0% to 21%, average of 4.4%). The rate of percutaneous transluminal coronary angioplasty (PTCA) and stent-restenosis at mean follow-up of 1 to 44 months was 0% to 30%. It is important to note, however, that several of the earlier studies were conducted using bare metal stents (BMS) and many of the earlier studies utilized PTCA alone and not the more durable DES, which were introduced in 2003.

In evaluating more recent studies of HCR using only DES far better outcomes have been observed. Thirty-day mortality in these studies is only 0% to 1.4% and in-hospital morbidity is only 0% to 4.2%, with an average of 1.0%. The rate of reported stent–restenosis at mean follow-up of 6 to 33 months is only 0% to 6.6%. Hence, it is evident that the advent of DES technology has substantially enhanced the potential benefits HCR has to offer. Table 53.5 provides data from the recent studies that used primarily DES or all DES.

### LIMITATIONS

The limitations of HCR arise from the respective limitations of minimally invasive CABG and PCI. Although the data on DES currently appear encouraging, their efficacy in certain complex situations is not as well defined. Complete total occlusions, bifurcated coronary lesions, diffuse disease or extensive lesions requiring multiple stents, ostial stenosis, and small or calcified vessels do not fair as well. Also certain high-risk subgroups, such as diabetics and those with high SYNTAX scores, have higher DES restenosis rates, which may limit the benefits of HCR in a given patient.

One of the main concerns with minimally invasive CABG is the long-term patency of the LIMA to LAD graft which may be lower than those performed through a conventional median sternotomy. Limited surgical exposure and the technical challenges facing a minimally invasive approach must be taken into account and all such procedures carry a steep learning curve. In addition, the previously described contraindications to the performance of certain minimally invasive techniques need to be taken into consideration. For these reasons, completion angiography of the LIMA to LAD graft after MIDCAB seems prudent.

### ANTI-PLATELET REGIMEN

The optimal anti-platelet strategy for use during single-staged HCR has yet to be defined. The challenge is to find the appropriate balance to achieve the appropriate levels of anti-platelet activity to prevent stent thrombosis, while simultaneously obviating the need for platelet transfusion due to bleeding and associated complications. Various anti-platelet strategies have been reported. In our series at Vanderbilt, we reported on 112 patients who underwent CABG with concomitant PCI. We administered a 300 mg loading dose of Clopidogrel® preoperatively in the holding area for electively planned hybrid procedures. For unplanned hybrid procedures, where the decision to perform PCI was made after surgery, the Clopidogrel® was given via nasogastric tube at the time the decision was made. Our choice to use a 300 mg loading dose of Clopidogrel® rather than the standard 600 mg dose used for conventional PCI was to balance the risks of significant bleeding complications against the risks of stent thrombosis. Only three patients (3%) required re-operation for bleeding and only one patient (1%) developed in-stent thrombosis during their hospital stay.

CONCLUSIONS

The feasibility and efficacy of HCR, based on the results from individual institutions, appears to be encouraging. In selected patients, HCR appears to be an effective therapeutic modality with good clinical outcomes. As our ability to develop hybrid strategies utilizing the tools of cardiovascular surgeons and interventional cardiologists improves, the potential to tailor therapies to a wider selection of patients seems limitless. However, randomized control trials will be required to determine the full scope of HCR and gauge its comparative efficaciousness to standard CABG and PCI. The data from the currently ongoing NHLBI study will be pivotal in answering these questions and advancing this field.

SUGGESTED READINGS

Leach M, Umakanthan R, Zhao DX, Byrne JG. Surgical update: hybrid procedures, do they have a role? Circ Cardiovasc Inter 2010;3:511-518, Review.

Until recently, several studies have shown that surgical left ventricular reconstruction (LVR) has been introduced as an optional therapeutic strategy aimed to reduce LV volumes through the exclusion of the scar tissue, thereby restoring the physiological volume and shape and improving LV function and clinical status. Later, the technique has been widely adopted by skilled surgeons and refined in an effort to standardize the procedure and to optimize the results. Until recently, several studies have shown that surgical LVR is effective and relatively safe with a favorable 5-year outcome. However, in spite of the large amount of reports drawn on various data sets, the additional benefit of LVR to CABG remains debated.

This chapter briefly discusses the rationale to surgically reverse LV remodeling through LVR, and, more extensively, the technique and the indications to the best of our knowledge.

INTRODUCTION

Despite many breakthroughs in cardiovascular medicine, MI and heart failure (HF) are still among the most major public health challenges in the developed countries. The 5-year survival rate of patients diagnosed with HF is still <50% and might even be underestimated. HF is associated with ischemic heart disease in a percentage of patients ranging from 46% to 68%. Research has been very effective in delivering major advances in therapy of ischemic HF patients, including drugs, device therapy, and surgery. However, despite advances in different therapeutic strategies, the prognosis for patients with chronic ischemic HF remains poor. Indeed, HF is a syndrome with a broad spectrum of heterogeneous symptoms and signs caused by cardiac dysfunction and resulting in a wide range of clinical expressions. Treating generically, HF syndrome is reductive and misleading: to be really successful, the underlying disease, namely LV remodeling, should be addressed and treated.

LEFT VENTRICULAR REMODELING: MECHANISMS AND CHARACTERISTICS

LV remodeling is a complex, dynamic, and time-dependent process that may occur in different clinical conditions, including MI, leading to chamber dilatation, altered configuration, and increased wall stress. MI, particularly large, transmural infarctions, results in a complex of structural changes involving both the infarcted and noninfarcted zones. LV remodeling usually begins within the first few hours after an MI and results from fibrotic repair of the necrotic area with scar formation, elongation, and thinning of the infarcted zone. LV volumes increase, a response that is sometimes considered adaptive, associated with stroke volume augmentation in an effort to maintain a normal cardiac output as the EF declines. However, beyond this early stage, the remodeling process is driven predominantly by eccentric hypertrophy of the noninfarcted remote regions, resulting in increased wall mass, chamber enlargement, and geometric distortion (Fig. 54.1). These changes, along with a decline in performance of hypertrophied myocyte, increased neurohormonal activation, collagen synthesis, fibrosis, and remodeling of the extracellular matrix within the noninfarcted zone, result in a progressive decline in ventricular performance. Left untreated, LV hypertrophy, dilatation, and contractile dysfunction may progress indefinitely as evidenced by progressive increases in LV volumes.

Furthermore, as part the complex process of LV remodeling, functional mitral regurgitation (MR) may occur to adversely affect the prognosis (Fig. 54.2). Chronic ischemic MR occurs in approximately 20% to 25% of patients followed up after MI and in 50% of those with postinfarct congestive HF. The papillary muscle displacement, which may occur as a consequence of the LV dilatation, results in tenting of the mitral valve at closure with lack of a proper coaptation, in turn leading to secondary MR. In addition, ventricular dilatation results in anular enlargement, which further increases valve incompetence. It is well known that functional MR, causing LV volume overload, worsens prognosis. Until recently, it was unclear if the volume overload created by MR adds a greater pathologic burden to an already adverse condition or, simply, the worse prognosis is related to a poorer LV function, and functional MR is merely an indicator of this bad condition. To this regard, a major contribution has recently been provided by Rossi and coworkers in a large population of patients affected by dilated cardiomyopathy and HF. The authors found that functional MR was strongly associated with the outcome after adjustment of left ventricular ejection fraction (LVEF) and restrictive mitral filling pattern, either in patients with ischemic dilated cardiomyopathy or nonischemic.
Section II: Adult Cardiac Surgery

The Rationale to Perform Left Ventricular Reconstruction in Reversing Left Ventricular Remodeling

Surgical LVR has been introduced as an optional therapeutic strategy aimed to reduce LV volumes through the exclusion of the scar tissue, thereby reducing the ventricle to a more physiological volume, reshaping the distorted chamber, and improving cardiac function through a reduction of LV wall stress in accordance with the principle of Laplace’s law. Since LV wall stress is directly proportional to LV internal radius and pressure and inversely proportional to wall thickness, any intervention to optimize this relationship would be beneficial either in terms of improving wall compliance and reducing filling pressure or, as wall stress is a crucial determinant of afterload, in terms of enhancing contractile performance of LV by increasing the extent and velocity of systolic fiber shortening. Furthermore, LVR of failing ventricles is usually combined with myocardial revascularization with the aim to treat the underlying coronary artery disease. Finally, although the matter of functional chronic ischemic MR, in terms of whether, when, and how it should be corrected is still considerably controversial, it should be pointed out that LVR offers either the possibility to repair the mitral valve through the LV opening or the potential of improving mitral functioning by reducing LV volumes, papillary muscles distance (which is a main determinant of functional MR), and hence rebuilding a more normal geometry.

Left Ventricular Reconstruction Technique

After the first description of the linear suture by Cooley in 1958 and the circular external suture described by Jatene in 1984, Dor started to use a circular patch to reconstruct LV cavity (“endoventricular circular patchplasty”—EVCPP), addressing anatomic situations different from the classical LV aneurysm. The technique, performed under total cardiac arrest, involved the opening of the ventricle in the center of the depressed area, thrombectomy when indicated, and exclusion of dyskinetic or akinetic LV free wall through an endoven-

tricular circular suture passed in the tissue above the transitional zone. A Dacron patch was secured at the junction of the endocardial muscle and scarred tissue, thereby excluding noncontractile portions of the LV and septum. In 1998, Dor further refined the technique by placing a volume-measuring device, in the form of a saline-filled balloon, into the ventricle before tightening the suture, thereby standardizing the conduct of the operation and ensuring that the ventricle was left neither too large nor too small. Later, the procedure has been adopted by many surgeons leaving, however, the technique far from a real standardization and making the results difficult to compare. McCarthy described a double purse-string suture no-patch technique. Mickleborough described a tailored scar excision along with septoplasty, when indicated (dyskinetic septum), and modified linear closure. We adopted a technique that does not differ substantially from the Dor procedure except for the use, since July 2001, of a preshaped mannequin (TRISVR™, Chase Medical Inc., Richardson, TX; Fig. 54.3). The operation is performed under total cardiac arrest, with antegrade cold blood cardioplegia. According to the potential of this surgery to address “ischemia, ventricle and valve,” we perform the procedure as follows.

Ischemia

Complete myocardial revascularization is performed first with particular attention to revascularize the proximal left anterior descending segment, to preserve the
upper part of the septum. For this purpose, a left internal mammary artery is almost always placed on the left anterior descending artery. Revascularization is completed, when indicated, through sequential saphenous vein coronary bypass grafting on right and circumflex arteries.

**Ventricle**

After completion of coronary grafting, the ventricle is opened with an incision parallel to the left anterior descending artery, starting at the middle scarred region and ending at the apex. The cavity is carefully inspected and any thrombus is removed if present. The surgeon must be careful to identify the transitional zone between scarred and nonscarred tissue, driven by cardiac magnetic resonance (CMR) with late gadolinium enhancement (LGE), when previously performed, or alternatively by echocardiographic analysis. After that, a preshaped mannequin is inserted into the LV chamber and inflated with saline (Fig. 54.3, upper panel on the left). The mannequin is useful to optimize the size and shape of the new LV, particularly when the ventricle is not very enlarged (to reduce the risk of a too small residual cavity), or when the transitional zone between scarred and nonscarred tissue is not clearly demarcated, as occurs in akinetic aneurysms. Furthermore, the mannequin is useful in giving the surgeon the correct position of the apex and in maintaining the long axis of the ventricle in a physiologic range (7.5/8.5), reducing thereby the risk of sphericalization of the new ventricle. The size of the device is defined by multiplying the body surface area of the patient by 50 or 60 ml. The exclusion of dyskinetic or akinetic LV free wall is performed through an endoventricular circular suture passed in the tissue of the transitional zone (Fig. 54.3, upper panel on the right). The conical shape of the mannequin guides the orientation of the plane of the endoventricular circular suture at the transitional zone, obliquely toward the aortic flow tract, mainly in rebuilding the new apex. The reconstruction of the apex may be difficult when the apical and inferior regions are severely dilated and scarred; in this case, we apply a modification of the Dor procedure that involves plication of the distal inferior wall before patch placement, thus placing the apex in a more superior position and leaving a small portion of scar (Fig. 54.4). The mannequin is removed before the closure of the ventricle and the opening is closed with a direct suture (simple stitches tangential to the mannequin) if it is <3 cm large or with an elliptical, synthetic patch if >3 cm to avoid distortion of the cavity (Fig. 54.3, lower panel on the left). In the first case, a second stratum with the excluded tissue is sutured on the first suture to avoid bleeding. If the closure is performed by using a patch, a few millimeters of border is left sewing the patch in the everting way (Fig. 54.3, lower panel on the right). This technique assures a good hemostasis and makes easier to

Fig. 54.4. The plication at the inferolateral portion of the ventricle is useful to lift up the new apex.

Valve
When indicated, mitral valve is repaired through the ventricular opening with a double-arm stitch running from one trigone to the other one, embedding the two arms in the posterior annulus of the mitral valve (Fig. 54.5). To avoid tears of the posterior left of the mitral valve, we reinforce the suture with a Teflon strip. After that, the suture is tied to undersize the mitral orifice. A Hegar sizer No. 26 is used to trim the mitral annulus. Alternatively, a restrictive mitral annuloplasty with a ring implantation has been recently introduced for selected patients, when the LV opening is not big enough to have a good exposition of the mitral valve.

Special Conditions
The surgical procedure as described above is usually performed to reverse LV remodelling after an anterior MI. However, beside the LV remodelling following an anterior MI, other pattern of postinfarction LV remodelling may occur, according to the site of coronary occlusion and varying from the classic posterior aneurysm with a bulging of the inferior wall and good contraction of the remaining cavity to a global dilatation of the LV chamber with regional wall dysfunction at the inferior and posterobasal region. In these situations, the same concept used for anteroseptal dilatation can be applied, excluding the scar tissue and reducing the volume. Surgery for the posterior aneurysm generally involves a patch to close the neck of dilatation. However, the treatment of global dilatation of the inferoposterior wall is more complex, especially for the relationship between the scar and the dilatation with respect to the papillary muscles. After an inferior MI,

Fig. 54.5. Mitral valve repair. Mitral valve is repaired through the ventricular opening with a double-arm stitch running from one trigone to the other one, embedding the two arms in the posterior annulus of the mitral valve.
there are two possibilities: (a) the dilatation is mainly between the two papillary muscles or (b) the dilatation is between the posteromedial papillary muscle and the septum, which is deeply involved. We use two techniques for LV dilatation after an inferior MI. The first (Fig. 54.6, on the left panel) involves the opening of the scarred wall at the level of the scar or at the level of the collapsed area, parallel to the posterior descending artery. A continuous 2-0 Prolene suture is performed to obtain the reapproximation of the two papillary muscles and the exclusion of the entire dilated zone. The suture is started at the beginning of the dilatation (sometimes just at the level of the mitral annulus) and continues toward the apex. According to the second technique (Fig. 54.6, on the right panel), the wall is opened and the continuous suture is brought behind the posteromedial papillary muscle, bringing the posterior wall against the septum.

**DRAWBACKS AND SUGGESTIONS**

**Inside the Ventricle**

Despite the use of the sizing device, the residual volume is not always congruent with the expected volume, since the operation depends not only on the preoperative volume but also on the preoperative shape, on the papillary muscles size and position, on the presence of trabeculae, or on the LV compliance. Despite any efforts to describe different LV shape abnormalities (Type 1, Type 2, and Type 3, according to Di Donato’s classification, or using old or new indexes, including sphericity index, eccentricity index, and/or conicity index), the true anatomy of the ventricle and the extension of the damage might not be extensively clear before the opening of the cavity. This is especially true when the anterior septum is deeply involved (Fig. 54.7). In this case, noninvasive imaging testing is mandatory to evaluate the feasibility of the procedure and to tailor eventually the operation for a specific patient.

Regarding the impact of LVR on LV compliance, our group reported for the first time that the likelihood for diastolic function worsening after LVR is higher when the LV cavity is globally dilated (i.e., akinetic aneurysm) and relatively too small at the preoperative evaluation (leading to a residual volume even smaller), suggesting a careful preliminary echo-Doppler evaluation. Furthermore, we reported that diastolic dysfunction (early-to-late diastolic filling pressure >2) increases the operative risk of mortality when associated with MR and a New York
Heart Association class > II, reinforcing the need for a more comprehensive and accurate preoperative evaluation of diastolic function, if any possible.

**Inside the Valve**

In agreement with the data from the literature, showing a recurrence of MR up to 30% in patients undergoing undersized mitral ring annuloplasty, we observed a recurrence of moderate or severe MR (grade 3 or 4+) of 29% at 6 months follow-up in a subgroup of patients with previous anterior MI undergoing CABG plus LVR combined with MV repair performed according to the above-mentioned technique. Among geometric factors associated with recurrence, the postoperative long axis was the most sensitive and specific, in the meaning that a residual too short long-axis (< 7.5) was associated with an increase in the sphericity index, which in turn plays a central role in the recurrence of MR. Therefore, surgeons must be aware to preserve the length of the ventricle. However, other preliminary remarks should be taken into account when we decide to repair the mitral valve in patients with chronic ischemic MR. In addition to having to distinguish between MR after inferior MI (which is the most common) and MR after anterior MI, it should be reinforced the concept that, in any case, chronic ischemic MR is a “complex and dynamic disease,” involving coronary arteries, mitral annulus, subvalvular apparatus, and ventricle, in which the large number of geometric and hemodynamic variables carries the risk of a suboptimal result at follow-up. Recently, Gelsomino and coworkers showed that anterior mitral leaflet tethering is a powerful predictor of MR recurrence after undersized mitral ring annuloplasty, suggesting the need for concomitant or alternative surgery addressing the leaflet tethering (i.e., papillary muscle repositioning). In this regard, LVR associated with MV repair takes the advantage to address both ventricle and mitral annulus, but it does not seem to be enough in saving the result, as in our cohort. It should be emphasized that LV adverse remodeling is a dynamic process as well as LV reverse remodeling, both evolving over time, the latter depending on the completeness of revascularization, the residual shape of the LV (in case of performing LVR), the technique to reduce the mitral annulus (with or without a prosthetic ring and type of ring), and the complex interaction between each other. Finally, it should be outlined that, although the term functional mitral regurgitation is commonly used to refer to ischemic MR without “organic lesions” of the mitral valve, pathologic studies have shown that, in patients with heart failure (therefore, potentially suitable for LVR), the mitral leaflets are thinned out with altered collagen composition compared with normal autopsy control. It could be hypothesized that in HF patients MR might not be purely functional, arising implications for alternative, extreme strategies including mitral valve replacement.

**HOW TO MAKE THE DECISION**

The choice to add LVR to CABG should be based on a careful evaluation of patients, including symptoms, measurements of the LV volumes, careful assessment of mitral valve, including geometry and MR severity, assessment of the transmural extent of myocardial scar tissue and viability of regions remote from the scar, and should be performed only in centers with a high level of surgical expertise.

**Symptoms**

In the last two decades, the indications for revascularization in patients with ischemic HF were limited to patients with angina and significant coronary artery disease. The management of patients with ischemic HF without angina has been a challenge because of the lack of randomized data with patients who predominantly had HF symptoms. Until recently, coronary revascularization has been supported for this population. However, only approximately 40% of patients with ischemic HF show improvement in LVEF after revascularization. The possibility to combine myocardial revascularization with surgical LVR has been addressed in the STICH (Surgical Treatment for Ischemic Heart Failure) trial that compared CABG alone with the combined procedure of CABG with LVR in 1,000 patients with CAD amenable to CABG, an LVEF of 35% or less, and a dominant anterior region of myocardial akinesia or dyskinesia amenable for LVR. The results show no difference in the occurrence of the primary outcome (a composite outcome of death from any cause or hospitalization for cardiac causes) between the two groups. However, only 49% of the STICH patients were in NYHA class III/IV and the same percentage...
were in CCS III/IV, indicating a population more representative of the real world of ischemic patients independently by the HF. We believe that in patients selected for LVR, HF symptoms should be predominant over angina.

**DIAGNOSTIC IMAGING TOOLS**

**Echocardiography**
Echocardiography (M-mode and two-dimensional transthoracic approach—TTE) is the first-choice diagnostic imaging tool, providing accurate information about LV dimensions (internal diameters and volumes) and systolic function (Fig. 54.8). The feasibility of a reliable echocardiographic examination is sometimes limited by poor acoustic windows, an inadequate endocardial border definition or, when the ventricle is particularly enlarged, by incomplete visualization of the apex. The assessment of LV volumes plays a central role in the decision making. The LV dilatation is the "conditio sine qua non," the volume reduction should not be performed, first to avoid deterioration in diastolic function, as we have previously reported. Furthermore, echocardiography provides information about regional wall motion abnormalities and diastolic function, according to the left atrium volume and, when combined with Color- and Tissue Doppler, transmitral flow velocity and TDI measurements. In addition, two-dimensional TTE is a reliable tool to assess the MV apparatus in terms of geometry (leaflet tethering, annulus dilatation, tenting area—the area between the tented leaflets and the annular plane in systole—and tenting height—the distance between the point of leaflet coaptation and the mitral annular plane in systole—and interpapillary muscle distance, Fig. 54.9) and MR severity, using a semiquantitative or quantitative methods. Recently, Rossi and coworkers showed that a quantitatively defined functional MR [using the vena contracta (VC) or effective regurgitant orifice (ERO) or regurgitant volume (RV)] was strongly associated with the outcome of patients with HF, independently of LV function, suggesting the following criteria to define severe MR: an ERO >0.2 cm², an RV >30 ml, and a VC >0.4 cm. However, resting examination may underestimate the full severity of ischemic MR especially in this subgroup of HF patients. Exercise echocardiography (using a semisupine...
Cardiac Magnetic Resonance

Cardiac magnetic resonance (CMR) is increasingly being used for the noninvasive imaging of the HF population and it is nowadays the gold-standard imaging technique to assess myocardial anatomy, regional and global function, and the extension of the scar. Unlike echocardiography, CMR has the ability to image in any desired plane and with a nearly unrestricted field of view, allowing unprecedented flexibility to evaluate abnormal cardiac and extracardiac structures. The functional information derived from cine CMR includes global LV and RV volumes and mass, without the need to make any geometrical assumptions, and therefore applies to ventricles of all sizes and shapes, even to those that have been extensively remodeled. A basic CMR protocol includes the assessment of LV volumes and global and regional function based on contiguous short-axis cine images. The greatest usefulness of CMR is in the detection of myocardial scar with LGE. LGE imaging visualizes irreversible damage (myocardial scar or fibrosis) due to an accumulation of contrast agent in areas with increased extracellular space. In LGE images, viable myocardium appears dark, whereas necrotic or fibrotic myocardial tissue appears bright (Fig. 54.10). LGE has unprecedented spatial resolution and can determine the transmural extent of scar, which is not possible with other imaging modalities. At the same time, CMR offers
the opportunity to assess thickness and function of the remaining nonenhanced viable myocardial tissue (“the remote regions”), which may be hibernating (ischemic but viable myocardium likely for functional recovering after CABG) or nonischemic but dysfunctional because of the high local tension that reduces shortening and likely for functional improvement after volume reduction obtained through LVR, as previously demonstrated. On the other hand, the detection of scar by LGE in the remote regions, especially at the level of basal segments, may predict an unsatisfactory LV systolic and diastolic functional recovery and adverse clinical outcomes after LVR, as recently reported. Commercially available software dedicated to LV analysis now provides a semi-automated assessment of thickening, global and regional function, and the percentage and extension of scarred tissue, which can potentially be combined in predicting myocardial viability without a need for pharmacologic stress (Fig. 54.10).

The main limitations, at this time, are the exclusion of patients with pacemakers or devices for cardiac resynchronization therapy and the potential reduction of image quality in patients with significant arrhythmia or severe shortness of breath. Therefore, both echocardiography and CMR, either for respective limitations or because of the fact that they provide different information, must be recommended in the surgical decision making.

Suggested Indications

According to our experience, we consider the following to be the indications for LVR:

- Previous anterior MI, as evaluated by electrocardiogram or CMR
- CMR should be preferred, when available and not contraindicated.
- LVESVI > 60 ml/m²
- Preoperative LVESV should be carefully evaluated to avoid the selection of patients with small ventricles for which the likelihood for diastolic function worsening is high.
- LV dysfunction with regional asynnergy, either dyskinetic or akinetic; when
LV asynergy is severe and diffuse, SVR should be performed only if regions remote from the scar show some degree of detectable contraction.

- To this aim, CMR should be mandatory.
- Predominant HF symptoms [New York Heart Association (NYHA)—class III/IV]
- The indication can also be expanded to patients presenting with ventricular arrhythmias and/or angina who need surgical revascularization if the previous conditions are present, to avoid further remodeling.

Suggested Contraindications

- Severe right ventricular dysfunction (biventricular dilated cardiomyopathy) (absolute).
- Severe pulmonary hypertension not associated with MR (relative).
- Severe regional asynergy without LV dilatation (absolute).
- Restrictive diastolic pattern associated with high functional class and MR (absolute).

LEFT VENTRICULAR RECONSTRUCTION AND OUTCOME: INSIGHTS INTO THE LITERATURE

The first consistent results on SVR have been reported by Dor and coworkers showing that the procedure improves LV systolic function, NYHA functional class and survival by a reduction in ventricular volumes, and an increase in EF not only in patients with classic dyskinetic aneurysm but also in dilated ischemic cardiomyopathy and severe LV dysfunction. After that, a large amount of reports drawn on various data sets from registries and mainly observational studies have shown that SVR is effective and relatively safe with a favorable 5-year outcome. The RESTORE Group (The Reconstructive Endoventricular Surgery returning Torsion Original Radius Elliptical shape to the left ventricle), the first international registry, including 1,198 patients undergone SVR, showed that the LVEF increased from 29.6 ± 11.0% preoperatively to 39.5 ± 12.3% postoperatively (P < 0.001) and the LV end-systolic volume index (ESVI) decreased from 80.4 ± 51.4 ml/m² preoperatively to 56.6 ± 34.3 ml/m² postoperatively (P < 0.001). Thirty-day mortality after SVR was 5.3%, and it was higher among patients in whom mitral valve repair was combined to SVR (8.7%) versus patients in whom no mitral valve procedure was required (4.0%; P < 0.001). Overall, the 5-year survival was 68.6 ± 2.8% and 5-year freedom from hospital readmission for CHF was 78%. In 2007, we published the largest single-center experience with SVR (1,161 patients) reporting a 30-day cardiac mortality of 4.7%. Patients requiring mitral valve repair/replacement (18%) had a significantly higher (13% vs. 3.0%; P < 0.001) operative mortality rate in agreement with the results from the RESTORE. In a subgroup of 254 patients, we reported that MR alone does not significantly increase operative mortality risk; conversely, if associated with NYHA class III/IV, it determines a significant increase in the mortality risk; and if a severe diastolic dysfunction is also present (E/A > 2), the risk is further increased, providing, for the first time, that severe diastolic dysfunction may be a risk factor for SVR. Furthermore, beneficial effects from SVR include an improvement in LV mechanical synchrony, resulting in more efficient myocardial pump function.

Along with the above-mentioned reports, other contributions have been published by many centers performing SVR with a good surgical outcome. However, all these studies were not randomized to compare the potential additional benefit of SVR with CABG alone. Only one single-center study randomized a small number of patients (n = 74) with dysysynergic myocardium to CABG with or without SVR and reported that outcome of CABG + SVR was better than that of CABG alone.

The STICH trial has been the first, multicenter, international, randomized controlled trial (RCT), designed to assess the potential superiority of CABG over intensive medical therapy in improving long-term survival (“the revascularization hypothesis I”), and the benefit of SVR combined with CABG in improving hospitalization rates for cardiac cause compared with CABG alone in patients with LV dysfunction (EF ≤ 35%) and coronary artery disease suitable for surgical revascularization (“the revascularization hypothesis II”). The results of the Hypothesis 2 STICH trial showed no difference in the occurrence of the primary outcome (a composite outcome of death from any cause or hospitalization for cardiac causes) between the CABG group and the combined-procedure group. The 30-day mortality was similar (5% and 6% for CABG alone and for CABG plus SVR, respectively), and no difference in the rate of death from any cause was observed in a median follow-up period of 48 months. Both CABG alone and the combined procedure were equally successful in improving the postoperative CCS angina class and NYHA functional class as well as had similar improvements in the 6-minute walk test and similar reductions in symptoms. However, there was a greater reduction in the ESVI with the combined procedure (16 ml/m²), a reduction of 19%, lower than the percentage of reduction reported in previous observational series, ranging from 30% to 50%; Fig. 54.11, as compared with CABG alone (5 ml/m², a reduction of 6%); difference between the two groups in the change from baseline was significant (P < 0.001). This improvement in ventricular volume did not translate into a measurable benefit for the patients in terms of survival; indeed, the postoperative IVEsVII still remained large (>60 ml/m²), in both arms. This observation, along with the relative small percentage of ESVI reduction observed in the combined group, raised concerns on the extent of the SVR procedure that was applied in this trial.

As a matter of fact, the role of LV end systolic volume in patients with previous MI and LV remodeling has been known for years. In 1987, White and coworkers...
showed that patients with LVESVI >60 ml/m² had approximately a fivefold increase in mortality compared with those with normal volumes after an MI. Ten years later, the GUSTO-I trial confirmed that an ESVI of 40 ml/m² or more was an independent predictor of early and late mortality after a reperused MI. Until recently, coronary revascularization has been strongly recommended for this population. However, it has been reported that patients with severely dilated left ventricles have a low likelihood of showing improvement in EF despite the presence of substantial viability. Bax and coworkers showed that the change in EF after revascularization was linearly related to the baseline LVESV, with a higher end-systolic volume being associated with a low likelihood of functional recovery after revascularization. In addition, patients with a large LVESV had a worse long-term prognosis as compared with patients with a smaller LVESV. Based on that, to better understand the STICH results, our group reported the impact on survival of a residual LVESVI ≥ 60 ml/m². We showed that LVESVI following SVR impacts on the probability of death, being significantly higher in patients who remain with a postoperative LVESVI of ≥60 ml/m². We hypothesized that the lack of additional improvement in terms of survival in the SVR group observed in the STICH trial might be due to the inadequate volume reduction, which left the patients in the two arms at identical risk. This observation has been recently confirmed by Witkowski and colleagues showing that a residual postsurgical LVESVI of at least 60 ml/m² was independently associated with a fivefold increase in death and HF rehospitalization at 2 years follow-up after SVR. On the other hand, in the same report the authors showed a significant increase in LV filling pressures after SVR, as determined by an increase in E/A ratio (from 0.9 to 1.5; P < 0.001) and in E/E’ ratio (from 17 to 31; P < 0.001), supporting the hypothesis advanced by the STICH Investigators that benefits anticipated from LV volume surgical reduction (reduced wall stress and improvement in systolic function) are counterbalanced by a reduction in diastolic compliance leading, in turn, to a worsening in diastolic function. Our group had previously showed that diastolic dysfunction occur in the majority of patients affected by ischemic HF and suitable for LVR. After surgery, diastolic function remains unchanged or improved in the great majority of patients, whereas it worsens in a minority of cases (18% at discharge up to 21% at mid-term follow-up). Nevertheless, it should be pointed out that in a study by Witkowski and colleagues, patients with MR were not excluded (as we did in our series, because of the fact that MR increases E wave velocity by itself) and, even more questionable, up to 58% of patients have had concomitant restrictive mitral annuloplasty, which may induce a more pronounced increase in LV filling pressure.

The STICH trial has also been strongly criticized because there were too many expectations from these long-awaited results. Several limitations have led to substantial clinical uncertainty in making such results widely generalizable. Generally, it is admitted that randomized trials enroll a relatively small percentage of the eligible population (20% in the STICH trial), not fully representative of the daily clinical practice: only 49% of the STICH patients were in NYHA class III/IV and the same percentage were in CCS III/IV, indicating a population more representative of the real world of ischemic patients independently of the HF; in other words, in spite of the acronym, the study shifted from a HF population (which was also missing in the previous studies) to a broad horizon of ischemic patients. Furthermore, in the STICH trial there was no registry to follow eligible patients who were not randomized. Furthermore, the design of the STICH trial initially excluded patients with a LVESVI <60 ml/m². As the STICH study evolved, due to the empirical nature of the entry criteria, it was decided to liberalize inclusion criteria to include patients amenable to SVR surgery in the opinion of the investigators. This led to the inclusion of patients with a broad range of baseline LVESVI in the STICH population (ranging from 22 to 231 ml/m²) reinforcing the question on which ventricles have been randomized. Changing the inclusion criteria was an effort to apply the concept of SVR to a larger population with low EF in which SVR has unknown effects. Moreover, viability assessment to optimize the patient selection was not required. As mentioned above, LGE-CMR is gaining widespread use because of the information provided on the amount of myocardial scarring and its relationship with the outcome. Consequently, LGE-CMR should be considered an important diagnostic tool to identify a subset of ischemic HF patients likely to benefit from surgical therapies. RCTs are the gold standard for building evidence, whereas observational studies are potentially more susceptible to both known and unknown confounding factors. However, the latter include a broad spectrum of patients, enroll very large samples, and extend over long periods, making the consistency of their findings nevertheless remarkable. Thus, the Task Force on Myocardial Revascularization of the European Society of Cardiology and the European Association for Cardio-Thoracic Surgery recognized the merit of SVR, which has been included as a surgical option combined with CABG in selected HF patients with a scar in the LAD territory and a baseline LVESVI ≥60 ml/m² (Class of Recommendation IIb; level of evidence B). Recently, the strength of recommendations issued in clinical practice guidelines has been questioned because of the fact that they are largely developed from lower levels of evidence or expert opinion. However, we believe that the problem is not how guidelines are drawn up but rather in the growing difficulties in developing rigorous RCTs, in which, first of all, the randomized population should reflect the patients who will ultimately receive the study treatment in practice. That having been said, it seems that the daily surgical practice is not likely to change based on the STICH trial.

Beyond the debate that will probably continue for a long time, the choice to add SVR to CABG should be based on a careful selection of patients, coming from a tight collaboration between surgeons, cardiologists, and radiologists. In the meantime, it is desirable that a more detailed analysis of the STICH data, if any, will solve long-standing unanswered questions.

**EDITOR’S COMMENTS**

I asked Dr. Menicanti to do this chapter because he is one of the true international experts on left ventricular reconstruction. He took Dr. Dor’s original techniques and has continued to expand its application. I also had the opportunity to scrub in on a case with him here at The University of Virginia and indeed we found our techniques were remarkably similar. The surgical aspects of this procedure are well described and are certainly safe. The big issues are application. A large randomized trial of this procedure versus coronary artery bypass grafting alone demonstrated no advantage to left ventricular reconstruction. There are a lot of issues about the STICH trial that have been discussed very carefully by Dr. Menicanti and his colleagues, but the fact reminds that the data noted in this investigation were not positive for routine left ventricular reconstruction. Having said that, this type of reconstruction for the treatment of left ventricular aneurysms certainly has been well described and is clearly better than other approaches of aneurysm reconstruction. For now, I believe this is where this procedure will have its greatest benefit. Further reviews of the STICH trial may show some other places where the technology works. ILK

BACKGROUND

Since 2000, two major developments have ushered in the modern era of left ventricular assist devices (LVADs): the 2001 Randomized Evaluation of Mechanical Assistance for the Treatment of Congestive Heart Failure (REMATCH) trial, which resulted in the Food and Drug Administration (FDA) approval of LVADs for long-term destination therapy and the emergence of smaller continuous-flow devices starting in 2005. It is now indisputable that implantable LVADs are an important therapeutic modality for patients with end-stage heart failure and will remain so for the foreseeable future.

Approximately 5 million Americans suffer from heart failure with over 550,000 new cases diagnosed each year and an estimated 287,000 deaths resulting from heart failure in the United States every year. In addition to the loss of life, heart failure poses a significant financial burden with estimated annual direct costs of $35 billion dollars per year in the United States alone. Despite advances in the management of heart failure, there may be as many as 100,000 people who have been treated with guidelines-based therapy but have remained relatively unresponsive in New York Heart Association (NYHA) Class IIIb or IV. In these end-stage heart failure patients with recurrent hospitalizations, few options exist. Orthotopic heart transplantation, the gold standard of therapy for end-stage heart failure, has been shown to definitively improve outcomes with median survival of 13 years but this is restricted to a select relatively young population. In addition, a critical shortage of suitable grafts limits the number of heart transplants performed in the United States to about 2,000 per year, only 2% to 4% of patients who need definitive therapy. With a growing population of end-stage heart failure patients and a static donor pool, additional treatment modalities must be pursued.

To date, the most promising new treatment to emerge for end-stage heart failure has been mechanical circulatory support with ventricular assist devices (VADs). The development of VADs began in earnest in 1964 with the National Institutes of Health establishment of the Artificial Heart Program, whose stated goal was putting a man-made heart into a human being by the end of the decade. Unlike the moon landing, this lofty goal was not met by the end of the decade; nevertheless, progress proceeded slowly and clinical use of VADs on a more routine basis began in the mid-1980s. The majority of implantable VADs are designed for the support of the left ventricle (LVADs) and our discussion will focus on these devices. Implantable LVADs function by removing oxygenated blood from the apex of the left ventricle, passing it through a mechanical pump, and returning pressurized blood to the ascending aorta. Despite the predominance of implantable LVADs, other temporary nonimplantable configurations do exist and the use of VADs designed for right ventricular assist devices (RVADs) failure, or biventricular failure is also well established.

Currently, implantable LVADs can be classified into two main categories: volume-displacement (pulsatile) and continuous-flow (nonpulsatile) pumps. Implantable LVADs are typically used for either bridge to heart transplantation (BTT) or long-term destination therapy for those patients not eligible for transplant. Initial clinical success was achieved with the so-called first-generation devices, or pulsatile pumps, which include the HeartMate XVE and its predecessors the HeartMate IPlOOO and HeartMate VE (Thoratec Corp., Pleasanton, CA), the Thoratec PVAD (Paracorporeal Ventricular Assist Device) and IVAD (Implantable Ventricular Assist Device; Thoratec Corp.), and the Novacor LVAS (World Heart Corp., Oakland, CA). These first-generation LVADs came into clinical use in the mid-1980s and all of the above are FDA-approved for the BTT indication. Of these first-generation devices, only the HeartMate XVE is FDA-approved for destination therapy. In the landmark 2001 REMATCH trial, patients with irreversible heart failure who were ineligible for transplantation were randomized to either maximal medical therapy or HeartMate XVE implantation. LVAD implantation doubled the 1-year survival rate of these patients from 25% to 52%. The FDA subsequently approved the HeartMate XVE for permanent destination therapy, ushering in the modern era of LVAD therapy.

In recent years, the pulsatile first-generation LVADs have been replaced in clinical practice by second-generation, continuous flow LVADs. These devices, which include the HeartMate II (Thoratec Corp.), Jarvik 2000 FlowMaker (Jarvik Heart, Inc., New York), and MicroMed–DeBakey (MicroMed Cardiovascular, Inc., Houston, TX), have an internal rotor within the blood flow path that is suspended by contact, blood-immersed bearings. These continuous-flow, rotary pumps were introduced to overcome many of the shortcomings of the first-generation devices, and they are simpler in design with only a single moving part: the internal rotor. Advantages over first-generation devices include smaller size requiring less extensive surgical dissection for implantation, the absence of valves that are a primary site of wear, higher efficiency with less energy requirement, and a smaller percutaneous lead. With these improvements, the second-generation devices have demonstrated improved reliability with device support of more than 6 years reported. The most extensive clinical experience is with the HeartMate II.

Currently, the HeartMate II is the only second-generation device approved for both BTT and destination therapy in the United States. In a recently published randomized clinical trial comparing the HeartMate II versus the first-generation HeartMate XVE for destination therapy, the HeartMate II was shown to be significantly better than the HeartMate XVE in achieving the primary end point of survival free from device failure or disabling stroke at 2 years. Moreover, patients with HeartMate
Il support also had significantly superior actuarial survival rates at 1 (68% vs. 55%) and 2 years (58% vs. 24%). More recent evidence shows that the actuarial 1-year survival rate for those patients receiving a HeartMate II is now almost 80%, a staggering improvement from the 52% seen in the REMATCH trial barely 10 years ago, and a number which approaches the accepted survival rate for the gold-standard of heart transplantation.

PATIENT SELECTION AND PREOPERATIVE EVALUATION

Despite recent developments in device technology and patient care, there is no substitute for proper patient selection in the achievement of optimal outcomes. Whenever possible, LVAD implantation should be performed under elective and not emergent circumstances. Appropriate patient selection and proper timing of implantation are likely more important than any other aspect of a successful LVAD program. Each patient’s comorbidity profile, ability to survive surgery, social support, and expected functional level after implantation should be carefully assessed prior to surgery. Optimal timing of LVAD implantation should occur prior to the development of irreversible end-organ damage but after correction of reversible comorbidities. Risk assessment of medical and surgical issues for both BTT and destination therapy are virtually identical and close collaboration with heart-failure cardiologists is essential for the identification of those patients who will benefit most from LVAD implantation.

Numerous factors are known to influence outcomes and most risk factors are additive. Several evidence-based predictive models, composite risk scores, and defined patient profiles are available, which are useful in selecting appropriate patients for LVAD implantation. For example, the Seattle Heart Failure model is a useful tool to identify those heart-failure patients who will derive maximum benefit from LVAD. Using easily obtained clinical parameters, a heart failure patient’s probability of 1- and 2-year survival with and without LVAD can be calculated using this validated model. In addition, the Lietz and Miller 90-day predictive model identifies nine weighted risk factors affecting mortality. This model has proven useful but must be applied with care as it was developed by analysis of 222 patients undergoing HeartMate XVE implantation for BTT and is not validated for continuous-flow LVADs or destination therapy.

The Interagency Registry for Mechanically Assisted Circulatory Support (INTERMACS) has defined seven patient profiles and Seattle Heart Failure model identifies nine weighted risk factors affecting mortality. This model has proven useful but must be applied with care as it was developed by analysis of 222 patients undergoing HeartMate XVE implantation for BTT and is not validated for continuous-flow LVADs or destination therapy. The Interagency Registry for Mechanically Assisted Circulatory Support (INTERMACS) has defined seven patient profiles and has correlated survival after LVAD with these patient profiles (Table 55.1). For example, those in profile 3, stable but inotrope dependent, have the best survival while patients in profile 1, cardiogenic shock, have high mortality and may be too sick for implantable LVAD placement. We find the combination of the INTERMACS profile and Seattle Heart Failure model most useful and believe that these tools support the trend in practice toward LVAD implantation earlier in the progression of heart failure.

One key factor for optimal patient outcome after LVAD implantation is RV function. RV failure is a leading cause of morbidity and mortality due to inability of the RV to pump sufficient blood through the pulmonary circuit. The LVAD unloads the LV allowing a decrease in pulmonary artery pressures and a corresponding reduction in RV afterload. On the other hand, LVADs increase systemic vascular return to the RV and reduced LV pressure can cause displacement of the interventricular septum into the left side, thereby reducing efficient RV function. In our practice, postimplant RV failure can be anticipated preoperatively and can be avoided through a combination of careful patient selection, prompt pharmacologic treatment of at-risk patients, and careful protection of the RV intraoperatively.

Other key factors that should be specifically addressed as part of a comprehensive preoperative assessment include nutritional status, renal function, hepatic function, gastrointestinal (GI) bleeding, pulmonary function, coagulation status, infection, neurologic function, and perhaps most importantly, psychosocial and psychiatric function. One of our key exclusion criteria for LVAD is the lack of a well-established social support system. Patients will require extensive assistance after leaving the hospital and must demonstrate the presence of a supportive network of family and friends who will be available to assist

with care. Given the complexity of management concerns, comorbidity profiles, and social issues associated with LVAD implantation, the importance of a multidisciplinary team approach to patient care cannot be overemphasized. All social and medical risk factors are assessed and addressed by our team of LVAD professionals including the surgeon, heart failure cardiologist, LVAD coordinator, nurse practitioners, social workers, pharmacists, dieticians, and many others. Table 55.2 lists our minimum goals with regard to standard metabolic markers associated with several patient risk factors. Nutritional status, as an example, demonstrates the importance of the multidisciplinary approach to optimizing patient outcomes. Malnutrition is common in patients with heart failure and if not addressed prior to implantation, it leads to increased infection risk, decreased functional recovery, and generally poor outcomes. For patients with a prealbumin <15, enteral feeding should be initiated preoperatively and should continue through the postoperative period until the patient is taking adequate oral nutrition. Caloric intake, nutritional supplementation, and the metabolic response to changes in nutritional management must be all be monitored carefully throughout the preoperative, postoperative, and outpatient course of care. This is best achieved with the input of multiple specialists. Similar proactive approaches must be taken toward the other mentioned patient comorbidities and directed therapy should begin prior to LVAD implantation and continue throughout the postoperative stay and outpatient course of therapy.

Implantation of a long-term LVAD should not be considered in patients with irreversible major end-organ dysfunction, severe hemodynamic instability, unknown neurologic status, major coagulopathy, irreversible respiratory failure requiring mechanical ventilation, bacteremia, or right heart failure. In patients who present in cardiogenic shock and accompanied end-organ dysfunction, we have found success with temporary mechanical support in the form of the TandemHeart® Percutaneous Ventricular Assist Device (pVAD) system (Cardiac Assist, Inc., Pittsburgh, PA). This device, which can be inserted under fluoroscopic guidance in the catheterization laboratory, employs a transeptally placed inflow cannula to pump oxygenated blood from the left atrium, through an external centripetal blood pump, and back into the outflow cannula which is secured in the femoral artery. Flow rates of up to 4.0 L/min can be achieved and we have successfully used this pVAD system in multiple patients who presented in cardiogenic shock, in whom the reversibility of their condition was unknown. In our experience, patients who demonstrate significant reversal of end-organ failure within several days after initiation of pVAD support are excellent candidates for subsequent implantable LVAD therapy. To date, we have successfully placed implantable HeartMate II LVADs in four patients who were bridged temporarily with a Tandem Heart pVAD.

### HEMODYNAMICS AND VALVULAR DISEASE

The physiologic goal of LVAD implantation remains the same regardless of the device implanted: mechanical unloading of the failing left ventricle along with an increase in aortic perfusion. The decompression of the LV and increase in systemic perfusion in turn lead to improved RV efficiency—via an increase in venous return to the RV and a reduction in pulmonary pressures by unloading the LV and decreasing pulmonary pressure afterload. All of these changes reduce cardiac work, improve myocardial perfusion, and allow for reversal of the neurohormonal activation and catabolic state present in patients with progressing heart failure. The combination of improved perfusion along with suspension of the heart failure milieu allows for recovery of non-reversible end-organ damage and, in rare cases, significant myocyte recovery allowing for subsequent device removal.

While the physiologic changes that accompany LVAD implantation have been proven to provide relief from heart failure for properly selected patients, the re-routing of blood flow and concomitant flow and pressure changes in the cardiac chambers and great vessels must be carefully considered in each patient. After LVAD placement, the majority of systemic blood flow bypasses the aortic valve, and the structural integrity and valvular function of the heart must be carefully evaluated in light of these anticipated changes. Echocardiography both prior to LVAD implantation and at the time of surgery is essential for the evaluation of cardiac function and identification of anatomic abnormalities that may warrant correction at the time of surgery. All atrial and ventricular septal defects should be repaired during LVAD implantation and a dedicated bubble study is an important part of the echocardiographic evaluation. Even the smallest patent foramen ovale (PFO) must be closed during the LVAD procedure as any PFO may become hemodynamically significant after LVAD placement. For this reason, it is imperative to perform careful echocardiographic evaluation for the presence of any atrial or ventricular septal defects both before and after initiation of LVAD support. In addition, the functional capacity of any valve may change after LVAD implantation so all valves should be carefully evaluated intraoperatively and monitored for changes in valve function after initiation of LVAD support. Particular attention should be paid to valvular lesions that impact forward flow, and therefore require surgical correction including aortic insufficiency, mitral stenosis, and tricuspid insufficiency.

In the case of aortic insufficiency (AI), we opt to replace the aortic valve with a tissue bioprosthesis or surgically close the aortic valve in all patients with moderate or severe AI, and most patients with mild AI. With the increased aortic root pressure and decreased LV pressure that accompany LVAD support, even mild or moderate AI can become hemodynamically significant after device placement. In our experience,
trace AI does not require treatment and does not tend to significantly progress during LVAD support but again we stress the importance of intraoperative postimplantation echocardiography to confirm this finding. A number of aortic valve fusion procedures are available (complete oversewing of valve leaflets, partial fusion, patch covering, etc.) and fusion has proven to be a successful method for addressing AI both at our institution and others. Nevertheless, fusion procedures render the patient completely dependent on the LVAD, such that even a short disruption in device support could prove fatal, and our preference is to perform a bioprosthetic valve replacement when significant AI is present. In most patients supported by an LVAD, the aortic valve does not open with every cardiac cycle and this decrease in valve movement and stasis in perivalvular flow puts those with a mechanical valve at a high risk for thromboembolic events. For this reason, we replace any existing mechanical aortic valve with a bioprosthetic valve at the time of surgery. In contrast to AI, it is generally agreed upon that no degree of aortic stenosis requires treatment.

With regard to the mitral valve, stenosis may require correction but mitral insufficiency does not cause significant problems after LVAD placement. In most cases, mitral insufficiency improves with decompression of the LV and resolution of ventricular dilatation. Furthermore, even severe mitral insufficiency does not impair forward flow through the LVAD because the passive pressure gradients in the supported ventricle prevent significant backflow across the valve. On the other hand, moderate or severe mitral stenosis is an indication for valve replacement with a bioprosthetic valve, as this lesion reduces effective inflow into LVAD pump and may prevent achievement of optimal flow rates. In patients with a mechanical valve at the mitral position, we again opt to replace the mechanical valve with a bioprosthetic valve given the increased risk of thromboembolic complications associated with the mechanical valve.

For the right heart valves, we agree with the general consensus that only severe tricuspid or pulmonary insufficiency should be repaired or treated with valvular repair or replacement. Efficient RV function is essential for successful patient outcomes after LVAD and in most cases, mild-to-moderate insufficiency of either the tricuspid or pulmonary valve will improve after LVAD placement, secondary to LV decompression and reduced pulmonary pressures and RV afterload. Again, we emphasize the importance of intraoperative postimplantation echocardiography to confirm appropriate valvular function in every patient and to rule out new pathologic blood flow caused by the changing pressure and flow gradients associated with LVAD support.

**HEARTMATE II PLACEMENT**

Specific aspects of the surgical procedure vary according to the device-type being implanted but the principles of placement are similar for every device. We will describe the operative procedure for the HeartMate II LVAD, as this device is the most commonly used at the time of writing. The device and its components are prepared on the back table according to the Thoratec directions. Briefly, the HeartMate II pump is removed from the sterile pack and the inflow conduit is attached to the pump housing, filled with sterile saline, and any air bubbles are removed by gently tapping the side of the pump. The fingertip of a powderless glove is used to cover the inlet extension of the inflow graft and the pump/inlet extension is covered with antibiotic-soaked sterile laparotomy pads until the time of implantation. The bend relief is placed over the sealed outflow graft but remains disengaged for the deairing procedure and is also put aside until needed.

Meanwhile, the patient is intubated and standard hemodynamic access and monitoring for major cardiac surgery is initiated. The transesophageal echocardiography probe is inserted and assessment of cardiac anatomy and function is performed. Careful attention is paid to RV function. A detailed assessment is made of cardiac valve function, in particular looking for the valvular lesions described above that may require surgical correction. Attention is also paid to cardiac anatomy looking for ventricular or atrial septal defects (ASDs) that require surgical closure prior to LVAD placement (i.e., PFO). In the case of patients already supported with the Tandem Heart, an iatrogenic ASD is present and this requires correction prior to implantable LVAD placement.

After the standard prep and drape, the surgical timeout is performed and checklist reviewed. While minimally invasive LVAD implantation techniques have been described, we opt to perform a median sternotomy in all patients. Access sites for cardiopulmonary bypass (CPB) are carefully considered preoperatively and in patients undergoing repeat cardiac surgery, a preoperative computed tomography (CT) is routinely performed to assist with decisions on appropriate cannulation sites. In the uncomplicated patient without additional anatomic concerns, we perform the LVAD implantation on the beating decompressed heart. However, if septal defects or valve pathology are present, we perform the necessary aortic cross-clamp with antegrade and retrograde cardioplegia. After completion of the sternotomy, the sternal retractor is placed and the pericardium is opened. Prior to LVAD pocket formation, it is important to expose the heart and any additional vessels to allow for the rapid initiation of CPB in the event of hemodynamic instability. Any pericardial adhesions are carefully taken down and pericardium is suspended to create the appropriate cardiac well. Next, attention is turned toward creation of the preperitoneal LVAD pocket.

The HeartMate II is designed for preperitoneal placement and many centers place the device between the left rectus muscle and the posterior rectus sheath. We opt to place the device directly between the posterior rectus sheath and the peritoneum as we feel creation of an appropriately sized hemostatic pocket is easier in this location and requires less extensive dissection. The pocket is created by electrocautery dissection below the suspended pericardium superiorly. The anterior border of the pocket is formed by the posterior rectus sheath and transversalis fascia, the posterior border by the diaphragm superiorly, and the preperitoneal fat and peritoneum inferiorly. The medial diaphragmatic attachments to the left ribs are taken down to allow for creation of an appropriately sized pocket, and dissection along the posterior rectus sheath is continued under the costal margin on both sides (space of Larrei). The plastic sizing device is used frequently to determine adequacy of the pocket and to guide further dissection, especially with regard to the necessary lateral diaphragmatic exposure. Care is exercised to create a completely hemostatic pocket as patients have varying degrees of coagulopathy postoperatively and a pump pocket hematoma increases infection risk and contributes to other wound-healing problems. If the preperitoneal cavity is entered, 4-0 Vicryl sutures are used to close the entry site. The pleural
spaces are often violated during lateral dissection, especially on the left side. Pleural openings do not require closure but do necessitate pleural drain placement at the conclusion of the operation. Once an appropriately sized cavity is created and the sizing device can be easily inserted into the appropriate position, the patient is prepared for the initiation of CPB.

In patients who are undergoing their first cardiac operation, we prefer central aortic and caval cannulation. For reoperative surgeries, preoperative planning is key and a CT scan with or without contrast is routinely performed preoperatively for anatomic assessment. If the aortic anatomy is not optimal for central cannulation, we prefer an axillary approach by placing the arterial cannula into an 8-mm Dacron graft sewn onto the axillary artery. In any patient with significant atherosclerotic disease as documented by CT, we avoid femoral cannulation due to the elevated thromboembolic stroke risk. For patients in whom the LVAD is the first cardiac operation, care is taken not to elevate the pericardium off the aorta so that a virgin plane will be present at the time of potential subsequent orthotopic heart transplant. With regard to venous cannulation, we prefer a standard dual-stage venous cannula for uncomplicated cases. When additional procedures are planned that require access to the right atrium (i.e., correction of PFO, repair of ASD, Tandem Heart removal, tricuspid valve repair), bicaval cannulation is performed. For single cannulation, a 3-0 Prolene purse-string suture is placed in the right atrial appendage and for bicaval cannulation, an additional 3-0 Prolene purse-string is placed at the junction of the IVC and right atrium. In both cases, we attempt to minimize caval dissection and employ vacuum-assisted venous drainage without caval tapes in order to maintain virgin tissue planes in the event of subsequent transplantation. In patients who have had previous cardiac surgery, we prefer percutaneous femoral venous cannulation again to minimize dissection and maintain tissue planes for subsequent transplantation.

Following preparation of CPB access sites, systemic heparinization is performed and the standard arterial cannula is placed according to patient size and secured. Next, the dual-stage venous cannula or bicaval venous cannulae are placed and secured according to standard procedure. If aortic cross-clamp and cardioplegia are necessary, a retrograde cardioplegia cannula is placed via a right atrial stab incision and is directed into the coronary sinus and the DLP cannula is placed into the ascending aorta. Following the placement of appropriate cannulae, CPB is initiated.

Attention is next turned to the ventricular apex and the chest is flooded with carbon dioxide at 2 to 4 L/min to minimize the risk of air embolism or entrapment. The carbon dioxide flow continues for the remainder of the procedure. Laparotomy pads are placed posterior to the LV to elevate the apex and with the ventricle distended, the characteristic LV apical dimple is identified. In our experience, the ideal coring site is at the anterior aspect of and slightly lateral to this dimple. Once the coring site is chosen, a 0.5-cm cruciate incision is made using a No. 11 blade scalpel. A 14-F Foley catheter is inserted through this incision into the LV cavity and is filled with 30 ml of sterile normal saline. The catheter acts as a centering device and the circular coring knife is advanced over the distal end and gentle traction is placed on the catheter. The coring knife is aimed away from the interventricular septum toward the mitral valve posteriorly, and laterally toward the lateral LV wall. When aiming the coring knife, it is important to consider the anticipated changes in ventricular size resulting from LVAD decompression, as obstruction of the inflow cannula must be avoided to achieve optimal postoperative flow rates. The cutting edge of the coring knife is applied to the endocardium and gently rotated back and forth until the LV cavity is entered (Fig. 55.1). The coring knife is removed, Foley catheter deflated and removed, and attention is turned to examination and completion of the ventriculotomy. Metzenbaum scissors are often necessary to excise residual endocardial muscle at the coring site and care should be taken to preserve the subvalvular apparatus of the mitral valve as this is done. Once the ventriculotomy is satisfactorily completed, the ventricular cavity is inspected for mural thrombi or crossing trabeculae. Loose thrombi must be thoroughly removed as well as any crossing trabeculae. If significant left ventricle thrombi are present, aortic cross-clamp and cardioplegia should be performed to allow adequate removal of all thrombi and minimize the chances of distal embolus.

After completion of the coring ventriculotomy, 12 to 16 circumferential double-armed 2-0 Ethibond sutures with 10 mm × 12 mm pledgets are placed at that site. These sutures are placed approximately 15 mm from the epicardial perimeter in a partial thickness horizontal mattress manner with minimal travel between adjacent sutures (Fig. 55.2). Next, the sewing ring is brought into the field and polar coordinates are marked on the ring to assure proper alignment. The Ethibond apical sutures are passed through the sewing ring in corresponding position, taking care to penetrate the sewing ring only and not the attached sleeve. The ring is then advanced to the apical surface and each suture is tied with six or seven knots snugly enough to cause slight dimpling of the pledged myocardial cuff (Fig. 55.3). Adequate positioning of the sewing ring is again verified, and the device is then brought into the operative field for attachment of the inflow cannula. Some have reported the use of BioGlue® (CryoLife, Kennesaw, GA) or other hemostatic agents at the apical cannulation site, but we have found that this is a low-pressure site and does not require any additional hemostatic agents to maintain an adequate and hemostatic seal.

The HeartMate II LVAD is placed into its preperitoneal pocket and the inflow

Fig. 55.1. Coring of the left ventricular apex.

Fig. 55.2. Placement of the apical ventricular sutures.
cannula is positioned toward the sewing ring. Once alignment is satisfactory, the inlet extension is inserted into the sewing ring and secured in position by tying the attached green nonabsorbable suture. Early in our experience, we opted to further secure the inlet extension using a standard zip-tie (such as those used to secure CPB tubing) deployed proximal to the green suture but on reoperation for subsequent transplantation, we encountered loose zip-ties on more than one occasion. Currently, we tie a single No. 5 silk suture distal to the green suture and have found this to be adequate. Once the inflow cannula placement is complete, exposed portions of the device are covered with antibiotic-soaked sterile laparotomy pads and attention is turned toward the outflow graft anastomosis.

The ascending aorta is exposed and a site for anastomosis on the right lateral aspect of the proximal aorta is selected. The aortic anastomosis should be performed as proximal as possible on the ascending aorta to provide for adequate distal length for potential future aortic cross-clamp application and aorto-aortic transplantation anastomosis. Moderate tension is then placed on the outflow Dacron graft extension of the device, and the Dacron graft is cut to appropriate length. Some describe cutting the graft at a 45-degree angle to facilitate anastomosis but we observe superior results when it is cut at almost 90 degrees, as this allows use of a shorter section of aorta. Before cutting, ensure that the outflow graft is not twisted by checking the position of the black line on the graft.

above and below the bend relief. The DLP cannula is removed, a partial occlusion clamp is placed along the right lateral aspect of the aorta, and a longitudinal aortotomy is performed. If the patient’s aorta is too small to allow appropriate placement of the partial occlusion clamp, aortic cross-clamp, and cardioplegia should be performed. The ends of the aortotomy are circularized using a 4.8-mm punch and the aortotomy is enlarged by trimming the intervening edges of aortic tissue. The end-to-side anastomosis is then performed using two separate 4-0 or 5-0 Prolene sutures with 2 mm × 3 mm pledgets running from each end of the anastomosis (Fig. 55.4). Following completion, we place Omnex™ (Ethicon, Somerville, NJ) surgical sealant along the anastomosis to help ensure adequate hemostasis. The partial occlusion clamp is then slowly released and after allowing momentary filling of the outflow graft, a cross-clamp is placed on the proximal portion of the outflow graft. A pledged purse-string is placed in the outflow graft distal to the cross-clamp followed by creation of a 3-mm graftotomy using a No. 11 blade. The DLP cannula is then placed and secured in the outflow graft for subsequent deairing.

The next step is tunneling of the percutaneous lead or driveline. The patient should be evaluated for lead site placement prior to the procedure and marked. The selected exit site should be two finger breadths below the right costal margin, midclavicular line, or slightly lateral, in a position that will allow for freedom from tethering on clothing while standing or sitting. The tunneling device is bent into a gentle curve and starting from the right inferior aspect of the pump pocket, the tunneler is slowly advanced to the skin surface at the marked site. The tunnel should take a long curved route to maximize the amount of velour-coated percutaneous lead in the subcutaneous space. This will promote optimal ingrowth of the percutaneous lead and help prevent postoperative driveline or pump pocket infection. We opt to make a small 1.5-cm latitudinal skin incision at the exit site rather than using the enclosed 8-mm skin punch due to improved experience with wound healing using this technique. The bullet on the percutaneous lead is then threaded onto the end of the tunneling device and the tunneler followed by percutaneous lead is pulled through the skin incision such that the velour coating ends approximately 2 cm below the skin surface and the rubber coating is in contact with the dermis and epidermis. While the Thoratec instructions recommend velour contact at the skin interface, we and others have noted a decreased infection rate when the entire velour coating remains below the skin surface. The percutaneous driveline is secured at the skin level with two 0 Prolene sutures, and the remaining skin incision is closed with a running subcuticular 4-0 Monocryl (Fig. 55.5). Excess percutaneous lead is shaped into a gentle loop in the LVAD pocket, and the loop is secured to the posterior rectus fascia with a 2-0 Prolene suture (Fig. 55.6). Once lead placement is completed, the lead is connected to the system power-based unit (PBU) and the patient is ready for deairing, weaning from CPB, and initiation of device support.

During deairing and device initiation, continuous echocardiographic monitoring is essential. The patient is placed in steep Trendelenburg position and the chest continues to be flooded with carbon dioxide. The LV and attached inflow graft

and pump are deaired through the Luer-lock connection on the outflow cap; the outflow graft itself is deaired by allowing aortic backflow via partial release of the graft cross-clamp. Once initial deairing using these techniques is complete, the outflow graft and overlapping bend relief are attached to the screw ring on the pump. With the outflow graft cross-clamp still in place, the HeartMate II is turned on at the lowest speed of 6,000 RPM to initiate flow through the pump. At this time, deairing is continued through the DLP cannula, which was previously placed at the highest point in the outflow graft, between the screw ring and graft cross-clamp. Close communication with the perfusionist is essential as CPB flow is now slowly decreased to allow for partial filling of the LV without overdistension. Once adequate deairing of the LV and aortic root is confirmed by both echocardiography and visual inspection of the DLP cannula showing no further egress of air bubbles, the outflow graft cross-clamp is removed. While monitoring the LV continuously with visual inspection and echocardiography, the device RPMs are slowly increased while CBP is weaned and then stopped. Before titration up to higher device RPMs (>8,000), CBP should be stopped and the LV should be filled to avoid air entrapment.

Selection of an optimal pump speed should begin in the OR while continuous echocardiographic guidance is available. An optimum speed is reached when the cardiac index and LV size are within normal limits, and there is no rightward or leftward deflection of the interventricular septum. A ramped speed study can be performed to determine the lower limit speed (when the aortic valve opens with every cardiac cycle and the septum begins to deflect rightward) and the upper limit speed (when the aortic valve ceases to open and the septum begins to deflect into the LV). The optimal pump speed will be somewhere between these two and should allow some pulsatility with an ideal aortic valve opening of once every two to three cardiac cycles. The usual speed fitting these parameters varies slightly for each patient but generally falls between 8,400 and 9,600 RPM for the HeartMate II. Notably with the HeartMate II, the most efficient mechanical speed for this device is approximately 9,000 RPM and one may observe slight decreases in pump power at this speed; these power decreases should not be confused with suction events.

While the speed is being adjusted in the OR under echocardiographic guidance, attention is turned toward drain placement and chest closure. The DLP catheter is removed from the outflow graft, the purse-string suture is tied down, and Omnex sealant is applied to this site. The aortic and venous CPB cannulae are removed and purse-string sutures tied. Hemostasis is confirmed at all anastomoses and cannulation sites, and anticoagulation is fully reversed with protamine sulfate. We typically place three 24-F Blake mediastinal drains: one posterior, one left lateral, and one right lateral. If either pleural space was entered, an additional 24-F Blake drain is placed in the pleural space. Patients are given 24 hours of appropriate perioperative antibiotics, cefazolin in most cases, and the mediastinal and pleural drains are left in place until they produce <100 ml per 24-hour period. Once drain placement is complete, hemostasis is adequate, and the appropriate initial speed setting has been determined, the chest is closed in standard fashion using six stainless steel sternal sutures. To minimize infection risk, we perform sternal closure in all patients. With this routine sternal closure, we have observed no mortality occurring from sudden cardiac tamponade and our reexploration rate is approximately 15%.

**Postoperative Management**

In most instances, the postoperative management of LVAD patients is similar to the care of any cardiac surgery patient. The continuous-flow LVAD does present some unique care considerations including blood pressure monitoring, anticoagulation, and management of RV function. In the immediate postoperative period, while invasive monitors are still in place, blood pressure monitoring is not a significant issue as mean pressure should be titrated to the same goals as for any other patient. Once arterial pressure lines are removed, the most effective way to monitor blood pressure is by using a standard sphygmomanometer and a Doppler probe typically placed over the radial artery. The goal at this point is to maintain the mean arterial pressure in the 70 to 80 mmHg range.

Anticoagulation is required for all currently FDA-approved continuous-flow LVADs to avoid thromboembolic complications. Experience from the HeartMate II BTT and destination therapy trials, along with subsequent reports, demonstrates that the level of anticoagulation needed is less than initially believed and that systemic heparinization prior to warfarin initiation is not necessary. In our institution, we hold all anticoagulant medications during the initial postoperative period until any coagulopathy or hemorrhage is definitively addressed. Usually, by postoperative day 2 to 3 the patient is started on 81 mg aspirin per day. A day or two later, typically postoperative days 3 to 5, oral warfarin is initiated and will be continued indefinitely with a target INR of 1.5 to 2.5. We no longer routinely use systemic heparinization prior to warfarin due to several hemorrhagic
complications along with recent evidence confirming this practice.

Postoperative right heart failure is a feared complication after LVAD placement but in our experience (91 HeartMate II patients at the time of writing), only one patient has required postoperative mechanical circulatory support of the right ventricle. That patient required temporary right ventricle support with the AB5000™ external VAD (Abiomed, Danvers, MA) and was successfully weaned from this device after several days of support. In the initial HeartMate II BTT trial, 20% of patients experienced some degree of RV failure with 6% requiring RVAD placement. In the subsequent HeartMate II destination therapy trial, RV failure requiring extended inotrope use was again 20%, but the requirement for RVAD placement decreased to 4%. We have found the management and prevention of RV failure after LVAD to be similar to management and prevention of RV failure after any major cardiac operation. RV failure after implant can be anticipated preoperatively via echocardiography and assessment of other clinical parameters (CVP, RV stroke work index, hepatic congestion) and an important aspect of prevention is appropriate patient selection. Patients with RV failure preoperatively are not appropriate for LVAD support. In addition, intraoperative protection of the RV is critical especially when additional procedures are being performed that require aortic cross-clamp and cardioplegia. In patients deemed preoperatively to be at a higher risk for RV failure, intra- and postoperative use of milrinone, epinephrine, and isoproterenol are important and vasopressor agents should be kept to a minimum whenever possible. Inhaled epoprostenol sodium (Flolan—GlaxoSmithKline, London) or nitric oxide have proven useful in several cases to decrease pulmonary vascular resistance but we have observed increased bleeding rates with the use of inhaled Flolan and now reserve its use for very select cases. Inhaled nitric oxide is an additional tool that may be useful to decrease pulmonary vascular resistance. Weder heavily on intraoperative echocardiography and frequent postoperative echocardiography to assess RV function and titrate pump speed to avoid deflection of the interventricular septum either into or away from the RV. Consideration of temporary mechanical RV support should occur if the cardiac index is persistently below 2.0 L/min/m², CVP is >20 mmHg, and all other management strategies have been exhausted.

**POTENTIAL COMPLICATIONS**

The most common complications associated with LVAD therapy include perioperative hemorrhage, infection, right-sided heart failure, acute renal failure, GI bleeding, and ventricular arrhythmias. Again, patient management for the majority of these complications is equivalent to the management of any patient after major cardiac surgery. Perioperative coagulopathy and hemorrhage is common with 80% of patients requiring postoperative packed red blood cell transfusion and about 15% requiring chest reexploration. Acute management of coagulopathy and hemorrhage is no different in the LVAD patient; however, LVAD recipients are more likely to experience coagulopathy and should be treated aggressively. Patients should have all coagulation factors checked preoperatively and repleted as necessary before surgery. Standard intraoperative strategies are useful to limit postoperative bleeding including careful hemostatic dissection, shorter CPB times, maintenance of normothermia, and close monitoring of platelets and coagulation factors intraoperatively with appropriate early replacement. When diffuse coagulopathy occurs and patients require large amounts of blood products, aminocaproic acid, recombinant Factor VII, and Factor IX complex should be considered. All anticoagulants should be held postoperatively until full resolution of coagulopathy and/or hemorrhage is achieved.

With regard to infection, LVAD recipients are at an increased risk for infection for multiple reasons. As mentioned previously, heart failure induces a catabolic state that depletes nutritional reserves, suppresses immune function, and increases infection risk. Whenever possible, nutrition should be optimized prior to LVAD placement and postoperative nutritional supplementation is crucial for minimizing infectious complications. In addition, the extensive dissection required for LVAD placement along with implantation of a large foreign body imparts a high risk for infection. The percutaneous driveline provides a site for pathogen entry and meticulous care of this site is essential for the prevention of driveline infection, pump pocket infection, and sepsis. The driveline exit site must be carefully immobilized, covered with a sterile dressing, meticulously cleaned on a regular basis, and we recommend continuous use of an abdominal binder to minimize driveline movement. As always, the mainstay of treatment for any infection that does develop is judicious use of appropriate antibiotics, surgical drainage, debridement as needed, and ultimately removal of the infected foreign body if necessary. If a pump pocket infection occurs, the only durable means for resolving the infection is transplantation. In the meantime, washout, drainage, and use of antibiotic beads may be used for infection control until a transplant graft is available. With regard to driveline infections, we have a very low threshold for drainage and debridement as we have had good success in treating these infections early and minimizing the development of the more serious pump pocket infection that could require device removal. When a driveline infection is present, the driveline exit site can be cored out and moved using the pictured technique with demonstrated success in achieving durable resolution of infection (Fig. 55.7).

Postoperative GI bleeding after LVAD implantation seems to be a particularly common problem after HeartMate II implantation with up to 20% of patients experiencing GI bleeding that requires transfusion. The cause of this bleeding is thought to be related to the axial flow pump. No definitive therapy for this syndrome is available and anticoagulation should be stopped in the event of bleeding and GI endoscopy colleagues consulted for assistance with the management of these patients. GI endoscopists should be aware that in a significant percentage of patients, bleeding may come from a small bowel source and a capsule endoscopy or push enteroscopy may be needed for definitive diagnosis. Some have reported success in controlling GI bleeding by decreasing pump speed and there are reports of extended cessation of warfarin and/or aspirin therapy without adverse events. In the case of intractable GI bleeding, lowering of anticoagulant goals or even complete cessation may be necessary and the risks of this approach should be discussed with patients prior to initiation.

Finally, ventricular arrhythmias are common before and after LVAD placement with one-quarter to one-third of all patients experiencing at least one episode of sustained (>30 seconds) ventricular tachycardia (VT) or fibrillation (VF) postoperatively. While these episodes are much better tolerated in the LVAD recipient than in the unsupported patient, and some may even be asymptomatic, VT/VF usually results in reduced pump flows and contributes to morbidity, mortality, and prolonged hospitalization after LVAD. Most of our patients have a defibrillator in place prior to surgery and in those who do not, we seriously consider postoperative defibrillator placement prior to discharge.
from the hospital. In patients with recurrent preoperative VT/VF, we have recently experienced success performing intraoperative epicardial and endocardial cryoablation at the time of LVAD implantation (Fig. 55.8). We have found this procedure to be useful in reducing the frequency of postoperative VT/VF and now consider this approach in every patient with a history of preoperative ventricular arrhythmias.

One aspect in the postoperative care of the LVAD patient that is worth reiterating is the importance of a multidisciplinary approach to care. Any successful LVAD program is reliant on a large team of cardiac surgeons, heart failure cardiologists, invasive and electrophysiology cardiologists, nurse practitioners, VAD coordinators, nutritionists, pharmacists, nurses, social workers, transplant coordinators, and many others. LVAD candidates present with complex physiologic and social comorbidities and the seamless interaction of all team members is necessary to help these patients through successful LVAD implantation, hospital discharge, potential transplantation, and beyond.

**CONCLUSION**

With the prevalence of congestive heart failure continually increasing worldwide and the frequency of cardiac transplantation remaining stable, it is clear that other options must remain available for effective care of the heart failure patient. With the dramatic improvements witnessed in post-LVAD survival and quality of life just in the last decade, LVAD implantation has now firmly crossed the cusp from experimental rescue surgery to an accepted and essential reality in the care of patients with end-stage heart failure. As LVAD outcomes and technology continue to improve, it is now increasingly apparent that the importance of LVAD implantation as a tool for the successful treatment of heart failure will only increase in the coming years. The progress witnessed in the field of ventricular assist should serve as another demonstration of the important interdependence between cardiac surgeons and mechanical circulatory support technology. With third-generation noncontact centripetal flow pumps available in Europe and in varying degrees of clinical testing here in the United States, further pump miniaturization in development, transcutaneous battery charging on the horizon, and wholly percutaneously inserted devices coming down the pipeline, the future of LVAD implantation has never been brighter. The pace of change in this rapidly developing field will continue to accelerate and decreased patient morbidity will allow for expansion into a broader class of less severe heart failure patients. The immediate and long-term future of heart failure therapies will be shaped by ventricular assist technologies, and the cardiac surgeon will play an essential role in guiding this exciting future development.

**SUGGESTED READINGS**

Lietz K, Long JW, Kfoury AG, et al. Outcomes of left ventricular assist device implantation as...

**EDITOR’S COMMENTS**

Drs. Mulloy and Kern have presented the UVA approach of ventricular assistance. Dr. Kern has done a great deal to make this procedure safe and predictable. It is his treatment regimens that have allowed outstanding results with the use of LVAD. I think the proper focus by both authors has been on RV function. The authors have a great approach, pharmacological support, and some contraindications to LVAD placement.

An important area of focus is that elective left ventricular assist should not be done on acutely ill patients. There are other forms of support that can be used until the patient is stabilized. Someone with gross end-organ failure will not be helped by the present support devices. These patients need to be optimized with more temporary support prior to permanent LVAD implantation.

ILK
Surgery for Complications of Myocardial Infarction

Philip W. Carrott, Timothy J. Gardner, and Irving L. Kron

INTRODUCTION
Surgical intervention is often required to manage acute mechanical complications of myocardial infarctions. These mechanical complications, which are responsible for 15% to 20% of deaths after acute myocardial infarction, have historically been considered to include free ventricular wall rupture, acute ventricular septal defects (VSDs), and acute ischemic mitral regurgitation (MR). An acute myocardial infarction complication increasingly considered to be mechanical and amenable to surgical intervention is “pump failure,” or cardiogenic shock refractory to maximal medical treatment and revascularization. Surgical techniques used for this complication include ventricular assist device implantation and transplantation.

FREE VENTRICULAR WALL RUPTURE

Incidence and Pathogenesis
Free ventricular wall rupture is found in approximately one-fourth of patients who die within 3 weeks of an acute myocardial infarction. Overall, free wall rupture occurs in up to 11% of patients after acute infarction. Rupture location depends on the site of the infarct, with the rupture tract most commonly occurring between viable and necrotic myocardium. Rupture usually occurs after acute expansion of a transmural infarction. Infarct hemorrhage may play a role because revascularization with thrombolytic therapy but not angioplasty has been found to be independently associated with rupture of both the free wall and the septum.

Clinical Presentation and Diagnosis
Free wall rupture has acute, subacute, and chronic presentations. Acute rupture usually results in death within minutes. Subacute rupture represents 20% to 40% of the cases of free wall rupture and presents as cardiac tamponade progressing to shock. Echocardiography evaluating for a pericardial effusion in the presence of ventricular wall defects in a patient with tamponade physiology after acute infarction is used for diagnosis. Chronic rupture is rare and involves a contained ventricular leak that results in a pseudoaneurysm. Most patients have symptoms of congestive heart failure (CHF), chest pain, or dyspnea, although 12% to 23% are asymptomatic. More than two-thirds of patients have a murmur, and virtually all patients have nonspecific electrocardiogram (ECG) abnormalities. Most patients have cardiomegaly on chest X-ray. Angiography, echocardiography, computed tomography scans, radionuclide scans, and magnetic resonance imaging can be used to identify the pseudoaneurysm.

Natural History
Acute rupture rarely allows time for intervention and is invariably fatal. Patients with subacute rupture have a median survival of 8 hours after symptom onset, with a range from 45 minutes to 6.5 weeks. Only 17 cases of survival without surgery for subacute rupture have been reported. The natural history of chronic rupture is not well defined. Frances et al. identified 290 patients with subacute rupture have a median survival of 8 hours after symptom onset, with a range from 45 minutes to 6.5 weeks. Only 17 cases of survival without surgery for subacute rupture have been reported. The natural history of chronic rupture is not well defined. Frances et al. identified 290 patients in the literature as having a contained ventricular pseudoaneurysm, 139 of which had resulted from a myocardial infarction. Of 81 patients treated conservatively, 15 died at <1 week from infarction and the other 66 survived long term, which suggests that chronic pseudoaneurysms are relatively stable.

Preoperative Treatment and Operative Timing
Acute rupture is generally not amenable to any attempts at repair. Emergent operative repair is needed for any patient with a subacute rupture, and the patient must be brought immediately to the operating room. Pericardiocentesis at the time of echocardiography can provide short-term hemodynamic improvement in some patients, allowing some degree of stability while preparing for surgery. Inotropes, fluid infusion, vasodilators, and an intra-aortic balloon pump (IABP) can also be used to maintain hemodynamics during transfer to the operating room.

Timing of surgical repair for chronic rupture depends on the interval between infarction and diagnosis. Patients who are within a few months of infarction are thought to have a high risk for rupture and should undergo urgent cardiac catheterization to evaluate the extent of coronary artery disease followed by operative repair of the pseudoaneurysm. The need for surgery in patients who present after an extended period after infarction depends on whether the pseudoaneurysm is >3 cm, expanding, or symptomatic, or if the patient has MR and/or severe coronary artery disease that requires intervention.

Operative Technique
Patients with subacute rupture are rapidly prepared for a standard median sternotomy, with close monitoring of hemodynamics during anesthesia induction because significant hypotension can occur. Close hemodynamic monitoring is also required when the pericardium is decompressed because hypertension can occur and possibly worsen the rupture size and the amount of bleeding. The tear location and status and the patient status determine the need for cardiopulmonary bypass. Cardiopulmonary bypass is instituted in all hemodynamically unstable patients. Bypass is also used if the rupture cannot be exposed adequately without excessive compromise of circulation or if the bleeding from the rupture cannot be controlled or prevent adequate repair.
Subacute rupture can be repaired by various techniques, which should be kept as simple as possible. Sutures should not be placed into friable myocardium. Epicardial repair can be performed by the placement of a patch of pericardium, Dacron, or polytetrafluoroethylene felt over the ventricular defect; the patch is sutured to healthy myocardium along the periphery of the infarct (Fig. 56.1A). The rupture can also be closed directly with horizontal mattress sutures buttressed with Teflon felt strips and a patch secured over the repair (Fig. 56.1B). Biocompatible glue can also be used to further reinforce the patch over the defect (Fig. 56.1C). Simple epicardial repair is not appropriate when an intraventricular defect such as septal rupture or papillary muscle rupture also exists. Operative options in these cases require cardiopulmonary bypass and aortic cross-clamping with infarct excision and defect closure using a patch or infarct exclusion, which are described in detail in the following sections.

A new product, Tachosil (Takeda Pharmaceuticals International GmbH, Zurich, Switzerland), which is a white collagen patch with a fibrinogen and thrombin coating on one side, has been used to buttress free wall rupture in leaking and blown out myocardium without need for further operative patching. The technique was used in six patients with good operative and long-term outcomes. For selected patients with small defects or oozing rupture, this simple repair offers a good option with minimal operative trauma to the myocardium.

Fig. 56.1. Repair of left ventricular free wall rupture with (A) epicardial patching, (B) direct suture, and (C) application of patch secured to ventricle with BioGlue.
The decision to repair a chronic ventricular rupture is partially based on the presence of either mitral dysfunction or coronary disease. Cardiopulmonary bypass is instituted, and the chronic rupture site is repaired similar to an acute rupture. Anterior pseudoaneurysms can usually be closed directly because of the presence of fibrotic edges. Posterior pseudoaneurysms are closed with a patch so ventricular geometry is not distorted. Even for cases in which the primary purpose of the operation is to repair a large or expanding pseudoaneurysm, cardiopulmonary bypass is indicated to allow adequate exposure for repair and to also prevent the systemic embolization of thrombotic material from within the pseudoaneurysm cavity.

**Survival**

Most reports of surgical intervention for subacute rupture involve a limited number of patients. These reports, however, indicate that a significant number of patients can be saved from this lethal condition with prompt diagnosis and intervention. In one series, two of five patients who were extremely unstable and underwent emergent repair of a subacute rupture survived 1.7 cm.

Historically, acute septal defects were described primarily in the anteropapillary septum as a result of left anterior descending artery occlusion. Recent data, however, suggest that the proportion of posterior VSDs is rising, and these now represent one-third to one-half of VSDs. Posterior VSDs result from occlusion of a dominant right coronary artery or a dominant circumflex artery. Defects are classified as either simple or complex. Simple defects are usually located anteriorly. Complex defects are usually located inferiorly and have a worse prognosis. Multiple VSDs occur in 5% to 11% of cases. One-third of cases involve mitral valve regurgitation, which results from either papillary muscle infarction (15% of cases) or left ventricular dysfunction and mitral annular dilation. The MR seen due to left ventricular dysfunction generally resolves with repair of the VSD, whereas papillary muscle rupture requires valve replacement.

**Clinical Presentation and Diagnosis**

An acute VSD typically presents with recurrent chest pain, a new holosystolic murmur and palpable left sternal thrill, and hemodynamic deterioration a few days after acute infarction. Septal rupture causes left-to-right shunting that can result in heart failure. Clinical presentation varies from an asymptomatic murmur to cardiogenic shock. Symptoms occur due to both ventricular dysfunction and the shunting caused by the VSD. Failure occurring with an anterior VSD is usually the result of both the VSD and extensive left ventricular infarction, whereas failure occurring with a posterior VSD is usually due to extensive right ventricular infarction. Infarct location on the ECG correlates highly with VSD location. The ECG often shows a rightward QRS axis shift and a right-bundle-branch block, and approximately one-third of patients get a transient atrioventricular conduction block before septal rupture.

The clinical appearance of an acute VSD is very similar to that of acute MR. Physical examination and the ECG are used to distinguish between the two entities. The murmur associated with a VSD is most prominent at the left sternal border and is often accompanied by a thrill, whereas the murmur from acute MR is best heard at the apex and has no thrill. In addition, acute MR is more commonly associated with inferior infarctions and no conduction abnormalities. Echocardiography has a very high sensitivity and specificity in identifying the presence, size, and location of a VSD and shows a diagnostic trans-septal flow jet, as well as an echo-free area of the septum.

**Natural History**

Patients with a postinfarction VSD treated medically have a 1-year mortality as high as 97%. One-fourth of patients die within 24 hours, and 80% die within 4 weeks. Death usually occurs as a result of end-organ failure due to shock.

**Preoperative Therapy and Operative Timing**

Because early surgical repair of acute VSDs had a very high mortality, surgical repair was previously delayed for 4 to 6 weeks to allow hemodynamic stabilization and fibrosis of the infarct to facilitate suturing around the VSD. Although some patients survived this delayed management, it became clear that only low-risk patients survived to surgical repair. Surgical intervention is now recognized as required before cardiogenic shock results in irreversible end-organ damage, and operative timing for repair is dictated by the patient’s hemodynamic status. Completely stable patients, comprising only a
small proportion of patients, should have elective repair sometime during their hospitalization for the acute infarction.

Patients requiring pharmacologic support for heart failure require intervention within 12 to 24 hours of diagnosis. A patient in cardiogenic shock is a true surgical emergency and needs immediate repair. Patients who have already developed multisystem failure or sepsis are extremely at high risk for emergency surgery and likely require further attempts at stabilization, with antibiotics as needed, before attempted repair. As more experience with ventricular assist devices evolves, their use in this complex population as a temporizing measure is expanding.

Danvers, MA

The Impella 5.0 catheter (Abiomed, Inc., Danvers, MA) is most useful since it can be placed through a femoral artery cut-down and does not require opening the chest for cannulation. As the name implies, the maximum flow is 5 l/min, which should help to off-load the right ventricle and allow the myocardium to heal. A delayed repair may then be undertaken with stronger myocardial tissue. Case reports describe deferring operative repair for around 14 days with a mortality rate of 40%.

The preoperative treatment goal is to divert blood systematically and maintain cardiac output, blood pressure, and coronary flow. Diuretics, inotropes, and vasodilators can minimize the left-to-right shunt; however, vasodilators are often not tolerated due to systemic hypotension. Vasconstrictors increase afterload and can worsen left-to-right shunting and should be avoided if possible. An IABP may improve cardiac output by reducing afterload and decreasing shunting and is mandatory in management of VSD patients who present in shock. However, IABP use has peak improvement within 24 hours and then no further benefit, so surgery should not be delayed beyond this time.

The role of preoperative coronary angiography is not completely clear; delaying surgical repair to perform cardiac catheterization during a period of patient instability is risky. In addition, the use of coronary angiography and coronary artery bypass grafting did not show improved short-term or long-term survival in a study of 179 patients with postinfarction VSD. However, routine coronary angiography detected significant coronary artery disease beyond the vessel that resulted in the acute infarction in 28 patients in another study of 54 patients with acute postinfarction VSDs. These patients underwent concomitant revascularization and experienced similar early and late survival compared with patients without associated coronary disease, suggesting that revascularization controlled the added risk of associated coronary disease. In another recent multi-institutional review, 42 of 65 patients who had coronary bypass grafting at the same time as VSD repair had significantly better survival both in the short-term and at 4 years. Given that coronary angiography can be performed very rapidly, a reasonable policy is to perform angiography with a limited amount of contrast in all patients who can be temporarily stabilized. Patients who are in severe shock should proceed directly to surgery for VSD repair.

Operative Technique

Several techniques can be used to repair acute postinfarction VSDs. Regardless of the specific technique utilized, a number of technical guidelines have been developed. A median sternotomy is performed with expeditious establishment of cardiopulmonary bypass using bicaval venous drainage. Cardioplegia should be first administered antegrade followed by retrograde via the coronary sinus to achieve optimal myocardial protection. In addition, patients with critical coronary stenoses identified preoperatively should undergo revascularization prior to VSD repair in order to maximize myocardial protection. A transinfarct approach to the VSD should be used. Because surgical success is completely dependent on adequate VSD closure, thorough evaluation for multiple defects must be performed both preoperatively and intraoperatively. In patients with associated significant MR, mitral valve replacement is needed only if frank papillary muscle rupture has occurred. The septal defect and the infarctectomy must be closed without tension, which generally necessitates the use of prosthetic material. Finally, all suture lines must be buttressed with pledgets or Teflon felt.

Apical septal ruptures can be repaired using the technique of apical amputation described by Daggett (Fig. 56.2). An incision through the infarct is made, and all necrotic muscle of both ventricles and the septum is debrided. The remaining apical parts of the ventricles and septum are approximated by a row of interrupted mattress sutures using buttressing strips of felt.

Operative procedures to repair acute anterior VSDs include both infarctectomy and infarct exclusion. For the infarctectomy technique, a transinfarct incision is made, and infarct debridement with thorough trimming of left ventricular margins to viable muscle with more conservative trimming of the right ventricle is performed to simply allow adequate visualization of the septal defect margins (Fig. 56.3A). Small defects can be closed using a plication technique (Fig. 56.3B). The VSD is closed by approximating the anterior edge of the septum to the right ventricular wall with mattress sutures buttressed with felt strips. The ventricular incision is also closed with mattress sutures over felt. Larger defects require reconstruction of the septum and ventricular walls with prosthetic material to reduce postrepair tension (Fig. 56.3C). Sutures are first passed from right to left through the septum, and then additional sutures are passed from the epicardial surface to the endocardial surface of the right ventricle. The anchored sutures are then passed through the patch and tied to close the VSD with the patch secured on the left side of the septum. The debrided infarct of the free ventricular wall is similarly closed with a patch as needed.

Infarct excision can distort ventricular geometry and has high potential for right heart dysfunction. David developed a procedure involving infarct exclusion rather than excision. A patch sutured to healthy myocardium excludes both the infarct and the VSD, preserving left ventricular geometry and function (Fig. 56.4). A transinfarct incision is made parallel to the left anterior descending coronary artery in the apex of the left ventricle. A patch tailored to the shape of the left ventricular infarction is sutured first to the endocardium of a noninfarcted portion of the septum and then to the noninfarcted endocardium of the anterolateral ventricular wall. The ventriculotomy is then closed over strips of felt.

The closure of posterior septal defects is technically challenging. The left side of the heart should be vented via the right superior pulmonary vein and the heart retracted as if preparing for a posterior bypass. As with anterior defects, repair can be performed with infarctectomy or infarct exclusion techniques. For the infarctectomy technique, a transinfarct incision is made, and the left ventricular portion of the infarct is thoroughly debrided to expose the septal defect. The papillary muscles should be inspected, and mitral valve replacement should be performed if papillary muscle rupture has occurred. As with anterior VSD repair, the portion of the right ventricle involved in the infarct is more conservatively trimmed to simply allow adequate visualization of the septal defect margins (Fig. 56.5A). Septal defects close to the adjacent ventricular free wall and not associated with significant loss of septal tissue can be repaired by approximating the septal rim of the posterior defect to the
Section II: Adult Cardiac Surgery

right ventricular free wall using buttressed mattress sutures (Fig. 56.5B). Larger defects require patch closure of both the septal defect and the infarct (Fig. 56.5C). Sutures are first passed from right to left through the septum, and then additional sutures are passed from the epicardial surface to the endocardial surface of the right ventricle. All placed sutures are then passed through the patch and tied to close the VSD.

David's infarct exclusion method can also be used to repair posterior defects (Fig. 56.6).

Fig. 56.2. Repair of apical ventricular septal defect. (A) The infarcted apex of the left and right ventricles is amputated to expose the septal defect. (B) The left ventricle, septal apex, and right ventricle are reapproximated with interrupted, buttressed mattress sutures.
Fig. 56.3. (A) A transinfarct incision is made in the left ventricle parallel to the left anterior descending coronary artery to repair an anterior postinfarction ventricular septal defect. (B) A small defect is repaired using the plication technique. The septal defect is closed by first approximating the anterior edge of the septum to the right ventricular wall with mattress sutures buttressed with felt strips, followed by buttressed closure of the ventricular incision. (C) Prosthetic material is used for the reconstruction of the septum to reduce postrepair tension in repair of a large defect. The patch is first secured to the left side of the ventricular septum using pledgeted sutures passed from right to left through the septum and then the patch. Sutures are then passed from the epicardial surface to the endocardial surface of the right ventricle and then through the patch and tied. The debrided infarct of the free ventricular wall is closed with buttressed sutures.

An incision through the midportion of the inferior wall a few millimeters from the posterior descending artery is extended proximally toward the mitral annulus and distally toward the apex of the ventricle. The base of a patch tailored in a triangular shape is sutured to the fibrous annulus of the mitral valve with a continuous suture starting at a point corresponding to the level of the postero medial papillary muscle and moving medially toward the septum until reaching noninfarcted endocardium. The suture is then interrupted with trimming of any excess patch material. The medial margin of the triangular patch is sewn to healthy septal endocardium with a continuous suture. The lateral side of the patch is sutured to the posterior wall of the left ventricle along a line corresponding to the medial margin of the base of the postero medial papillary muscle. Sutures placed into infarcted myocardium require full-thickness bites buttressed with felt on the epicardial surface. The infarct incision is closed in two layers of buttressed sutures, leaving the infarcted right ventricular wall undisturbed.

Another approach for closing small posterior defects is through the right atrium. The ventriculotomy is avoided, but the exposure and repair necessitate limiting this approach to smaller defects. In addition, there are multiple reports of, which we have utilized as well, the use of a percutaneous closure device for small postinfarction VSDs. This should be regarded as a temporizing measure for an extremely unstable patient, as the friable nature of the necrotic tissue does not hold the closure device well. Despite reports in the literature,
we have seen very limited success with this minimally invasive approach.

**Survival**

Although survival for the treatment of an acute postinfarction VSD has improved significantly over time, operative mortality in most large series is between 30% and 50%. In the largest published series, involving 179 patients, survival at 1, 5, and 10 years was found to be 60%, 49%, and 31%, respectively. The observation that mortality is not significant between 1 and 5 years indicates that those patients who survive the perioperative period have reasonable long-term survival. The technique of infarct exclusion has been associated with both a low operative mortality of 14% and an actuarial survival of 66% at 6 years, which is significantly better than all previous series.

**ACUTE ISCHEMIC MITRAL REGURGITATION**

**Incidence and Pathogenesis**

Ischemic MR is mitral insufficiency caused by myocardial infarction. From 17% to 55% of patients have either echocardiographic evidence of MR or a new mitral systolic murmur early after acute infarction. The MR is mild or disappears in many patients but is moderate to severe in as many as 4% of patients. Overall, acute severe MR complicates 0.4% to 0.9% of acute myocardial infarctions.

Acute ischemic MR is actually a myocardial problem, not an intrinsic valve problem. Of the six components of the mitral valve (the leaflets, chordae tendineae, annulus, papillary muscles, left ventricle, and left atrium), the leaflets, chordae, and annulus are not acutely affected by a myocardial infarction. Myocardial injury involving papillary muscle rupture or displacement causes acute severe MR. The posterior papillary muscle, which has a single blood supply from the circumflex coronary artery, is involved 6 to 12 times more frequently in acute severe MR than the anterior papillary muscle, which is supplied by both the left anterior descending and circumflex coronary arteries. The MR is also usually more severe when the posterior papillary muscle is affected by the infarction.

Papillary muscle rupture results in a flail valve leaflet and generally occurs 2 to 7 days after infarction, with a mean of 4 days. Trunk rupture leads to complete dehiscence of the papillary muscle and the rapid onset of severe MR, pulmonary edema, and shock.

Tip rupture of smaller papillary muscle heads also causes severe MR but results in less severe clinical deterioration initially, although the subsequent course is unpredictable. Complete trunk rupture usually occurs within the first week after the acute infarction, whereas partial rupture can be delayed for as long as a few months. Both types of rupture are highly lethal conditions without surgical intervention.

Acute ischemic MR due to papillary muscle displacement results from a number of small geometric changes in left ventricular shape, size, and wall motion that lead to incomplete coaptation of intrinsically normal leaflets. Papillary muscle ischemia alone usually causes a murmur but not severe MR with significant hemodynamic compromise. In the absence of papillary muscle rupture, left ventricular wall ischemia in conjunction with papillary muscle ischemia is required to cause severe MR. Severe MR resulting from papillary muscle displacement, although generally more compatible with short-term survival than severe MR resulting from rupture, can cause impairment of cardiac function similar to papillary muscle rupture and also almost always requires surgical intervention to ensure long-term survival.
Fig. 56.5. (A) A transinfarct incision is made, and the left ventricular portion of the infarct is debrided to expose the septal defect. (B) The infarctectomy technique is used to repair small posterior septal defects. The septal rim of the posterior defect is approximated to the right ventricular free wall using buttressed mattress sutures. (C) Large posterior defects are repaired using patch closure with the infarctectomy technique. Sutures are first passed from right to left through the septum, and then additional sutures are passed from the epicardial surface to the endocardial surface of the right ventricle. All placed sutures are then passed through the patch and tied to close the ventricular septal defect. The debrided infarct of the free ventricular wall is then closed with a patch and buttressed sutures.

Both papillary muscle rupture and displacement result in regurgitant flow into the left atrium during systole, with volume overload of the left atrium during systole and the left ventricle during diastole. The regurgitant flow causes an increase in stroke volume and a decrease in cardiac output. In acute MR, there is usually a marked increase in pressure in the noncompliant left atrium. This pressure increase actually helps to decrease the left ventricular–left atrial pressure gradient and may decrease the regurgitant volume.

**Clinical Presentation and Diagnosis**

Patients who develop acute MR after acute infarction typically have acute chest pain or shortness of breath with the appearance of a systolic murmur 2 to 7 days after the initial infarction. Acute severe MR due to either papillary muscle rupture or displacement leads to pulmonary edema and cardiogenic shock that is usually more abrupt and severe than that resulting from an acute VSD. Patients have a mean age of 60 years, usually have a history of hypertension, and
Section II: Adult Cardiac Surgery

Fig. 56.6. Repair of a posterior postinfarction ventricular septal defect using the infarct exclusion technique. An incision is made in the inferolateral wall of the left ventricle a few millimeters from the posterior descending artery. The base of a triangular patch is sutured to the fibrous annulus of the mitral valve with a continuous suture from the level of the posteromedial papillary muscle toward the septum until one reaches noninfarcted endocardium. The suture is then interrupted with trimming of any excess patch material. The medial margin of the triangular patch is sewn to healthy septal endocardium with a continuous suture. The lateral side of the patch is sutured to the posterior wall of the left ventricle along a line corresponding to the medial margin of the base of the posteromedial papillary muscle. The infarct incision is then closed in two layers of buttressed sutures.

are more commonly male. Chest X-rays usually show a normal-sized heart and pulmonary edema. Right heart catheterization generally shows elevated pulmonary artery pressures and tall V waves, but there is no oxygen step-up in the pulmonary artery.

As described, the clinical appearance of acute MR is very similar to that of an acute VSD. Again, physical examination and the ECG can distinguish acute MR from an acute VSD. The holosystolic murmur associated with acute MR is best heard at the apex, has no thrill, and is associated with an atrial gallop (S3), whereas the murmur associated with a VSD is most prominent at the left sternal border and is commonly accompanied by a thrill. Acute MR is more commonly associated with an inferior infarction and the absence of conduction abnormalities than an acute VSD.

Echocardiography with Doppler color flow mapping is the preferred diagnostic tool for acute severe MR. Transthoracic echocardiography is useful for assessing the degree of MR and can confirm wall motion abnormalities. In the case of papillary muscle rupture, echo can demonstrate flail mitral leaflets and also possibly a mass attached to the chordae, which is the ruptured portion of the papillary muscle. Even if a flail leaflet is not seen, the diagnosis of acute papillary muscle should be suspected if intact systolic function is seen in the clinical setting of acute pulmonary edema and shock. Transthoracic echocardiography can be a reliable diagnostic test for direct transfer to surgery when there is no question in the diagnosis. Transesophageal echocardiography is the tool of choice when the diagnosis is in question because it more definitively assesses the degree of MR and wall motion abnormalities while also assessing the posterior papillary muscle. Transthoracic echocardiography also does not always reliably distinguish papillary muscle rupture versus displacement.

Natural History
Acute severe ischemic MR is associated with a mortality of 24% at 30 days, 42% at 6 months, and 52% at 1 year. For an acute papillary muscle rupture, approximately 50% of patients die within 24 to 48 hours without surgical intervention.

Preoperative Therapy and Operative Timing
Acute ischemic MR that is not severe requires no specific treatment other than that used to treat the infarction. Immediate surgery is indicated for patients with severe MR and cardiogenic shock or CHF. Attempts are made to stabilize hemodynamics while surgery is arranged. As the size of the regurgitant orifice is increased by increased afterload and volume overload, inotropes, vasodilators, and an IABP can decrease the regurgitant flow and increase cardiac output.

As with acute VSDs, the role of preoperative coronary angiography for acute severe MR is not entirely clear. Delaying surgical repair to perform cardiac catheterization in a potentially unstable patient can be risky. Revascularization also prolongs both surgery and the duration of cardiopulmonary bypass and likely has no impact on immediate survival, particularly in the case of a ruptured papillary muscle, although it may be beneficial in those patients who cannot be weaned off bypass. However, given the etiology of myocardial infarction as the cause of MR and the fact that approximately
half of the patients with acute ischemic MR have three-vessel coronary disease, identifying and bypassing associated coronary lesions can improve long-term prognosis. Given that coronary angiography can now be performed rapidly so that surgical intervention is not delayed, a reasonable policy, as with acute VSDs, is to perform angiography with a limited amount of contrast in all patients who can be temporarily stabilized medically or with the use of a balloon pump. Patients who cannot be stabilized must go directly to surgery.

**Operative Technique**

Transesophageal echocardiography must be used in the operating room to guide and assess surgical results. A standard median sternotomy is performed with expeditious establishment of cardiopulmonary bypass. Bicaval cannulation with caval tourniquets is used to minimize systemic venous return, which could warm the heart and decrease myocardial protection during aortic cross-clamping. An alternative approach such as via a right thoracotomy with bypass established by peripheral cannulation is not appropriate in these emergency situations, except possibly in cases in which a patient has had a previous sternotomy and is known to have patent midline bypass grafts. The patient is cooled systematically to 28°C. The heart is arrested with cold cardioplegia solution delivered retrograde via the coronary sinus after the aorta is cross-clamped, and cold blood cardioplegia is delivered both antegrade and retrograde intermittently to maximize myocardial protection. The left atrium is opened to decompress the heart, and patients with associated critical coronary stenoses should then have the distal anastomoses completed.

Mitrval valve exposure must allow full evaluation of all components of the valve and the subvalvar apparatus so that a decision to either repair or replace the valve can be made. The sternotomy must be well centered, with the right side of the pericardium suspended to sternal fascia. An incision is made in the left atrium near the right superior pulmonary vein, parallel to the interatrial groove, extended behind the superior vena cava and below the inferior vena cava, which must be fully dissected (Fig. 56.7). The superior vena cava is dissected to the level of the innominate vein to maximize mitral exposure. The aygos vein is divided as needed during dissection of the superior vena cava to prevent tearing due to traction during valve exposure.

Although the feasibility of valve repair should be assessed, repair in the setting of acute severe MR is very difficult. Given that these patients are usually in extremis, the possible benefits of repair instead of replacement are generally not worth the risk that surgery and bypass time could be significantly prolonged if revising or even replacing the initial repair is ultimately required. In the case of a ruptured papillary muscle, repair by reimplantation of the ruptured muscle with the placement of sutures into freshly ischemic, friable tissue is quite precarious and generally not advisable, although sometimes for distal partial papillary muscles the disrupted fibrous tip of the papillary segment can be reimplemented into an adjacent noninfarcted papillary muscle or adjacent noninfarcted ventricular myocardium (Fig. 56.8).

Because of the difficulties in performing mitral valve repair, mitral valve replacement is almost always required for patients in the setting of acute severe ischemic MR. As many chordal attachments to the annulus as possible should be preserved when replacing the valve to maintain the mitral subvalvar apparatus and optimize postoperative left ventricular geometry and function (Fig. 56.9A). Although the need for chronic anticoagulation and questions of valve durability may not be particularly great concerns in the setting of emergency surgery, the surgeon must choose between a mechanical valve and a bioprosthetic valve. Some recommend that a mechanical valve be used in patients already chronically anticoagulated. Otherwise, the surgeon must consider the patient’s age and comorbid conditions to evaluate whether the patient is likely to outlive a bioprosthetic valve if he/she survives his/her current state. The valve chosen is sutured to the annulus with interrupted sutures (Fig. 56.9B and 56.9C). For a bioprosthetic valve, the sutures can be passed from the ventricular to the atrial side within the annulus. For a mechanical valve, the sutures are placed from the atrial to the ventricular side. The atrium is closed with a running suture, and proximal coronary anastomoses are completed.

**Survival**

The 30-day mortality for surgical repair for acute severe MR is 18% to 27%. The 1-, 5-, and 10-year survival rates are 75% to 81%, 65% to 68%, and 32% to 56%, respectively. The relatively stable long-term mortality observed in these series indicates that although this condition is highly lethal, left ventricular function is usually maintained, particularly in the case of a ruptured papillary muscle, and surgical correction can indeed be life-saving. Operative risk factors for mortality include advanced age, preoperative shock, other comorbidities, infarction size, and operative delay.

**PUMP FAILURE**

**Incidence and Pathogenesis**

Cardiogenic shock occurs in 6.7% of patients after acute myocardial infarction, and predominant left ventricular failure is the cause of shock in >75% of these cases. Cardiogenic shock results from a cycle of progressive myocardial damage and necrosis beyond the initial infarct. The overall incidence is decreasing due to better medical and interventional
treatments for an acute myocardial infarction. Failure occurs when left ventricular function is <30% of normal or when the abnormally contracting segment is >25% of the left ventricular circumference. Complete regional myocardial ischemia usually results in only 60% to 70% necrosis of the cardiomyocytes in the ischemic area, which probably explains why the decrease in function seen in these instances is only transient for 24 to 72 hours in two-thirds of cases. When the damage involves <35% to 40% of the left ventricle, the usual clinical scenario is left ventricular dysfunction and pulmonary congestion but no evidence of end-organ hypoperfusion. Cardiogenic shock occurs when >35% to 40% of the left ventricle is involved in the infarct.

Clinical Presentation, Diagnosis, and Natural History

Patients in cardiogenic shock have left ventricular dysfunction and end-organ hypoperfusion manifested by oliguria, decreased mental status, and cold, clammy skin. Pulmonary congestion may or may not be present. Cardiac index is <1.8 l/min/m², systolic blood pressure is generally <80 to 90 mmHg, and pulmonary capillary wedge pressure is >18 mmHg. Echocardiography shows severe left ventricular dysfunction without evidence for any of the mechanical complications described. Patients with persistent cardiogenic shock after acute myocardial infarction despite maximal therapy have mortalities of 35% to 80%.

Preoperative Treatment and Operative Timing

The treatment goal of a patient in cardiogenic shock is to increase both coronary and end-organ perfusion and maintain oxygenation. Volume is used to keep the pulmonary capillary wedge pressure >15 mmHg. Inotropes and vasopressors are used as needed to maintain blood pressure. If tolerated, vasodilators are useful in reducing afterload. An IABP reduces afterload to decrease left ventricular work and myocardial oxygen demand while diastolic aortic pressure is increased to improve coronary blood flow to the myocardium. Any patient who does not respond to these measures must be taken for cardiac catheterization and restoration of coronary blood flow with either angioplasty and/or stenting or surgically with coronary artery bypass grafting. Revascularization does not significantly reduce mortality at 30 days but does have a significant survival benefit at 6 months. Patients who remain in cardiogenic shock refractory to these maximal measures require additional circulatory assistance to prevent otherwise certain death. A new treatment paradigm in suitable patients with “pump failure” is implantation of a ventricular assist device, which unloads the left ventricle to greatly reduce myocardial oxygen consumption and may salvage critical myocardial mass and act as a bridge to

Fig. 56.8. The fibrous tip from (A) a ruptured papillary muscle head can be reimplanted into either (B) an adjacent noninfarcted papillary muscle or (C) adjacent noninfarcted left ventricular free wall.
recovery (Fig. 56.10A). For those patients who do not recover adequate myocardial function, this technique can act as a bridge to transplantation. The ventricular assist device is implanted as quickly as possible when it becomes clear that the patient’s status is not improving with maximal conventional therapy; otherwise, univentricular failure can progress to biventricular failure, and end-organ dysfunction may become permanent.

**Operative Technique and Survival**

A median sternotomy is performed, and the patient is prepared for bypass and heparinized. Device preparation is performed according to the manufacturer’s protocols. The outflow tract for the assist device is sewn into the aorta; this can either be done before institution of bypass using a side-biting aortic clamp to reduce bypass time or after instituting bypass if partial clamping off bypass is not tolerated by the patient. The assist device inflow tract is sewn into the heart while on bypass. The inflow tract can be sewn into either the left atrium or the left ventricle. Left ventricular cannulation may prevent left ventricular stasis and therefore reduce the risk of subsequent thrombus formation. If device flows are not adequate, a right ventricular assist device should also be implanted. Anticoagulation is reversed at the end of the case, and heparin is started 24 hours later if significant post-device insertion bleeding has not occurred.

Short-term (days to weeks), intermediate-term (weeks to months), and long-term (months to years) ventricular assist devices are available. Patients suffering from refractory postinfarction cardiogenic shock generally should have a short-term device such as the Abiomed AB5000 (Abiomed, Inc., Danvers, MA) or CentriMag (Thoratec, Pleasanton, CA) initially implanted. These devices can be implanted at virtually any cardiac center, although a tertiary care institute that performs heart transplantations should be available for patient transfer if indicated. Assist-device weaning is begun after the patient begins to demonstrate end-organ recovery. Device flows are reduced with minimal-to-moderate pharmacologic support while hemodynamics is closely monitored. Consideration can be given for explanting the device if the patient’s hemodynamic status is stable on moderate amounts of pharmacologic support; otherwise, the device is maintained. If the patient is not weaned from assistance within 1 week and is a transplant candidate, then the short-term device should be exchanged in the operating room.
Fig. 56.10. (A) Ventricular assist device with outflow tract sutured to the aorta and the inflow tract being sutured to the left ventricular apex. (B) Percutaneous ventricular assist device (PVAD).

for a longer term implantable device to act as a bridge to transplantation. If additional myocardial recovery does not occur, transfer to a transplant center is indicated. If the patient is not a transplant candidate, then the original device should be maintained until a decision is made that further support is futile or patient death or recovery occurs.

Multiple series show success in treating patients with acute infarction and refractory cardiogenic shock with a left ventricular assist device. In one series, 22 of 25 patients were successfully bridged to transplant, with six early posttransplant mortalities and 1-, 2-, and 5-year survival rates of 71%, 71%, and 51%, respectively. In another series, 10 of 15 patients were successfully bridged to transplant with this strategy, with 1 patient having the device explanted without requiring transplant. Six of seven patients in another series were successfully bridged to transplant, with five patients well at a median follow-up of nearly 900 days.

A percutaneous ventricular assist device as described by Thiele has also been used for patients with acute myocardial infarction and delayed recovery of myocardial function and continued shock after revascularization. This method uses percutaneous left atrial-to-femoral artery bypass, with the venous cannula introduced via the femoral vein and a trans-septal puncture and the arterial cannula introduced via the femoral artery and advanced into the iliac artery (Fig. 56.10B). This device, which is deployed in the cardiac catheterization laboratory, provides up to 4.0 l/min of assisted cardiac output to allow unloading of the left ventricle. In one study of 18 patients, support was maintained for an average of 4 days, with a 30-day mortality of 44%.

Double-bridge mechanical resuscitation has also been used to treat acute cardiogenic shock. With this technique, extracorporeal membrane oxygenation (ECMO) is used acutely for the treatment of profound cardiogenic shock with an early bridge to a ventricular assist device before transplantation. In one study, 9 of 23 patients were transferred to ventricular assist device, with 7 transplanted, 3 of 23 weaned off ECMO, and 11 of 23 withdrawn from support due to severe neurologic injury or multiorgan failure. In a similar study, 7 of 14 patients were transferred to ventricular assist device, with 1 directly transplanted.

Chapter 56: Surgery for Complications of Myocardial Infarction

EDITOR’S COMMENTS

Drs. Carrott, Gardner, and Kron have contributed an extensive and detailed review of the mechanical complications seen after transmural myocardial infarction, including frank rupture, ventricular septal defect, acute ischemic mitral regurgitation, and “pump failure” requiring mechanical support. The detail with which the chapter addresses these uncommon but potentially life-threatening problems confronted by the practicing cardiac surgeon makes this chapter extremely valuable for those on the front line.

The pathogenesis and natural history of each complication are detailed along with “how to fix it” and the optimal clinical outcome. The section on mechanical support is particularly useful as it emphasizes the use of this technology to address ventricular failure when it presents as a complication of myocardial infarction and specifically urges early institution of this type of support to best manage the patient.

Another outstanding aspect of this chapter is the operative technical details for management of these uncommon problems. For instance, ischemic ventricular septal defects represent a daunting technical challenge, especially for a surgeon who has little experience in dealing with this complication. A quick review of the outstanding description of the operative techniques presented in this chapter will prove extremely helpful to the surgeon in alleviating some of the anxiety in approaching this problem.

For each of the pathologic entities discussed in this chapter, the authors emphasize the importance of rapid intervention. In the current era of delayed surgical revascularization following a completed transmural infarction, it is helpful to be reminded that there are still indications for emergency surgery in this setting, including frank rupture, ischemic mitral regurgitation, and pump failure! In such instances, surgical repair often cannot be delayed as the primary problem is a mechanical one that may rapidly be fatal without timely intervention. Only a mechanical solution can solve a mechanical problem and hopefully prevent a patient’s death.

The authors are to be congratulated for having produced such a comprehensive review of this subject and in particular making it of tremendous practical value for cardiac surgeons.

LRK and TSG
The term "annuloaortic ectasia" was first used by Denton Cooley in 1961 to describe aortic root aneurysm due to Erdheim's cystic medial necrosis in a patient without the stigmata of Marfan syndrome. Although annuloaortic ectasia is often associated with aortic root aneurysm, it may also occur in patients without aneurysm but with aortic insufficiency due to bicuspid or tricuspid aortic valve disease and in those with subaortic ventricular septal defect. Conversely, not all patients with aortic root aneurysm have annuloaortic ectasia. Annuloaortic ectasia is now used to describe a dilated aortic annulus, which is often found in patients with connective disorders of the aortic root. This chapter is dedicated to surgery for aortic root aneurysm with or without annuloaortic ectasia.

The aortic root has four distinct anatomic components: aortic annulus, aortic cusps, aortic sinuses, and sinotubular junction. In addition, the triangles beneath the commissures of the aortic valve are also affected in annuloaortic ectasia, although anatomically they are part of the left ventricular outflow tract. The aortic annulus is the structure that attaches the aortic root to the left ventricle. The aortic annulus is attached to the ventricular myocardium (interventricular septum) in approximately 45% of its circumference and to fibrous structures (anterior leaflet of the mitral valve and membranous septum) in the remaining 55%. Dilation of the aortic annulus alters this relationship and occurs along the fibrous insertion of the aortic annulus. The subcommissural triangles, particularly those beneath the noncoronary cusp, tend to become more obtuse as the annulus dilates. Annuloaortic ectasia usually occurs in patients with aortic root aneurysm due to inherited connective tissue disorders such as in Marfan syndrome and others but it is also often associated with incompetent bicuspid aortic valves.

Cardiac surgery in patients with aortic root aneurysm may be necessary because of aortic insufficiency, dilation of the aortic sinuses, acute type A aortic dissection, or a combination of these problems. The first effective surgical treatment of aortic root aneurysm was described by Bentall and DeBono in 1968. It consisted in replacing the aortic valve and ascending aorta with a Dacron conduit containing a mechanical valve, and the coronary arteries were reimplanted into the graft in a side-to-side manner and the aneurysm wall wrapped around the graft to control hemorrhage. False aneurysm of this graft-to-coronary artery anastomosis was common. Reimplantation of the coronary arteries using the button technique largely resolved the problem. Composite replacement of the aortic valve and ascending aorta with a valved conduit (mechanical, biological, or bioprosthesis) became the standard treatment for patients with aortic root aneurysms for several decades. In 1992, David and Feindel and 1 year later Sarsam and Yacoub pointed out that patients with aortic root aneurysm often had normal aortic cusps and a conservative procedure, whereby the aneurysmal aortic sinuses could be excised and the aortic root reconstituted with a tubular Dacron graft was feasible. We coined the term aortic valve-sparing to describe these operations to distinguish them from aortic valve repair, which largely addresses problems with the aortic cusps. There are basically two types of aortic valve-sparing operations to treat patients with aortic root aneurysms: remodeling of the aortic root and reimplantation of the aortic valve. Several modifications of these two types of aortic valve-sparing have been described and although the early outcomes appear satisfactory, there are long-term data only on the two original procedures, which will be described in detail in this chapter.

Aneurysms often alter the anatomic relationships of the various components of the aortic root (subcommissural triangles, aortic annulus, aortic cusps, aortic sinuses, and sinotubular junction) and aortic valve-sparing operations were developed to correct these abnormalities, which can be quite challenging if all components are abnormal. A sound knowledge of functional anatomy of the aortic valve and how the various components of the aortic root interplay is indispensable to perform these operations. The feasibility of an aortic valve-sparing operation is largely dependent on the quality of the aortic cusps. If the cusps are grossly abnormal, replacement of the entire aortic root is necessary.

Remodeling of the Aortic Root

This procedure should be reserved for older patients with normal aortic annulus (e.g., ≤25 mm for women and 27 mm for men). Most of these patients have primarily ascending aorta aneurysm and the aortic sinuses become secondarily involved by a degenerative process. Remodeling of the aortic root is performed by excising the aneurysmal aortic sinuses and leaving approximately 5 mm of aortic wall attached to the annulus as illustrated in Figure 57.1. The three commissures are pulled upward and approximated until
Fig. 57.1. Aortic root aneurysm. The aortic sinuses are excised, and coronary arteries are detached from the aortic root leaving 5 to 6 mm of arterial wall attached to the aortic annulus and around each of the coronary arteries.

Fig. 57.2. Remodeling of the aortic root. The three commissures are resuspended into a tailored tubular Dacron graft with neoaortic sinuses. The neoaortic sinuses of Dacron are sutured to the junction between remnants of the aortic sinuses and aortic annulus.

Fig. 57.3. Remodeling of the aortic root. The coronary arteries are reimplanted and the distal anastomosis is performed.

Chapter 57: Annuloaortic Ectasia

the cusps touch each other centrally, and the diameter of the imaginary circle that includes all three commissures is probably the ideal diameter of tubular Dacron graft if the cusps are not elongated. Three neoaortic sinuses (two for bicuspid aortic valves) are tailored in one of the ends of the graft. The height of the sinuses should be approxi-}

mately equal to the diameter of the graft. The width of each neoaortic sinus should be proportional to the intercommissural distance. That is, larger cusps should have proportionally larger neoaortic sinuses. Next, the three commissures are sutured on the outside of the graft, immediately above the neoaortic sinuses as illustrated in Figure 57.2. The neoaortic sinuses are sutured to the remnants of arterial wall and aortic annulus with continuous 4-0 polypropylene sutures. This suture line must be carefully done with bites close together to avoid bleeding, a common complication in this operation. We do not use Teflon felt on this suture line. If the arterial wall is paper-thin, we use 5-0 polypropylene sutures in a fine needle, otherwise a 4-0 polypropylene suture in a fine needle.

The coronary arteries are reimplanted in their respective neoaortic sinus. Following that, the cusps are inspected for the level of coaptation. The three cusps should coapt at the same level and several millimeters above the level of the aortic annulus. If one or more cusps appear to be coapting at a lower level than the other two, its free margin should be shortened by plication on the central portion along the nodule of Arantius as illustrated in Figure 57.3. If large stress fenestration is present, we routinely reinforce the free margin of the cusp with a double layer of a fine Gore-Tex suture (W.L. Gore & Associates, Langstaff, AZ) as illustrated in Figure 57.4. Clamping the distal end of the graft and injecting cardioplegia into the reconstructed aortic root is a reliable method to test for valve competence. Finally,
Fig. 57.4. Repair of cusp prolapse. The free margin of the prolapsing cusps is plicated along the nodule of Arantius with fine polypropylene sutures.

the graft is sutured to the distal ascending aorta or transverse arch graft if it also was replaced as illustrated in Figure 57.5. Valve competence is assessed by intraoperative echocardiography. In addition to a competent valve (no more than trace aortic insufficiency should be accepted), the coaptation level and coaptation length should be measured. Ideally, the coaptation height should be at least 9 mm from the nadir of the aortic annulus and the coaptation length at least 4 mm.

Reimplantation of the Aortic Valve

This type of aortic valve sparing is complicated because it addresses every component of the aortic root. The aortic root has to be dissected circumferentially down to just below the level of the nadir of the aortic annulus. This is not always possible along the membranous septum because the right ventricular is often attached a couple of millimeters higher than the nadir of the cusps. The aortic sinuses are excised as described above (Fig. 57.1). Selection of the size of the graft is based largely on the ideal diameter of the sinotubular junction as described above. A tubular Dacron graft of diameter of the estimated sinotubular junction is selected (usually 26 to 30 mm) and secured to the outside of the aortic root at a level below the nadir of the aortic annulus. A small triangular segment is cut from one of the ends of the Dacron graft to correspond to the commissure between the left and right aortic cusps as illustrated in Figure 57.6. This tailored end of the graft is secured on the outside of the left ventricular outflow tract with multiple horizontal mattress (9 to 12) 2-0 or 3-0 polyester sutures. This suture line follows the scalloped shape of the aortic annulus along its muscular portion and it is as horizontal as possible along the fibrous portion of the left ventricular outflow tract. In the area of the membranous septum, this suture line may have to be slightly higher than the level of the nadir of the annulus because of the insertion of the right ventricle. If one suture is higher than the other, the same thing must be done when passing it through the Dacron graft. Teflon-felt pledgets are used along the membranous septum and subcommissural triangle between the left and noncoronary cusps because the tissue is often very thin. We believe this suture line is crucial in patients with annuloaortic ectasia and the reduction in annular diameter must be beneath the subcommissural triangles of the noncoronary cusp. The three commissures are suspended inside the graft and fixed to the wall with transfixed 4-0 polypropylene sutures with Teflon-felt pledgets. The spatial relationship of the three commissures is very important for proper cusp coaptation. Once the proper level and orientation are determined, the remnants of aortic sinuses and aortic annulus are secured to the tubular Dacron graft with a full thickness, transfixed sutures along the scalloped shape annulus, creating a crescent shape aortic annulus for each cusp. The coronary arteries are reimplanted into their respective neo-aortic sinuses as illustrated in Figure 57.7. This technique of aortic valve implantation creates an aortic root without aortic sinuses. It is possible to create an aortic root with neo-aortic sinuses by using a Dacron graft 4 to 6 mm larger than the diameter of the sinotubular junction (usually 30 to 34 mm in diameter). The diameter of the aortic annulus is also measured. If the diameter of the aortic annulus is less than the sinotubular junction, the graft is plicated to reduce its diameter to that of the aortic annulus plus 6 mm in the end, which will be sutured to the left ventricular outflow tract as illustrated in Figure 57.8. The graft

Fig. 57.5. Reinforcement of the free margin of the aortic cusp. A double layer of 6-0 expanded polytetrafluoroethylene suture is woven along the free margin. If there is a large fenestration, the first layer runs along the upper and lower rims of the fenestration.

**Fig. 57.6.** Reimplantation of the aortic valve. (Right) A small triangular segment is cut from one of the ends of the Dacron graft to correspond to the commissure between the left and right aortic cusps. (Left) Multiple horizontal mattress sutures are passed from the inside to the outside of the left ventricular outflow tract along a single horizontal plane immediately below the aortic annulus along its fibrous components and following the scalloped shape of the annulus along the muscular interventricular septum.

**Fig. 57.7.** Reimplantation of the aortic valve. The remnants of the aortic sinuses are sutured to the Dacron graft recreating a scalloped shape aortic annulus. The coronary arteries are reimplaned into their respective aortic sinuses.

is secured to the left ventricular outflow tract as described above and the commissures resuspended inside the graft and the scalloped shape of the aortic annulus recreated by suturing the remnants of aortic sinuses with the graft. The coronary arteries are reimпланed. Darts are placed in the graft in spaces between commissures to create neoaortic sinuses as illustrated in Figure 57.9. This maneuver reduces the diameter of the sinotubular junction at the rate of 1 mm for each 3 mm of graft plication. Since a graft larger than needed was selected, creation of neoaortic sinuses should not cause cusp prolapse. Whether neoaortic sinuses are created or not, at the completion of the procedure the cusps must coapt at the same level as described for remodeling of the aortic root. Valve competence and hemostasis along the coronary artery buttons can be assessed by injecting cardioplegia in graft with the distal end occluded. Finally, the graft is sutured to the distal ascending aorta or transverse arch graft if it also was replaced.

In a small proportion of patients, particularly those with bicuspid aortic valve, one coronary artery orifice may be too close to a commissure to be safely detached and reimпланed. In this case, the coronary artery is left in situ, the graft incised vertically in that area and after being secured in the annulus, an opening is created and the tissue around the artery is secured to the graft.

Aortic valve function and cusps coaptation level and coaptation length should be assessed after discontinuation of cardiopulmonary bypass as described above.

**REPLACEMENT OF THE AORTIC ROOT AND ASCENDING AORTA**

In patients with aortic root aneurysm and grossly abnormal aortic cusps, the best treatment is replacement of the entire aortic root and ascending aorta. A valved conduit is needed to replace the aortic root and there are several choices of valves and conduits. There are commercially available conduits of Dacron graft containing mechanical valves as well as glutaraldehyde-fixed porcine aortic root. Some valve manufacturers provide the choice of having mechanical valves into a straight tube or
or blood flow. Valved conduits can also be custom-made during surgery by securing a heart valve (bioprosthetic or mechanical) inside a Dacron graft. This approach is useful when a skirt of Dacron graft is desirable beneath the level of the sewing of the valve or whenever a bioprosthetic valve is used to facilitate reoperations should it become necessary. Aortic root homograft can also be used to replace the aortic root. The Ross procedure is not advisable in patients with aortic root aneurysm because inherited connective tissue disorders are the most common cause of aortic root aneurysm, and the genetic abnormality is also probably present in the native pulmonary root. The choice of one over other types of valves is largely made in consultation with the patient. It is important to consider that reoperative aortic root replacement is a more complicated procedure than isolated aortic valve re-replacement and it is probably associated with higher operative mortality and morbidity. Thus, patients who are likely to outlive their biological or bioprosthetic valve, the risk of reoperation must be weighed against the risk of life-long anticoagulation. Aortic root homograft is probably the best conduit for patients with aortic root abscess that required extensive resection and reconstruction of the left ventricular outflow tract.

Aortic root replacement is performed by clamping the ascending aorta close to the origin of the innominate artery and transecting the aorta just above the sinotubular junction. The aortic cusps are excised and the annulus is debrided when calcified. The coronary arteries are detached from the root leaving 4 to 5 mm of aortic sinus wall around their orifices. When the coronary arteries are not displaced, they should be mobilized to avoid tension after their reimplantation into the valved conduit. If the aneurysm is limited to the aortic root, the ascending aorta is resected up to 8 to 10 mm to the aortic clamp to allow enough tissue for the anastomosis. If the entire ascending aorta and/or the transverse arch are aneurysmal, hypothermic circulatory arrest is needed for replacement. We use systemic hypothermia of 25 to 28°C and antegrade cerebral perfusion at 10 ml/kg/min (see also Chapter XX on aortic arch surgery).

The valved conduit is then secured to the aortic annulus. When the annulus is dilated, the issue of valve size is unimportant and a valve of appropriate size is used to match the patient’s body surface area. In this case, we use multiple inverting interrupted horizontal mattress sutures of 2-0 polyesters with pledgets. These sutures are passed through the sewing ring of the mechanical valve and tied down as illustrated in Figure 57.10. Because the aortic annulus may be larger than the prosthetic valve in the conduit, some plication of the native aortic annulus is necessary. This plication should be performed along the fibrous portion of the aortic annulus. Thus, the sutures should be evenly spaced in the sewing ring of the valve and in the aortic annulus along its muscular component and closer together in the sewing ring than in the aortic annulus along its fibrous portion, mostly in the subcommissural triangles. Round openings 2 to 3 times larger than the diameter of the coronary arteries are made in the graft, and the remnants of the arterial walls around the coronary arteries are sutured to the graft with continuous 5-0 polypropylene sutures. It is imperative that the coronary arteries be implanted without tension in any direction to prevent kinking and/or bleeding when the ventricles distend and the heart begins beating. The distal end of the conduit is anastomosed to the distal ascending aorta or Dacron graft used to replace the arch. It is important to remember that the length of a normal ascending aorta is no more than 5 or 6 cm. Excessively long grafts can kink and cause obstruction and hemolysis. Long grafts can also make the mitral/aortic annuli more acute and increase turbulence along the left ventricular outflow tract.

If the aortic annulus is normal in diameter, we implant the largest possible mechanical valve and secured it to the annulus with multiple (20 to 24) simple sutures of 2-0 polyester without pledget. If the annulus is too small for the patient’s body surface area and age, it should be enlarged to accommodate a valve of appropriate size.

We no longer use xenograft porcine aortic root because they do not appear to be more durable than stented bioprosthetic valves, and reoperations can be troublesome because of the inflammatory reaction with surrounding tissues. If a bioprosthetic aortic valve is desirable, we suture it in a Dacron graft approximately 1 cm from one of its ends as illustrated in Figure 57.11. This is easily done by inverting the graft and using a continuous suture between the Dacron graft and sewing ring of the bioprosthetic valve. The skirt of Dacron beneath the valve can be sutured to the aortic annulus with continuous polypropylene sutures. This technique has allowed for re-replacement of the aortic valve without taking down the graft from the aortic root and coronary arteries.
POSTOPERATIVE COMPLICATIONS

Bleeding is probably the most common complication of aortic root surgery. Bleeding after remodeling of the aortic root is particularly troublesome along the suture line between graft and the remnants of aortic sinuses. That anastomosis must be meticulously performed and care must be exercised to avoid tears in the aortic wall. Bleeding from the coronary artery buttons can also be a problem but largely preventable by injecting blood cardioplegia into the graft under pressure before performance of the distal anastomosis. Finally, these operations usually require long cardiopulmonary bypass time and a degree of coagulopathy is common. Thus, transfusion of clotting factors, including recombinant factor VII, may be necessary.

Myocardial ischemia due to poorly aligned coronary artery buttons in the Dacron graft is probably the second most common intraoperative complication of aortic root replacement. If the right ventricle is hypokinetic, careful inspection of the right coronary artery button may disclose a kinked artery because of incorrect orientation or reimplantation level. A common problem in patients with bicuspid aortic valve is the nondominant right coronary artery, which is sometimes
suboptimally perfused during aortic clamping, and the right ventricle may become ischemic and hypokinetic after discontinuation of cardiopulmonary bypass.

Temporary heart block is common after long operations when cold blood cardioplegia is used for myocardial protection but permanent block is rare. We routinely place temporary pacer wires in the atria and ventricle in all heart valve operations and often use atrial or atrioventricular pacing to optimize heart rate and cardiac output.

Stroke is rare in these patients because most of them are relatively young and free of arch atherosclerotic disease. Postoperative bacteremia is extremely serious in these patients and must be promptly treated to prevent endocarditis. We routinely do a transthoracic echocardiogram prior to discharge to evaluate valve and ventricular function and to make sure the patient is not developing pericardial effusion, which can cause delayed tamponade.

**CLINICAL OUTCOMES**

First time, elective aortic root surgery should be associated with very low operative mortality, probably no higher than 1% or 2%. Surgery in patients who require urgent or emergency surgery because of acute type A aortic dissection, infective endocarditis with annular abscess, or advanced functional class for any reason is associated with increased operative mortality. The operative mortality and morbidity also increase when additional procedures such as aortic arch replacement, mitral valve surgery, and myocardial revascularization are needed.

In our latest report on outcomes of aortic valve-sparing operations for aortic root aneurysm, there were 289 patients whose mean age was 47 years. They were prospectively followed for a mean of 7.2 years (ranging from 0 to 20 years). The operative mortality was 1.7% in spite of the fact that 25 patients had acute and 19 had chronic type A aortic dissection, 20 required mitral valve surgery, 56 arch surgery, and 35 needed myocardial revascularization. The survival at 12 years was 82.9%. The freedom from reoperation on the aortic valve was 94% at 12 years, and the freedom from aortic insufficiency greater than mild was 86.8%. Reimplantation of the aortic valve provided more stable aortic valve function than remodeling of the aortic root.

The long-term results of aortic root replacement with mechanical valves are also excellent and similar to those of aortic valve-sparing operations. Several studies attempted to determine the superiority of one versus the other procedure, and the general consensus was that they provided similar outcomes. Aortic valve-sparing operations are associated with risk of aortic insufficiency that may need reoperation, whereas aortic root replacement with mechanical valves is associated with risk of hemorrhage and thromboembolic events.

**SUGGESTED READINGS**

Aortic Dissection
Nimesh D. Desai and Joseph E. Bavaria

INTRODUCTION
Thoracic aortic dissection is often a catastrophic disease with an incidence estimated to range from 2.9 to 3.5 per 100,000 person-years in the United States. Appropriate treatment is best managed by a team approach, as the aortic dissection process may affect any part of the circulation leading to potential organ malperfusion of the heart, the brain, the spinal cord, the gastrointestinal tract, the kidneys, and the extremities. A more focused understanding of the causes of death and morbidity of aortic dissection has allowed the development of operations specifically targeted to improve clinical outcomes. Further refinements in management such as the use of the operating room as the diagnostic suite have also contributed to improved survival.

ETIOLOGY
Aortic dissection develops from a tear within the intima of the aortic wall. Blood flows across this “entry point” into a weakened media, splitting the medial layer along the direction of flow, thus creating a new “false” channel, within the aortic media. This new channel progresses downstream and significant pressure/mechanical stress is exerted by the advancing column of blood on the aortic branches encountered in its path. An individual branch will either tear, leading to a communication from the false lumen into the original, “true” lumen of the aorta, or close off causing “malperfusion” of the organ supplied by the given arterial branch. The multiple torn branches down the path of the false lumen become known as reentry points or “fenestrations.” The false lumen, thus, does not usually become a blind pouch with the potential for thrombosis but is kept patent by the many exit and reentry points of variable sizes. If the reentry points are, in aggregate, small or restrictive, a pressure gradient will develop between the false lumen and the true lumen. This pressure differential will cause the false lumen to expand in an amount commensurate to the gradient, causing the true lumen to contract. A new equilibrium is eventually reached with equalization of pressure within the two lumens, typically leaving a small true lumen and a larger false channel. This final equilibrium point is reached within minutes to hours from the time of the original tear, such that the dissection is established and relatively stable by the time the patient reaches medical attention, with a false lumen extending from the entry site most often all the way down to the aortic bifurcation.

Although the final initiating event in an aortic dissection is an intimal disruption, the disease is not an intimal disease. Endothelial cells and their basement membrane do not possess significant intrinsic tensile strength, and their disruption is due to a lack of appropriate mechanical support from the medial layer. The media can be abnormal secondary to a genetic structural abnormality as in Marfan syndrome, where abnormal fibrillin causes loss of elasticity in the medial layer. Marfan syndrome is an autosomal-dominant syndrome with complete penetrance with an overall incidence of 1 per 3,000 to 10,000 live births. It is caused by alterations in the gene coding the aortic wall protein fibrillin-1, leading to elastin derangement. Increased TGF-β activity that negatively affects smooth muscle development and the extracellular matrix has also been implicated. More often other less clearly identified genetic conditions can predispose to abnormalities in the media which lead to dissection. These less well-defined heterogeneous abnormalities are often grouped in the category of annuloaortic ectasia where different abnormalities in the media lead to the common end pathway of dilatation of the aortic diameter with thinning of the aortic wall. Atherosclerotic disease will also damage the media in a variable pattern. Wall weakness in atherosclerotic disease is more often combined with sustained high blood pressure leading to increased stress on the abnormal aortic wall. Within this hypertensive background, a paroxysm of increased arterial blood pressure will incite the initial tear.

CLASSIFICATION
Anatomic classifications of aortic dissection are based on the location of the initial tear and are important in terms of treatment modality and prognosis (Fig. 58.1). The first classification scheme was designed by DeBakey, who classified dissections into the following:

Type I. The process involves the ascending aorta, the aortic arch, and the descending thoracic and often the abdominal aorta.

Type II. The dissection involves the ascending aorta, but stops at the level of the aortic arch, and does not involve the aorta beyond the subclavian artery takeoff.

Type III. The dissection starts distal to the subclavian artery and extends to the entire thoracic aorta (IIla) or the thoracic and abdominal aorta (IIlb). The following Stanford classification has become more commonly used as it readily translates to clinical decision-making:

Type A. The dissection involves the ascending aorta, regardless of tear site, and will most often extend into the descending thoracic as well as abdominal aorta. The subsets of DeBakey types I and II are included in this class.

Type B. The dissection starts beyond the aortic arch usually at the subclavian artery and progresses distal, thus not involving the ascending aorta or the aortic arch. The subsets of DeBakey type IIla and IIlb are included in this class.

The power and popularity of the Stanford classification is due primarily to the very different natural history of the two types of dissection and the requirement of very different surgical approaches to successfully treat them. A type A dissection...
Type I

Type II

Type IIIa

Type IIIb

Fig. 58.1. Classification.

carries a high risk of early mortality and morbidity if not treated surgically. A type B dissection has a much lower early mortality, with early surgical treatment providing no clear advantage or even a higher mortality over observation alone except in cases of rupture or severe malperfusion. If the prognosis of type A dissection is so ominous early in the process, this represents a surgical emergency. Type B dissection is a much lower risk aortic process with a relatively low risk of rupture. The primary acute problems caused by type B dissections are malperfusion syndromes of those organs in the path of the descending thoracic or abdominal aorta or the iliac arteries.

CLINICAL PRESENTATION AND DIAGNOSTIC EVALUATION

The aortic media have a high density of nerve endings, so when medial disruption takes place, the acute onset of sharp pain is a nearly uniform presenting symptom, occurring in over 80% of patients. Atherosclerotic degeneration of the media may result in less acute and sharp pain during the dissection progression. In an acute type A dissection, the pain is classically described by the acute onset of sharp, severe chest pain which then migrates to the upper back and is often described as extending/progressing down to the lower back and even the groins depending on the dynamics of growth of the false lumen. Once the false lumen is fully established and has stabilized, the acute pain may change into a more persistent and dull pain, which is often not as easy to localize and may involve the chest and back in variable patterns with additional elements of nausea, abdominal pain, diaphoresis, and shortness of breath. The presence of new focal neurologic deficit suggests aortic arch involvement. Flank pain may also be described in patients who are suffering an acute malperfusion of one of the kidneys. Signs and symptoms of venous hypertension suggest that pericardial tamponade are usually accompanied by poorly perfused extremities, sweaty and clammy appearance, and presyncope symptoms, consistent with a low cardiac output state. Additional presenting symptoms can be the sudden onset of a cold and pulseless extremity, most commonly the right lower extremity. A right upper extremity vascular impairment is often associated with a neurologic event, especially in a patient with an incomplete circle of Willis. These patients can have a catastrophic hemispheric infarct with a dense contralateral hemiplegia. Rarely, paraplegia can be a presenting symptom. This may occur in cases where a false lumen supplying blood to the spinal cord thromboses or the spinal blood supply is sheared off by an intramural hematoma. Acute paralysis usually associated with signs of spinal shock, which, compounded to other cardiovascular effects of the acute dissection, can
further complicate the early assessment of the patient. Similar paralysis symptoms may occur in the setting of total occlusion of the thoracic or abdominal aorta with no blood flow to the extremities, although this is also associated with pulselessness. Abdominal pain can occur in either type A or type B dissection, and it is often associated with stenosis or occlusion of either the celiac or the superior mesenteric arteries.

In a relatively young patient without significant risk factors for atherosclerotic disease, the index of suspicion for aortic dissection should be very high when any of these symptoms are described. Screening tests should include a chest X-ray and an electrocardiogram (ECG). ECG is often nondiagnostic, and occasionally it may show inferior wall changes suggestive of right coronary artery compromise by the dissection. Proximal dissection extension into the left main coronary artery causing occlusion is typically a fatal event, and such patients rarely survive long enough to reach medical care. Chest X-ray is a very nonspecific exam and it may show a dilated mediastinum or a large cardiac silhouette possibly due to an acute pericardial effusion.

Patients with chest or back pain that is not keeping with typical anginal symptoms, particularly in the setting of an abnormal chest X-ray, should undergo emergent contrast computed tomographic (CT) angiography. In most emergency departments today, a CT scan with contrast can be obtained within a few minutes of admission. Most modern multidetector CT scans with contrast will make the diagnosis of aortic dissection with exceptional accuracy and often will be the only test required prior to proceeding to definitive treatment. Rarely in a CT scan, particularly when the scan was done to search for a pulmonary embolism and the intravenous contrast is not well timed, the ascending aorta can show artifactual lines that may be interpreted as a type A dissection. These scans represent the few false-positive studies.

Transesophageal echocardiography occasionally is used to make the diagnosis of aortic dissection by visualizing either the ascending aorta or abdominal aorta. A transthoracic echo may be difficult to carry out and poor windows may limit its usefulness. If the aortic root is clearly visualized, a variable degree of aortic valve insufficiency with a dilated root or the suggestion of an intimal flap will suggest the diagnosis of type A dissection. Acute dissection flaps are not always visible with this technique, and transthoracic echo cannot definitively rule out aortic dissection. Pericardial effusion may also be seen.

After a screening transthoracic echo is suggestive but not diagnostic of an aortic dissection, a transesophageal echocardiogram (TEE) can nearly always make an accurate diagnosis of the type of dissection present. While there is no need to delay definitive treatment by adding transesophageal echo to a diagnostic contrast CT scan, in our recent experience it is as accurate as any other diagnostic study and allows rapid evaluation of an unstable patient. This is usually done in the operating room with a full cardiac surgical team available.

Contrast magnetic resonance imaging (MRI) provides excellent images of any dissection; it is not often readily available and it usually requires long acquisition times with the patient not as closely monitored because of the technical requirement of the high magnetic field. It should not be used as a primary modality except when it is more rapidly available than TEE, and the patient has evidence of renal dysfunction, making contrast CT angiography less desirable. In cases where the index of suspicion for acute aortic dissection is high, even in cases of renal dysfunction, CT angiography with contrast provides the most rapid and definitive diagnosis and should be used to avoid unnecessary delays in treatment. MRI can be extremely valuable in following a type B dissection after the initial diagnosis or in evaluating any chronic dissection.

Diagnostic catheter-based aortography has become an uncommon primary diagnostic evaluation. Typically, diagnosis is made by aortography only when the patient presented with an acute coronary syndrome with coronary malperfusion or diagnosed at the time of another cardiovascular intervention causing iatrogenic aortic dissection. Taking a patient with acute aortic dissection to the cardiac catheterization lab carries a very high mortality. Suspecting coronary disease leads to the use of platelet-inhibiting agents, anticoagulants, and occasionally fibrinolytics, all of which can transform a contained rupture into a free disruption or can increase the diffuse blood extravasation occasionally noted in a dissected, extremely thin aorta. Catheter manipulations performed can cause dangerous direct damage to the freshly dissected aorta. When obtained, aortography will only show the presence of a dissection flap and does not provide the anatomic detail a standard CT scan with contrast, a TEE or an MRI can provide today.

The question occasionally arises over the value of elective coronary evaluation after making the diagnosis of type A dissection. Retrospective reviews suggest that the incidence of coronary disease in this population is sufficiently low that more patients are placed at risk by the delay and technical risks of a cardiac catheter than are saved by the discovery of occult coronary disease. The only exception may be in patients who have undergone previous coronary bypass surgery, where the knowledge of coronary disease, graft position, and patency can contribute to a safer operation. When the technology of intraoperative coronary angiogram is available in a dedicated hybrid operating room suite, that may become an option for patients after completion of the proximal repair.

Once the diagnosis of a type A dissection is suggested by any screening test, the patient should not be delayed in the emergency department by further testing but should be transferred to an appropriate institution that can proceed with expeditious surgical repair. Over the last several years, our policy has been to transfer any patient with a documented or highly suspected type A dissection immediately to the operating room to minimize any delay. As soon as the patient arrives to the operating room, if sufficient suspicion or good studies are available, the patient is placed under general anesthesia and a TEE is obtained. If dissection is demonstrated by transesophageal echo in the ascending aorta, the patient undergoes emergency surgery. With this policy, 5% to 10% of patients admitted directly to the operating room are found to have a negative transesophageal echo and are then transferred to the intensive care unit for further evaluation. Most commonly, motion artifact in younger patients, type B dissections with some degree of arch involvement but no flap in the ascending aorta, or intramural hematomas are present in these patients.

**ACUTE TYPE A DISSECTION**

Patients with an acute type A dissection have a risk of death traditionally estimated at 2% per hour in the first 48 hours from their presentation. More recent data suggest that the early mortality may be as low as 60% over the first 2 to 5 days in patients without a concomitant root aneurysm and with aggressive use of antihypertensive medications, especially beta blockers.
Either way, medical therapy generally has no role in acute type A dissection except to allow a safer transfer to a center with experience in complex aortic repair or in inoperable patients. Historically, type A dissection surgery was focused on placing a short segment of Dacron graft in the ascending aorta in the hope of eliminating the entry tear and obliterating the false lumen both proximally into the aortic root and distally into the arch and beyond. This was frequently done by sewing the Dacron graft proximally to the aorta just proximal to the tear with no stabilization of the aortic root or valve and sewing distally to clamped aorta and not utilizing an open arch anastomosis. That principle often led to recurrent malperfusion proximally (myocardial infarctions and recurrent aortic insufficiency) and distally (stroke, organ, limb malperfusion) as well as a moderate distal early rupture rate. Furthermore, a high incidence of long-term failure was seen with aneurysmal degeneration of both the root and the distal ascending aorta and aortic arch.

As better understanding of the etiology for early complications and death was gained, a better operation could be designed to address those factors. There are four primary causes of early death from type A dissection, and the modern approach to surgical correction involves an operation addressing these four problems appropriately and directly.

1. Aortic rupture. The ascending aorta is subjected to more stress than any other portion of the aorta. It is the site of the majority of medial degeneration and thus intimal tears. Once dissection has occurred, the ascending aorta is at very high risk of early rupture. This risk is magnified when the aortic root and ascending aorta are dilated as the tension exerted on the remaining media and adventitia increases according to the Laplace law by the square of the diameter. To prevent this lethal complication, the ascending aorta needs to be completely replaced.

2. Congestive heart failure due to acute onset of aortic valve insufficiency. Aortic valve support is lost due to prolapse of the intimal layer at the level of one or more commissures. The most commonly affected is the noncoronary to right coronary sinus commissure, followed by the noncoronary to left coronary sinus and least common is the right coronary to left coronary commissure. To eliminate aortic valve regurgitation, the operation should include either a repair or a replacement strategy as necessary. The most common repair technique consists of aortic valve resuspension to reestablish normal commissural support (Fig. 58.2). Furthermore, the sinotubular junction may be dilated and may need to be brought back to a geometrically normal size. The ascending aortic graft is sized to best return the sinotubular dimension to its normal state.

3. Acute myocardial infarction due to malperfusion of the coronary arteries. Very few patients with left main coronary compromise survive to reach medical attention. Right coronary malperfusion is much more common. At surgery, the root needs to be repaired definitively to treat ongoing coronary stenosis/occlusion or to prevent future coronary compromise or late root dilatation. The incidence of aortic root dissection is quite high, especially in the noncoronary sinus where the great majority of aortic root will often be dissected down to the annulus. The second most commonly dissected sinus is the right coronary sinus with often some element of coronary malperfusion. Occasionally, the left coronary sinus of Valsalva will be also dissected and while in the past that was considered to be an indication for root replacement, as long as the intima within the root is intact and the valve leaflets are otherwise normal, dissection of the left coronary sinus can be also managed by repair techniques. Our preferred technique consists of reinforcing any dissected component of the root with an appropriately fashioned Teflon-felt sheet, placed between the intima and the adventitia becoming essentially a neome dia (Fig. 58.3). The Teflon neomedia is fashioned to allow an appropriate opening for the coronary ostia and is secured in place either with a running monofilament fine suture of either 4.0 or 5.0 at the level of the sinotubular junction or by utilizing a very small amount of biologic glue. It is important to utilize minimal amount of glue as any of them has the potential of causing long-term wall damage, especially of the adventitial layer. Over the last 10 years, repair of a nondilated dissected root with Teflon neomedia has been safe and effective with excellent and highly reproducible physiologic results leading to sparing of the aortic root in over 80% acute type A dissection, with no incidence of redisse ction or dilatation of the repaired root and no postrepair coronary malperusions. Alternative procedures include complete valve-sparing root replacement where the valve is placed within an appropriately fashioned Dacron graft, or aortic root replacement with a biologic or mechanical composite graft.

4. Stroke due to malperfusion of the aortic arch vessels. The innominate artery is the most commonly dissected of the arch vessels, followed by the left common carotid and at a much lower rate by the left subclavian artery. Replacement of most or all of the aortic arch with reinforcement of the arch vessels insures true lumen patency and prevents most perioperative strokes, frequently reversing preoperative focal neurological deficits.

We usually resect all of the lesser curvature of the aortic arch leaving a
strip of arch tissue comprising the three-arch vessel connected to the descending thoracic aorta. Teflon-felt strips can be placed between the intima and the adventitia as a neomedia to achieve restoration of the true lumen perfusion within the arch vessels to prevent postoperative malperfusion syndromes and reinforce the arch anastomosis suture line, preventing distal disruption (Fig. 58.4). Between 80% and 90% of false lumen beyond the arch will be widely patent after the complete hemi-arch repair has been achieved. That does not represent the failure of the arch reconstruction. The reentry fenestrations at the time of surgery are in aggregate so large that it is unrealistic to hope that closing the proximal entry site will ubiquitously result in thrombosis of the false lumen. Our observation is that closure of the false lumen only occurs in limited dissections as DeBakey type 2 or when dissections occur in the setting of atherosclerotic disease where variably fibroed and calcified media may prevent the usual extension of the dissection and limit reentry sites; in these patients, obliterating the entry point in the presence of low flow from the few exit sites may cause false lumen thrombosis. Total arch replacement may be technically challenging in acute dissection and is only necessary when there are large tears in the greater curve of the arch.

A successful operation for acute type A dissection will leave the patient with a reconstructed or replaced root, a well-functioning aortic valve, a completely replaced ascending aorta, a partially or completely replaced aortic arch with true lumen patency in the arch vessels, and a distal “Type B like” residual aorta (Figs. 58.5 and 58.6). The patient in most instances will have been shifted from a dissection with a high likelihood of death (type A) to a dissection with a very low risk of early rupture and only a moderate risk of long-term aneurysm formation in the residual dissected aorta (type B).

**SURGICAL TECHNIQUE**

Once the diagnosis of an acute type A dissection is established, the patient is anesthetized under endotracheal general anesthesia. Minimal arterial monitoring consists of a right radial artery catheter and if feasible also a left radial artery line. The most common arch vessel to suffer malperfusion is the innominate artery; thus, the right radial artery would provide early warning of the most likely malperfusion syndrome affecting the brain. If time allows, a left radial artery catheter can give further information about the presence of downstream less common arch malperfections. Left radial artery pressure monitoring is highly advised if the right axillary artery is being cannulated for bypass. A pulmonary artery (PA) catheter is routinely placed to optimize preoperative hemodynamics, but more importantly

**Fig. 58.4.** Obliteration of distal false lumen.
for postoperative management. High filling pressures correlate with bloody pericardial effusion and tamponade. High central venous pressure with low left-sided filling pressures and low PA pressures are highly suggestive of right ventricular ischemia secondary to right coronary artery malperfusion. If a patient is unstable, large bore IV and arterial lines are placed, deferring the PA catheter to a more controlled time. Whenever possible, electroencephalography (EEG) monitoring should be placed both to monitor for any asymmetry of perfusion at the level of the cerebral cortex and to utilize the EEG monitoring as a criterion for achieving adequate cooling to maximize safety to the brain and improve surgical efficiency. Near-infrared cerebral oximetry monitoring is an essential tool to monitor adequacy of brain perfusion during the various phases of the operation. The patient’s chest, abdomen, and both lower extremities are then prepped and draped. We currently favor either axillary artery cannulation or in experienced hands, direct over the wire ascending aortic cannulation. For axillary cannulation, an 8- to 10-mm Dacron graft is anastomosed in an end-to-side manner to the vessel. The arterial cannula is then secured to the Dacron graft. This allows for antegrade cerebral perfusion during the arch repair. At the end of the procedure, the graft is oversewn close to the anastomosis. Direct ascending aortic cannulation is performed after sternotomy and heparinization. An 18-gauge needle is placed into the dissected aorta angulated toward the arch, usually initially into the false lumen and advanced through the intimal flap and into the true lumen. A soft wire is then passed into the descending thoracic aorta in the true lumen, and the cannula is passed over the wire after serial dilatation. In a hemodynamically unstable patient without significant atherosclerotic disease, the most expeditious method to obtain arterial access for bypass is the common femoral artery, although malperfusion syndromes are more common with femoral artery cannulation. Malperfusion syndromes of the lower extremities will affect as many as 20% of patients, most commonly the right leg. If both femoral arteries have good pulses, either side can be used. In an unstable patient, the femoral artery has the clear advantage over the axillary artery of allowing two surgical teams to work simultaneously without having to share the same limited thoracic space.

Once the sternotomy is performed, the pericardium is opened. It is common to find a variable amount of blood-tinged pericardial fluid or even moderate amount of blood under tension. Often the ascending aorta will be moderately dilated, as aneurysm is a major risk factor leading to an ascending aortic dissection. The most common area of ascending aortic leak we found is the mid-ascending aorta. Most often blood enters the areolar tissue between the main PA and the ascending aorta, sometimes dissecting down onto the right ventricular outflow tract which may look quite discolored by blood and thrombus extending often all the way down to the RV to RA groove. It is important early in the process not to
disturb this discoloration or dissected tissue, as it is easy to convert this process into a free rupture. With arterial access obtained, the right atrium is cannulated in the usual manner. We routinely place a retrograde cardioplegia cannula at this time into the coronary sinus, and if needed, an SVC cannula that we will utilize during the circulatory arrest period for retrograde cerebral perfusion either alone or as an adjunct to antegrade cerebral perfusion. The patient is then placed on full cardiopulmonary bypass. During institution of cardiopulmonary bypass, very close monitoring of arterial waves from the right radial and if available the left radial artery are monitored to detect an arch malperfusion syndrome potentially caused by placement on cardiopulmonary bypass. When available, EEG is also closely monitored for hemispheric asymmetry. When EEG monitoring is not available, carotid artery interrogation can be performed by a hand-held probe connected to the same echo machine used for TEE. Anesthesiologists should be proficient with this simple technique of common carotid artery evaluation. The detection of poor or no perfusion in one of the carotid arteries will prompt appropriate action by the surgical team. If a malperfusion syndrome is documented by ultrasound, EEG or a persistent radial artery pressure differential, the patient is weaned off bypass and a different arterial cannulation site is often necessary to resolve the problem. Occasionally, two cannulation sites may be necessary, presumably one supplying the true lumen and the other the false lumen. As soon as adequate cardiopulmonary bypass is noted and no malperfusion syndrome is documented by EEG, arterial pressures, carotid ultrasound, as well as monitoring of the back pressure of the arterial cannulas, the left ventricle is vented via the right superior pulmonary vein. In many of these patients significant aortic valve insufficiency will be present. Core cooling is then begun with the goal of achieving flatline EEG if available or, based on our experience with several hundred monitored circulatory arrest cases, cooling is continued to either achieve a nasopharyngeal temperature of 16°C to 18°C, or for a total period of 50 minutes, whichever one is reached first. Our data suggest that at this level, the vast majority of patients will have a flatline EEG. Moderate hypothermia (22°C to 26°C) may be performed safely if antegrade cerebral perfusion is used. Patients with more severe atherosclerotic disease will likely require longer periods of cooling to achieve uniform end-organ cooling, and adjunctive techniques of retrograde cerebral perfusion or selective antegrade perfusion may be less effective in these situations.

Shortly after beginning the cooling phase, the heart will usually fibrillate. Aortic cross-clamp is then applied to the distal ascending aorta. In reoperative cases, it is critical to develop a cross-clamp site prior to cooling as wide open aortic insufficiency in combination with fibrillation will lead to catastrophic ventricular dilatation. While in the past, there may have been reluctance to cross-clamp a dissected ascending aorta, over the last 15 years, no aortic disruption has resulted by cross-clamping, even in patients with severe collagen vascular disease such as Marfan and Ehlers–Danlos syndrome. Clearly, the aortic cross-clamp should be placed well below the innominate artery takeoff to allow for more margin of safety as sometime more than one cross-clamp may be necessary to fully control this friable, diseased, and often-dilated ascending aorta. At the time of ascending aortic clamping, it is again very important to assess for malperfusion syndromes. It is possible, especially when perfusing from the femoral artery, that the application of the cross-clamp may close the largest communication between the true and false lumen in the ascending aorta, precipitating an aortic arch malperfusion. Monitoring lines in the right and left radial arteries, EEG monitoring of both hemispheres, and common carotid artery Doppler interrogation may show significant asymmetry. If a malperfusion syndrome is documented, expeditious surgical correction is necessary. Cardiopulmonary bypass is turned off with the patient in deep Trendelenburg position. The aortic cross-clamp is removed and the ascending aorta is opened proximal to the clamp site to visualize the dissection flap extending into the aortic arch. The dissection flap is then cut deeply into the aortic arch, thus creating a wide communication between the true and false lumen at the arch. The cross-clamp is then reapplied to the distal ascending aorta as cardiopulmonary bypass is restarted slowly, making sure to avoid cerebral air emboli. While such episodes are rare, occurring in 3% to 4% of our dissection experience, the maneuvers described have been successful in avoiding neurologic injuries that may have lead to ultimate mortality if unrecognized and left untreated. In the era of axillary or direct aortic cannulation, such occurrences have become exceedingly rare.

Once the ascending aorta is cross-clamped without distal malperfluions, it is divided at the level of the right PA and cold blood cardioplegia is given both by retrograde coronary sinus infusion as well as antegrade via direct coronary ostia cannulation. The right coronary is commonly involved in the dissection process and cannulation for cardioplegia gives the first opportunity to assess for the presence of false lumen-induced stenosis or occlusion or even for the presence of complete disruption. If cardioplegia extravasation is demonstrated in the very proximal portion of the right coronary, a segment of saphenous vein should be obtained by a second surgical team to bypass the right coronary arterial system in case a right button ostial repair proves impossible. Left main coronary problems are rare as they are usually fatal out-of-hospital. If they are noted at this point in the operation, additional vein grafts can be obtained to deal with them.

Next, the aortic root is exposed to assess whether it is repairable. If the intima within the aortic root is intact, and the aortic valve leaflets are normal, the root is usually repairable. Mild dilatation of the sinotubular junction up to about 34 mm in maximum diameter can be tolerated with an adequate repair. If the aortic root is severely aneurysmal, consideration of either a valve-sparing root replacement or a mechanical or biological root replacement should be planned at this time. With normal leaflets and intact root intima, the aortic root is mobilized circumferentially insuring adventitial root integrity. The aorta is then transected approximately 3 mm above the sinotubular junction, and three Teflon pledgeted monofilament sutures are placed approximately 2 mm above each of the three commissures. These resuspension sutures allow reestablishment of appropriate commissural geometry. Attention is directed next to the sinuses of Valsalva. The noncoronary sinus is nearly always dissected down to the annulus. Any debris or thrombus within the noncoronary sinus false lumen is cleared. Teflon felt is then fashioned to completely fit within the dissected space of the noncoronary sinus and is then inserted between the intima and the adventitia as a “neomedia.” It is secured in place either by utilizing 5.0 or 4.0 monofilmament sutures at the level of the sinotubular junction. Attention is next directed to the right coronary sinus of Valsalva. This is involved in over 50% of acute type A dissections and often requires very similar repair technique as used in the noncoronary sinus. Teflon felt is placed between the intima and the adventitia, fashioned in such a way to avoid any narrowing of the right coronary lumen as it courses through the dissected sinus. The left coronary sinus of Valsalva is then inspected. It is rarely involved in the dissection, but when it is, it is treated in a
similar manner as the right coronary sinus with a similar Teflon felt inserted between the intima and the adventitia and secured in the same manner.

If the aortic root is not reconstructable either because of pre-existing root disease or because of significant intimal root destruction and/or leaflets disease or tears, the coronary ostia are mobilized for root replacement. Valve-sparing root replacement is an excellent option in patient <50 years old, with collagen vascular disease and normal leaflets. A mechanical valved conduit also remains an excellent option in younger patients. A biologic root replacement, with a porcine root or handsewn pericardial composite root, should be considered in anyone over 60 years of age as the avoidance of coumadin greatly simplify postoperative management. Patients in this age group who have suffered an acute type A dissection are not likely to outlive their biologic prosthesis.

Usually, adequate cooling will be reached prior to completion of root replacement. To maximize the overall operative efficiency, all proximal work is stopped once flatline EEG, core temperature of 16°C to 18°C, and 50 minutes of cooling are reached, and attention is directed to the aortic arch. Antegrade cardiopulmonary bypass is interrupted, and either antegrade cerebral perfusion via the axillary artery or retrograde cerebral perfusion is begun via the snared SVC cannula. Antegrade perfusion is maintained at 10 cm³/kg/min and mean pressures are 40 to 70 mmHg. For retrograde perfusion, flows of 150 to 250 cm³/min are typically used to a target jugular venous pressure of 20 to 25 mmHg. Jugular venous pressure is measured via the right internal jugular sheath used to introduce the PA catheter. The ascending aortic cross-clamp is removed and the aorta is assessed. Now the goal is to excise the remainder of the ascending aorta and to prevent arch malperfusion once antegrade cardiopulmonary bypass is reestablished. The remainder of the ascending aorta is, therefore, debrided. The majority of the undersurface of the arch is excised. The details of the true and false lumen relationships are assessed carefully as there can be significant individual variation. The amount of aortic arch removed depends in large part on the relationship of the arch vessels to the arch false lumen.

In general, the entire lesser curvature of the arch and the majority of the anterior and posterior aortic arch are excised leaving a lip of aortic tissue encompassing the left subclavian, left common carotid, and innominate artery. A thin Teflon-felt strip is placed within the false lumen areas around the arch vessels and as necessary into the dissected portions of the residual proximal descending thoracic aorta. Again, the primary goal here is to prevent arch malperfusion with the secondary goal to create a layer that will robustly hold sutures for aortic arch reconstruction. The strip of Teflon felt is secured between the intima and the adventitia around the arch vessels and the dissected portion of the proximal descending thoracic aorta with a few interrupted or short running of 5.0 monofilament nonabsorbable sutures. A Dacron graft is then appropriately beveled and sewn to the reinforced arch tissue utilizing running 4.0 monofilament sutures. Multiple interrupted pledgeted monofilament reinforcement sutures are placed wherever necessary to further buttress the suture line. Deairing maneuvers are meticulously performed.

Occasionally, the aortic arch disruption is so severe that a total aortic arch replacement is necessary. Selective antegrade cerebral perfusion can be carried out via manually inflated balloon tip cannulas inserted in the innominate and the left common carotid arteries. A Dacron graft is sewn to the neo-media-reinforced proximal descending thoracic aorta usually utilizing the elephant-trunk technique. The arch graft is then sewn either to a reinforced island containing the arch vessels or to the individual branches as necessary. Prior to resuming antegrade cardiopulmonary bypass, deairing maneuvers are then performed with the aid of retrograde cerebral perfusion. In our experience, <10% of acute type A dissections required total aortic arch replacement, with another 5% requiring a separate graft to the innominate artery only.

After either a “hemiarch” or a “total arch repair,” the Dacron graft is directly cannulated and antegrade cardiopulmonary bypass is reestablished if central aortic or femoral cannulation were used as the initial bypass strategy. Antegrade reperfusion after arch repair minimizes potential malperfusion or arch suture line disruptions. If flow is reestablished via the right axillary artery in the setting of a distal innominate artery dissection, a right common carotid artery malperfusion could develop. Furthermore, the innominate artery false lumen may still have a sufficient distal entry point to sufficiently pressurize the arch suture line to cause disruption of the reconstructed aortic arch. Direct cannulation of the aortic arch graft should be performed in these situations to prevent such local perfusion anomalies, minimizing the risk of arch suture line disruption and maximize true lumen flow. A few minutes are taken early after full flow is established to assess the arch suture line and insure adequate hemostasis. This may be the only opportunity to treat significant bleeding points from the reconstructed aortic. Full rewarming is then allowed to begin while the proximal repair is completed.

The appropriate sized Dacron graft to restore normal sinotubular junction geometry is selected and it is then sewn to the reinforced sinotubular junction with 4-0 nonabsorbable monofilament suture. The proximal reconstruction is then tested by infusing cardioplegia solution into the repaired or replaced aortic root to assess for the presence of significant aortic valve insufficiency as well as suture line hemostasis. The proximal reconstruction is then sewn to the arch graft with running 4-0 nonabsorbable monofilament suture. Cardiac deairing maneuvers are performed and the heart is allowed to reperfuse. During reperfusion, the peripheral arterial cannulation site is appropriately repaired. After full rewarming, the patient is weaned off cardiopulmonary bypass. Early postpump, it is important to assess for significant aortic valve insufficiency. Any more than trace or 1+ AI will result in poor long-term valve durability. If the patient can tolerate going back on cardiopulmonary bypass, 2+ and higher AI should be fixed now, either by valvular replacement within the repaired root or by complete root replacement if necessary. Once the cardiac repair is noted to be satisfactory, the systemic vascular system is assessed to exclude new malperfusion syndromes, or to reassess preoperative ischemic regions. The vast majority of preoperative limb ischemia will resolve after adequate proximal aortic repair. If one limb remains pulseless with good perfusion in the contralateral limb, a femoral–femoral bypass can be performed. If both lower extremities continue to have poor pulses at this stage, an axillary–femoral or axillary–bifemoral reconstruction is favored over opening the abdomen and subjecting the patient to very morbid additional surgery. Stent grafting may provide an effective and durable treatment for abdominal and bilateral lower extremities malperusions in this setting as well. In the future, a stent graft may be deployed routinely in the proximal descending thoracic aorta via the open aortic arch at the original surgery. This may significantly increase the likelihood of obliterating the distal false lumen, with minimal added operative risk, hopefully sparing many patients from late dissecting aneurysms.
ACUTE TYPE B DISSECTION

Acute type B aortic dissection is defined by the development of the primary tear distal to the origin of the left subclavian artery. Complicated type B dissection is defined as the presence of end-organ malperfusion or rupture. Overall, early risk of mortality is between 5% and 10% in the early period. The major early morbidity and mortality are due to malperfusion syndromes, which in the current era, are typically managed with endovascular intervention. Malperfusion of the viscera or lower extremities may occur as a result of true lumen compression at the level of the aorta itself (pseudocoarctation) or impingement of the true lumen at the level of the branches (Fig. 58.7). Branches may also be sheared off the true lumen and only be supplied by false lumen flow. Rupture is a less common variant occurring in <5% of cases.

The mainstay of early therapy for uncomplicated acute type B dissection remains medical management primarily consisting of strict blood pressure control. Beta-blocking agents provide excellent control of absolute systolic pressure and also minimize aortic wall stress by minimizing the blood pressure rate of rise (dP/dt). In the early phase, intravenous control is usually achieved with esmolol and labetalol. Additional IV vasodilators can be utilized including calcium blockers, such as nicardipine. We try to avoid nitroprusside, except for very short periods very early in the stabilization process. Once the patient has passed the acute phase, oral beta blockers and calcium channel blocking agents are titrated to maintain appropriate blood pressure and heart rate levels. Many of these patients may have presented with a very malignant pattern of hypertension and often require chronically three or four drugs including beta blockers, calcium blockers, clonidine, a central alpha-agonist, angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, and diuretics.

It is very important to minimize aortic stress early in the process primarily to avoid rupture, control pain, stabilize treated or mild malperusions, and allow stabilization of the weakened aorta. Once in the chronic state, tight blood pressure control is maintained to limit aneurysmal degeneration. Many of these patients have severe atherosclerotic distal vascular beds, including cerebrovascular intracranial disease, as well as renovascular and occlusive disease in their abdominal visceral and lower extremity beds. These patients may not respond favorably to “normalization” of their blood pressure. Often a balance has to be reached between minimizing aortic disruption and allowing adequate perfusion of very extensively diseased vascular beds.

Surgical interventions in type B dissection need to be tailored to the specific problems encountered by the individual patient. Unlike type A, most patients with type B dissection are more likely to have significant atherosclerotic disease, with the tear often within a ruptured plaque. In severely atherosclerotic aortas, dissection extension may occasionally be quite limited due to the fibrotic media resisting establishment of a false lumen. Endovascular intervention for complicated type B dissection is highly effective to treat malperfusion and rupture and is associated with <10% mortality versus >50% mortality for traditional open repair. Endovascular therapy allows for more expeditious reexpansion of the true lumen and avoids the massive bleeding and physiologic insult associated with open dissection repairs. Given these dramatic improvements, endovascular techniques have virtually completely supplanted open surgery when technically feasible. Current technique consists of establishing iliofemoral access and placement of a wire in the true lumen using intravascular ultrasound guidance. A covered aortic stent graft is placed across the intimal entry point at the level of the subclavian artery, which is usually at least partially covered to achieve a proximal landing zone of at least 2 cm proximal to the entry tear. Malperfusion syndromes are typically treated with initially stent grafting the proximal third to

Fig. 58.7. (A) Pseudocoarctation. (B) Malperfusion syndrome.
half of the descending thoracic aortic true lumen (Fig. 58.8). In situations with pseudo-coarctation, where the true lumen is totally collapsed, extension of the stent grafts to the level of the celiac artery may be required to achieve reexpansion. This may be extended even further distally with bare-metal stents across the visceral segment. Individual branch vessel malperfections either in the iliofemoral system or the visceral segment may also be stented open with bare-metal stents as adjunctive procedures. Ruptures are treated with complete coverage of the thoracic aorta from left subclavian artery origin to the celiac artery origin.

Open surgical techniques for dealing with malperfusion include placement of a short segment graft in the descending aorta to reestablish the true lumen, extra-anatomic bypasses, and open surgical fenestration. If anatomy is not favorable for stent grafting, limb malperfusion is expeditiously managed with femoral–femoral bypass.

SPECIAL CASES: INTRAMURAL HEMATOMAS AND RETROGRADE EXTENSIONS OF TYPE B DISSECTIONS

Intramural hematoma is a variant of aortic dissection in which there is hematoma within the aortic wall in the absence of a classical intimal tear and no flow within a false channel. More common in older patients with severe atheroma of the aorta, intramural hematoma typically occurs as a result of bleeding into an atherosclerotic plaque or spontaneous bleeding in the vasovasorum of the aorta. They are best classified in the same manner as classic aortic dissections but may be managed somewhat differently. Type A aortic intramural hematoma is generally managed with urgent surgery as there is a significant risk of progression to frank aortic dissection or rupture. As these patients are frequently older and may have more comorbidities, medical management with strict blood pressure control and reversal of anticoagulants may be employed in patients with suitable anatomy who are poor surgical candidates. Favorable anatomy for medical management includes an absolute aortic diameter including hematoma of $<$4.5 cm with a hematoma thickness of $<$0.5 cm and absence of pericardial effusion. Serial CT angiogram should be performed within 48 hours of presentation for the determination of progression. Type B intramural hematoma is generally managed medically unless there is concern for rupture or impending rupture. In these cases, thoracic aortic stent grafting is the treatment modality of choice with full subclavian to celiac coverage. These cases are particularly high risk for spinal cord ischemia as the intercostal arteries are frequently sheared off by the hematoma and spinal perfusion is already compromised.

Occasionally, both type A and B dissections may present with either a partially or completely thrombosed false lumen, in which there is a true intimal tear but no flow within the false lumen. This may be indistinguishable from an intramural hematoma but typically has a more classic spiral dissection appearance with a compressed true lumen, as opposed to intramural hematoma, which has a more circumferential appearance without true lumen compression. Our approach has been to treat such patients with a thrombosed false lumen in the ascending aorta in the same manner as a standard type A dissection, thus proceeding to surgery without delay. Often these patients have a higher degree of atherosclerotic disease which may account for the lack of further progression of their dissection or for the early thrombosis due to sluggish false lumen flow secondary to minimal reentry sites. A type B dissection with thrombosed false lumen should be treated in the same manner as a standard type B dissection, with primary medical treatment. However, a partially thrombosed false lumen when pressurized is more likely to compromise true lumen flow leading to pseudocoarctation. Appropriate assessment and potential stenting or extra-anatomic bypass of the pseudocoarctation should be considered.

Aortic dissection may rarely arise in the distal arch and then progress both retrograde and antegrade. This process may on occasion be difficult to classify within the Stanford system and it may be difficult to decide whether the initial management should be surgical or medical. Most of these patients will have significantly atherosclerotic aortas with the false lumen becoming pressurized early in the descending thoracic aorta exerting significant retrograde forces to extend the dissection retrograde as the path of least resistance. If the retrograde extension ends at the level of the aortic arch and does not involve significant portions of the ascending aorta, the primary additional risk to a standard type B dissection is a cerebrovascular accident. The risk of rupture is relatively low. While our management remains individualized, we would initially observe patients with this type of retrograde extension and treat them as type B dissections. If, however, the ascending aorta becomes involved, either acutely or during follow-up, these patients should be treated as a standard type A dissection as they do suffer from the same risks of rupture, aortic valve insufficiency, and aortic root compromise leading to coronary malperfusion. We find, furthermore, that these patients have a higher surgical risk because the aortic arch is often completely destroyed and very difficult to piece back together. These are the classes of patients in whom an often very technically challenging total arch replacement may need to be performed, with an attendant higher mortality and a higher incidence of neurologic complications. Hybrid arch debranching procedures may by particularly useful in this setting as this limits the complexity of the arch repair. In this hybrid procedure, the ascending aorta is replaced as in a standard dissection, with an open distal anastomosis to the distal ascending, avoiding a deep arch anastomosis. The head vessels are rerouted using extra-anatomic bypasses from the ascending aortic graft. A stent graft is then deployed using fluoroscopic guidance with a proximal landing zone in the ascending aortic graft and distally in the descending aorta.
LONG-TERM FOLLOW-UP AND CHRONIC DISSECTIONS

Any patient with a valve-sparing repair or replacement of their aortic root needs lifelong surveillance to monitor the long-term durability of their aortic valve function. Patients with <1+ AI at the time of primary surgery have had an extremely durable repair utilizing the technique described. If the valve fails, regurgitation is typically the problem and an aortic valve replacement alone is often sufficient as the aortic root has been reinforced sufficiently to make the incidence of root dilatation very low.

All patients who have undergone proximal repair for an acute type A dissection will need lifelong surveillance of the residual aorta. Approximately, 90% will have a residual type B-like dissection beyond the completion of the arch repair. This residual dissection is at risk for aneurysm formation. If a dissecting aneurysm develops, they are candidates for repair based on standard aneurysm management criteria. We find 30% to 40% of patients will require downstream aneurysm surgery after proximal type A repair over 5 to 10 years of follow-up, and the risk will be higher the younger the patient, with a risk as high as 70% to 90% in patients with collagen vascular disease. Any patient who requires a distal aortic arch and descending thoracic aortic replacement must have a very careful evaluation for the presence of significant aortic valve insufficiency. Full cardiopulmonary bypass through the left chest with hypothermia leading to fibrillation can be very problematic in the presence of more than one aortic valve insufficiency. It is difficult to control the ascending aorta from the left chest and significant left ventricular distension can occur, even with a well-positioned LV vent. This can lead to cardiac and pulmonary dysfunction at the completion of the distal arch and descending thoracic replacement. To prevent such problems, the aortic valve may need to be replaced ahead of the distal aortic repair.

Occasionally, a patient will survive an undiagnosed acute type A dissection and will present months to years later with a large ascending dissecting aortic aneurysm with variable amount of AI. These patients are treated surgically in an urgent manner because the risk of rupture is higher than a nondissected ascending aneurysm of equal size. These aneurysms may have grown quite rapidly and present occasionally with compression symptoms to surrounding structures. At surgery no attempt should be made to obliterate the distal false lumens as many distal vascular beds will have become dependent on false lumen flow. The dissection flap should be resected as far as reachable to maintain free flow in all distal lumens. Depending on the sinus involvement and the chronicity, valve resuspension techniques may not be effective. If the aortic leaflets appear relatively preserved, a valve-sparing root replacement may be a good option. In the chronic setting, total arch replacement with branched arch grafts is more often required, and it carries a significantly lower morbidity and mortality compared with the acute setting.

CONCLUSION

Aortic dissection remains a catastrophic diagnosis with a time-related, high early mortality rate. Improvements in mortality for the treatment of acute type A dissections has been achieved by improvements in diagnostic techniques, expeditious transfer to the operating room prior to cardiovascular collapse, better physiologic understanding of intraoperative malperfusion syndromes especially affecting the arch vessels, intraoperative neurologic monitoring leading to real-time surgical maneuvers to reverse abnormalities, precise repair or replacement of the aortic root, and precise and durable anastomoses at the level of the arch. Type B dissections have remained a relatively low-risk early process where medical management remains the mainstay. Thoracic aortic stent grafts have converted extremely high-risk complicated type B dissections into rapidly managed problems with generally good outcomes. Application of stent graft technology to uncomplicated type B dissection to promote distal remodeling, and eventually, novel catheter-based prostheses for type A dissection represent the future directions of innovation in this field.

SUGGESTED READINGS

Dr. Bavaria and his team have set the standards for the surgical treatment of aortic dissection. I agree completely with their overall strategy. Certainly, the treatment of type A dissection is a surgical emergency. I very much like their approach of bringing patients urgently to the operating room and ruling them out there. Obviously, if they come in with a diagnosis and appropriate imaging that is one thing but certainly the most urgent case just need to be in the operating room.

I also agree entirely with their approach at doing their best to spare the aortic root unless there is evidence of annuloaortic ectasia. I agree with their approach of replacing sinuses if needed based on where the tear occurs. I also agree entirely with cannulation strategy. I think axillary approach may be a little more time-consuming in patients who are serious and femoral cannulation is appropriate. We almost always use a side arm graft to use central cannulation once the distal repair is done. We have a somewhat different approach to the anastomoses. I have used no glue and very little pledgeted material but very small needles to do the repair. I have found this in fact makes hemostasis easier because one can easily identify bleed points and fix them with a small suture.

Finally, I very much agree that distal dissections following the proximal repair are the norm rather than the exception. There are multiple reentry points and clearly there needs to be surgical follow-up of these patients for the rest of their lives.

ILK
INTRODUCTION

Aortic aneurysms are defined as a doubling of the normal aortic diameter for a particular body surface area, age, and gender. Advancements in open surgical technique and the advent of endovascular treatment have supported a significant improvement in outcomes and survival for many with descending thoracic and thoracoabdominal aortic aneurysms. Since the inception of successful thoracic and thoracoabdominal aortic reconstruction by Etheridge and DeBakey in 1955 and 1956, commitment to technical refinement and risk stratification has expanded the treatment potential for patients with thoracoabdominal aortic aneurysmal disease. The promise of current treatment has introduced preventative standards for reconstruction in the setting of chronic aortic aneurysm while advancing the success of treatment for acute aortic rupture and malperfusion. A principle achievement over the past decade of care has been the standardization of operative and critical care techniques for the maintenance of branch vessel and end-organ perfusion, which have minimized rates of postoperative organ failure and paraplegia. As we embark on a promising future for open and endovascular repair techniques, a continued commitment to evidence-based practice is imperative to further the curative potential for patients with descending thoracic and thoracoabdominal aortic disease.

The focus of this chapter is to review the current diagnostic standards and operative principles for the surgical treatment of thoracic and thoracoabdominal aortic aneurysmal disease. Open and endovascular techniques are presented as both independent and hybrid approaches to thoracic and thoracoabdominal aortic reconstruction.

ANATOMIC PRINCIPLES

Descending thoracic aortic aneurysms arise in the thoracic aorta distal to the origin of the left subclavian artery. Thoracoabdominal aortic aneurysms span the diaphragmatic hiatus at the level of T12 and introduce important considerations for pleural entry, peritoneal access, and diaphragmatic conservation for aortic repair. In addition, phrenic nerve localization and preservation are imperative within the pericardium as it crosses the left atrium and terminates distally on the abdominal surface of the diaphragm.

Thoracoabdominal aortic aneurysms may be classified according to the anatomic extent of disease as proposed by the Crawford classification system: type (or extent) I (24%) involving the proximal descending thoracic to proximal abdominal aorta, type II (26%) involving the proximal descending thoracic to infrarenal abdominal aorta, type III (26%) involving the distal descending thoracic and abdominal aorta, and type IV (24%) involving the abdominal aorta and including visceral vessel segments (Fig. 59.1). An understanding of the visceral and somatic branches along the thoracoabdominal aorta provides the foundation for operative techniques that maintain spinal cord and organ perfusion. Paired somatic branches arise from the third intercostal arteries and continue to the fourth lumbar arteries. The critical vascular zone of the spinal cord from T4 to L1 vertebral levels is characterized by the least prominent blood supply and is the zone at which interference with the circulation is most likely to result in paraplegia. Importantly, this anatomic guideline may vary based on the presence and extent of preexisting aortic reconstruction. The artery of Adamkiewicz is the largest anterior medullary feeder for the supply of the lumbar cord and arises from the lower intercostal or lumbar artery on left in 65% to 80% of cases between T6 and L4 levels. The lower intercostal and lumbar artery supplying the artery of Adamkiewicz should be preserved or reconstructed to maintain blood supply to the lumbar spinal cord to minimize the risk of spinal cord injury. Perfusion through medullary arteries maintains spinal cord blood supply proximal to the aortic cross-clamp and determines postoperative neurologic function. Visceral branches are located on the ventral aorta as the caval, superior mesenteric, inferior mesenteric, and paired or multiple renal arteries.

Localization of somatic and visceral branches during each individual aortic reconstruction guides decisions regarding clamp placement, perfusion techniques, and the need for reimplantation or graft reconstruction. Multidetector row computed tomography (CT) provides characterization of the critical spinal cord blood supply for targeted reconstruction and may be considered for elective complex repairs. The anterior spinal artery is a principal component of the extensive intraspinal and paraspinal collateral blood supply to the anterior spinal cord, with 75% of all segmental arteries providing direct anterior spinal artery-supplying branches. This extensive collateral network imparts a responsibility to define dominant intercostal and lumbar arteries for each individual patient to guide operative planning for reconstruction and preservation of blood supply to the spinal cord.

EPIDEMIOLOGIC AND DIAGNOSTIC CONSIDERATIONS

The prevalence of thoracic aortic aneurysms has tripled over the past two decades to a current estimate of 10.4 cases per 100,000 person-years. Patients with thoracic aortic aneurysms are at a mean age of 59 to 69 years with a 2:1 to 4:1 male predominance. Unlike ascending aortic aneurysms, descending aneurysms are often associated with significant atherosclerosis, yet this may represent more of an association than causal relation. The natural history of aortic aneurysm formation is diverse and may...
result from cystic medial necrosis, chronic dissections, aortitis, traumatic transaction, or conditions related to the degeneration of the aortic media such as Marfan syndrome, Ehlers-Danlos, annuloaortic ectasia, trauma, infections, mycotic conditions, syphilis, or idiopathic causes. Hypertension predisposes a patient to aortic dissection and subsequent potential aneurysm formation secondary to the increased thrombogenicity and incomplete decompression of the aortic false lumen. In retrospective review, the incidence of degenerative aneurysms without dissection was 73%, concomitant chronic dissection was 23%, and acute aortic dissection was 4%.

History and physical examination remain principal tenants to the management of a patient with presumptive descending thoracic and thoracoabdominal aortic aneurysm. The primary aim of physical examination is to exclude acute dissection, rupture, and malperfusion. Neurologic deficits, acute abdominal pain, hematuria, and lower extremity ischemia are indications of aneurysm-related malperfusion or distal embolism and prompt immediate intervention. Hypotension with hemorrhage into the left chest and pericardium represent rupture and support emergent resuscitation and repair. Acute or chronic enlargement of the thoracic aorta may manifest as chest and back pain or hoarseness secondary to recurrent laryngeal nerve compression. A nonproductive cough or hemoptysis may represent contained rupture or bronchial irritation, while gastrointestinal hemorrhage may occur in the setting of an aortoenteric fistula.

While an estimated 65% of patients with thoracic aortic aneurysms are symptomatic at the time of operative intervention, an increasing number of asymptomatic aneurysms are now detected on unrelated imaging. Primary risk factors for the development and size progression of thoracic aortic aneurysm include hypertension, smoking, and chronic obstructive pulmonary disease. Aortic wall tension and associated risk of rupture increase as the aneurysmal segment increases in diameter, as represented by Laplace’s law. The descending thoracic aorta is estimated to grow on average 0.19 cm per year and can attain a growth rate as high as 0.28 to 0.48 cm per year in the presence of aortic dissection.

**IMAGING**

The choice of imaging technique for evaluation of the thoracic aorta is determined by patient-related factors (hemodynamic stability, renal function, contrast allergy) and institutional capabilities (technologic capability, expertise). CT-induced contrast nephropathy and magnetic resonance (MR)-associated gadolinium nephrogenic systemic fibrosis are principal considerations for patients with borderline kidney function (serum creatinine > 1.8 to 2.0 mg/dl).

Chest X-ray has demonstrated specificity for acute aortic pathology of 86% in prospective study of patients undergoing evaluation for acute thoracic aortic disease. This imaging modality is, however, insufficient to definitely exclude thoracic aortic aneurysm in high-risk patients and lacks anatomic detail necessary for directed treatment. CT angiography (CTA) is accepted as the primary diagnostic imaging modality for the thoracic aorta with a demonstrated accuracy of 92% for all-inclusive abnormalities of the thoracic aorta and has an established efficacy in the prediction of the need for hypothermic circulatory arrest during surgical repair. Image acquisition should include thoracic branch vessels and femoral vessels to determine aneurysm extension and to guide potential endovascular access. Three-dimensional CTA reconstruction may provide additional advantages to operative planning.
MR angiography (MRA) provides similar advantages to CTA without the limitations of radiation exposure or iodinated contrast. Phase-contrast techniques and two-dimensional time-of-flight modalities have increased the application of MRA in the setting of thoracic aortic aneurysm and dissection, with beneficial applications in the determination of flow dynamics within the false channel. First-line adoption of this imaging modality in the setting of thoracic aortic aneurysm remains limited by institutional capabilities and the time required for acquisition. Current aortic sizing for intervention and endograft sizing are based on the external aortic diameter derived from CTA or MRA or the internal aortic diameter on echocardiography. In addition to providing insight regarding aortic size and anatomic aneurysm characteristics, both CTA and MRA guide the selection of safe sites for arterial cannulation and cross-clamp application.

The overall risk of rupture at 5 years following the initial diagnosis of descending thoracic or thoracoabdominal aortic aneurysm is estimated to be 20% and is dependent on the aortic size at diagnosis: 0% for aneurysms <4 cm diameter, 16% for those 3 to 5.9 cm, and 31% for aneurysms 6 cm or more. In addition, yearly composite adverse outcomes of rupture, dissection, and death are estimated to occur in 14.1% of patients with aneurysms 6 cm and greater in diameter in the absence of surgical intervention. These data support size-related treatment as represented by the expert American Heart Association consensus guidelines for intervention based on Class I evidence:

1. Open repair is recommended for chronic descending thoracic aortic dissections with an aortic diameter exceeding 5.5 cm.
2. Endovascular repair should be considered for degenerative aneurysms exceeding 5.5 cm, saccular aneurysms, and postoperative pseudoaneurysms.
3. Elective surgery is recommended for thoracoabdominal aneurysms exceeding 6.0 cm or less in the setting of connective tissue disease with limited endovascular options and elevated surgical morbidity.
4. Additional revascularization procedures are recommended for patients with end-organ ischemia or visceral artery athero-sclerotic disease.
5. Patients with symptoms consistent with thoracic aneurysm enlargement warrant prompt surgical intervention unless candidacy is limited by comorbid disease or quality of life.

For endovascular techniques, a suitable landing zone of normal diameter with no circumferential thrombus 2 to 3 cm distal to the left subclavian or left common carotid artery and proximal to the celiac axis is required. For patients with anatomic limitations, endovascular techniques may also create landing zones for candidate aneurysms. In addition, a femoral vessel diameter > 7 mm and an aortic curvature <60 degrees optimize sheath advancement and stent deployment. Endograft sizing recommendations are to aim for 10% to 20% over sizing at the proximal landing zone. These guidelines represent current suggested thresholds within the rapidly advancing field of endovascular aortic aneurysm repair and should not be accepted as absolute criteria. With both endovascular and open repairs, the decision for surgical intervention and reconstruction is founded on a calculated heightened risk of nonoperative medical management that exceeds the risk of the selected operation. A preoperative understanding of potential ischemic heart disease, obstructive lung disease, and renal impairment is imperative prior to operative intervention. Medical management and optimization of end-organ function prior to endovascular or open repair is a critical consideration for all patients to minimize perioperative morbidity and mortality.

**OPEN DESCENDING AND THORACOABDOMINAL RECONSTRUCTION**

**Anesthesia and Monitoring**

Induction and maintenance of general anesthesia are achieved by double-lumen endotracheal intubation. A single-lumen endotracheal tube may be utilized for aneurysms isolated to the lower thoracic and upper abdominal aorta. Large-bore peripheral access, central venous pressure monitoring, continuous arterial pressure assessment, pulse oximetry, and foley catheter are imperative to guide intraoperative resuscitation and support. Transesophageal echocardiography, continuous electrocardiographic monitoring, and a pulmonary artery catheter provide additional adjuncts for intraoperative cardiac evaluation and are routine at our institution. Femoral artery access is needed with cardiopulmonary bypass to maintain balanced pressures. Temperature monitoring is achieved at two access sites to estimate cerebral (blood, esophageal, tympanic membrane, nasopharynx) and visceral (bladder, rectal) temperatures. Cerebrospinal fluid (CSF) drainage is the principal modality for spinal cord protection utilized at our institution due to the established benefit and low-risk of this protective strategy. Motor-evoked potential (MEP) and somatosensory-evoked potential (SSEP) monitoring may be applied in addition to CSF drainage for spinal cord protection and monitoring. Following anesthesia induction, the patient is rolled to expose the left flank and chest wall with the pelvis rolled half-anteriorly to enable access to the left femoral vessels (Fig. 59.2). The table is flexed to open the intercostal spaces, axillary rolls are applied, and pressure points are padded with care.

**Incision and Exposure: Thoracic Aneurysms**

An extended posterolateral thoracotomy is performed to expose the entire length of the thoracic aorta. The latissimus dorsi and a minimal portion of the serratus anterior muscles are divided. Left lung ventilation is terminated prior to entry into the pleural cavity. Aneurysms of the upper or middle thoracic aorta are accessed through a single intercostal space, which may be facilitated by division of one of the ribs posteriorly. We prefer two separate sites of entry through the fourth interspace and the seventh or eighth interspace for more extensive descending thoracoabdominal aneurysms. The fourth interspace is critical to proximal clamp application. Careful entry into the pleura allows anterior retraction of the lung under sponges to expose the aorta. The pleura over the aorta is divided. The intrathoracic course of the vagus nerve, recurrent laryngeal nerve, and proximal phrenic nerve at the aortic arch is identified. The aorta is then taped immediately proximal to or at the origin of the left subclavian artery where careful, sharp dissection allows for future application of the aortic cross-clamp. The thoracic duct and adjacent lymph vessels should be avoided. Intraoperative lymph leaks should be immediately repaired. The identification of the esophagus may be augmented by the direct palpation of the nasogastric tube or transesophageal echocardiography scope to avoid inadvertent injury.

Following achievement of the proximal aortic dissection, attention is directed to the aorta distal to the aneurysm. In the setting of extensive thoracic aortic involvement, a second pleural entry through the separate intercostal incision may be needed. Careful sharp dissection of the distal aorta is performed to achieve adequate control.
Importantly, no attempts are made in the dissection of the aneurysm along its entire length to avoid potentially hazardous bleeding; however, posterior mobilization of the aneurysmal segment may be necessary to support clip application to the intercostals prior to opening of the aorta.

**Incision and Exposure: Thoracoabdominal Aneurysms**

Our standard incision is started posterolaterally over the ribs of the seventh, eighth, or ninth interspace dependent on the proximal extent of the aneurysm. The incision is then advanced across the ninth interspace at the costal margin to curve inferiorly to run parallel and left-lateral to the midline and rectus sheath. Single right lung ventilation is initiated and the left pleural space is entered. The abdominal muscles are divided and the peritoneum is preserved. Special care is needed at the lateral edge of the rectus abdominis muscle where the peritoneum and transversalis fascia are closely apposed to the abdominal wall. While the retroperitoneal approach is our preferred technique, we recognize that the intraperitoneal approach affords mobilization of the spleen and left colon, which may enable better access to the abdominal aorta in select patients. The diaphragm may be taken down with a curved incision along the costal margin with care to preserve a 3-cm rim along the posterior aspect of the rib. The tendinous center of the diaphragm is then conserved when anatomically feasible to improve postoperative respiratory recovery and weaning time. This limited phrenotomy technique allows passage of the graft through the natural hiatus of the diaphragm. The incision is continued down to the crura, and the left crus may be divided to expose the aorta beneath. A radial diaphragmatic incision may also be utilized and has become our preferred technique (Fig. 59.3).

Progressive retraction of the peritoneum and its contents will facilitate exposure of the retroperitoneum and a self-retaining retractor is necessary. The aorta is located medial to the ilio-psoas muscle. Mobilization of the left kidney from the bed of the psoas muscle may provide additional exposure and is preferred at our institution. Importantly, this step is deferred in patients with a retroaortic left renal vein. Anterior visceral branches are identified and sharply dissected with attention to mobilization should reimplantation or bypass be required. Dissection is performed proximal and distal to the aneurysmal segment of aorta and each site is tapped in preparation for cross-clamping.

**Hemodynamic Support during Aortic Cross-Clamping**

Proximal aortic cross-clamp application induces a significant increase in cardiac afterload. Sudden afterload reduction following clamp release is associated with an acute relative hypovolemia and systemic hypotension. These periods...
of hemodynamic change are managed through the following intraoperative strategies.

**Pharmacologic Manipulation and Clamp Application Technique**

Direct and cooperative communication between surgeon and anesthesiologist is imperative during periods of cross-clamp application and release. Our approach to cross-clamp application and distal aortic perfusion involves active distal aortic perfusion with femoral-to-femoral bypass for all but type IV and V aortic aneurysms, for which we minimize supraceliac clamp times with no active distal perfusion. This perfusion strategy maintains distal aortic perfusion with warm, oxygenated blood and provides the time necessary to safely perform the most complex of repairs. With this strategy, maintenance of distal aortic blood pressure is imperative and is achieved through the titration of pharmacologic agents and pump flow rates to maintain optimal perfusion. Infusion of nitroglycerine, trimethaphan, or sodium nitroprusside prior to the application of the aortic cross-clamp may be performed to lower systolic blood pressure to 70 to 80 mmHg. The anticipated acute rise in blood pressure with aortic cross-clamp application should necessitate aggressive blood pressure control until planned clamp release. Sodium bicarbonate, calcium, and rapid volume infusion may be initiated prior to unclamping to prevent acute hypotension. Vasopressor agents may also be utilized to augment these resuscitative measures to maintain blood pressure upon clamp release. Importantly, our principal focus is to carefully titrate both volume and pump flow rate to maintain target pressure, often eliminating the need for these additional interventions throughout the critical periods of clamp application and release.

Progressive clamp application and release over a period of 2 to 4 minutes may blunt the imposed physiologic insult and hemodynamic response. In assessment of end-organ ischemia, cross-clamp time is measured from the first click of clamp application until its complete release. Despite these preventative and resuscitative measures, hemodynamic instability may occur and should be anticipated with appropriate preparation.

**Extracorporeal Circulation**

Extracorporeal circulation support provides after load reduction and continuous end-organ perfusion during the aortic cross-clamp period. Techniques for the maintenance of extracorporeal circulation include passive aorto-aortic shunt, left atriofemoral bypass, and femorofemoral cardiopulmonary bypass.

**Left Atriofemoral Bypass**

Atriofemoral bypass is achieved through an inflow circuit cannula that is introduced into the left atrial appendage or inferior pulmonary vein. The left atrial inflow blood is powered through a centrifugal or roller pump and returned to a nondiseased region of femoral artery or aorta below the level of the distal clamp. Femoral-to-femoral bypass has mostly replaced this technique at our institution due to the potential for air in the circuit and the absence of a heater-cooler pump mechanism. This technique may, however, be beneficial in patients with poor hemodynamics, impaired cardiac function, or during prolonged cross-clamp times. Improvement in long-term survival with distal aortic perfusion in addition to measures for cerebral protection supports the efficacy of both techniques in the mitigation of ischemic end-organ injury.

The technique for initiation of circuit support involves exposure and taping of the left femoral artery prior to systemic heparinization. The pericardium is opened to expose the left atrial appendage and a purse string is placed. We prefer the use of the inferior pulmonary vein to avoid opening of the pericardium and potential injury to the fragile left atrial appendage. Prior to aortic cross-clamp application, heparin (100 U/kg) is administered to achieve an activated clotting time of 200 seconds. A heparin-bonded circuit provides a measure for the reduction of systemic heparin. The pump inflow cannula is placed in the left atrial appendage or inferior pulmonary vein and the pump outflow cannula is inserted in the left femoral artery to close the circuit. The pump is activated prior to clamping to achieve a high flow rate for reduction of preload prior to the significant increase in afterload imposed by clamp application. Pump flows are maintained and adjusted to achieve target pressure above and below the aortic cross-clamp of 80 to 100 mmHg. Following reconstruction, pump flow can be terminated to increase preload prior to clamp release and the associated afterload reduction.

**Femorofemoral Cardiopulmonary Bypass**

Femorofemoral bypass is our preferred technique for distal aortic perfusion and is especially beneficial in the setting of a heavily calcified proximal aorta. The principal benefit to this technique is the maintenance of warm, oxygenated blood perfusion to the distal aorta and branch vessels with precise control of perfusion pressure and temperature. The inclusion of cooling capabilities within the femorofemoral bypass circuit allows the achievement of circulatory arrest when necessary. Additionally, pump sucker return to the pump reservoir minimizes transfusion requirement.

The technique for circuit achievement involves femoral vein and artery exposure preferentially on the left side for cannulation following systemic heparinization. Longer activated clotting times are required secondary to the circuit components. An extended 21-F multistage femoral vein cannula is advanced from the left femoral vein toward right atrium to achieve adequate venous drainage of 1.5 to 3 L. Arterial access is achieved at the left femoral artery, left internal iliac artery, or by direct cannulation of the distal aorta with a 15- to 17-F arterial cannula. Cardio-pulmonary bypass is initiated immediately prior to aortic cross-clamp application. In patients requiring circulatory arrest, the patient is cooled to 15 to 18 degrees Celsius and circulatory arrest is initiated to allow creation of the proximal anastomosis. The left ventricle should be vented upon fibrillation in the setting of aortic insufficiency. Prior to clamp release, additional volume may be needed in the reservoir to allow rapid transfusion and high pump flows upon clamp release and anticipated hypotension.

**Spinal Cord Protection**

The inherent threat of unavoidable temporary cord ischemia during repair and the potentially preventable lasting ischemia resulting from inadequate perioperative cord perfusion in patients with descending thoracic and thoracoabdominal aneurysms have supported significant technical advancements in spinal cord protection. Central to methods of cord protection is an understanding of the axial network and the supplying segmental, subclavian, and hypogastric arteries and the protective effect of permissive hypothermia on neural tissue. This collateral network may increase flow through alternative routes when another is reduced; however, this network may also result in steal that will result in decreased nutrient flow to the cord. Steal may occur secondary to the absence of visceral and iliac artery perfusion, during the cross-clamp period, or as a result of pharmacologically induced arteriovenous
shunting when bleeding intercostals into an excluded aortic segment. With these considerations, we have adopted the liberal use of multihead perfusion cannulae and pediatric coronary sinus catheters for the maintenance of perfusion to the visceral and subclavian aortic branches and dominant intercostal arteries, respectively (Fig. 59.4). The detection of potentially reversible delayed paraplegia may be achieved by MEP and SSEP monitoring with immediate assessment of function postoperatively. It is not our routine practice to perform MEP or SSEP monitoring. The adoption of the following provocative techniques for reduction of spinal cord ischemic-induced injury has resulted in a significant decrease in the incidence of paralysis following open repair that is dependent on the extent of repair: 15% for type I, 30% for type II, 7% for type III, and 4% for type IV. Additional predictors of delayed neurologic deficit for thoracoabdominal aneurysms include emergent operative status, prolonged aortic cross-clamp time, level of cross-clamp, hypogastric artery exclusion, aortic rupture, preoperative renal dysfunction, prior abdominal aortic aneurysm repair, acute dissection, and extent II involvement. These techniques and the avoidance of hemodynamic instability and significant blood volume loss have offset the influence of cross-clamp time on induced spinal cord injury.

1. **Distal aortic perfusion.** The presented techniques of atriofemoral and femoro-femoral cardiopulmonary bypass have proven efficacious in the reduction of postreconstruction neurologic deficit, particularly in extent II aneurysms. Lower body pressure monitoring is imperative to maintain appropriate cord perfusion which may necessitate flow rates as high as 3 to 3.5 L/min.

2. **Intrathecal vasodilators and topical cooling.** Experimental porcine studies have established the protective effect of intrathecal administration of vasodilators during the aortic cross-clamp period. This technique dilates spinal arteries and prevents spasm and may be combined with local cooling of the cord with 4°C saline to extend the potential aortic cross-clamp time. Topical cooling of the spinal cord is associated with increases in CSF pressure; however, this technique has proven to be a protective adjunct in the reduction of postoperative paralysis and paraplegia. Additionally, prospective clinical study has demonstrated the efficacy of combined CSF drainage and intrathecal papaverine administration in the reduction of spinal cord injury for high-risk thoracoabdominal aortic operations.

3. **Cerebrospinal fluid drainage.** Randomized and nonrandomized clinical trials in addition to cohort studies have demonstrated the efficacy of CSF drainage for the prevention of postoperative paraplegia. In randomized prospective study, the incidence of paraplegia or paraparesis was reduced with CSF drainage from 13.0% to 2.6%, *P = 0.03*. A lumbar catheter is introduced into the subarachnoid space at the L3 or L4 intervertebral space and connected to a pressure transducer and drainage set to achieve CSF pressure monitoring and drainage. CSF pressure is maintained <10 mmHg with mean perfusion pressures of 85 to 90 mmHg to enhance spinal cord perfusion. Lumbar drains are generally removed on postoperative day 2 in patients without neurologic deficit. Our preference in high-risk patients is to leave the lumbar drain in place for 72 hours, while in select low-risk patients we consider removal at 24 hours.

4. **Reattachment of intercostal and lumbar arteries.** Retrospective study has demonstrated acceptable rates of paralysis and paraplegia following sacrifice without reimplantation of as many as 15 intercostal and lumbar arteries during thoracoabdominal aneurysm reconstruction. In addition, porcine studies suggest that all segmental arteries may be ligated with preservation of spinal cord function. Prompt ligation of nonimplanted intercostal arteries is recommended to avoid steal from the cord circulation. While multimodality approaches have implemented complete intercostal reimplantation, the demonstrated efficacy remains undefined and the prolonged ischemia imposed by this technique may increase the risk of postreconstruction paralysis and paraplegia.

5. **Hypothermia.** Moderate (29 to 32°C) to profound (<20°C) hypothermia is associated with improved outcomes following thoracoabdominal and descending aortic operations. The proposed mechanism of hypothermia-induced protection involves the reduction of excitatory neurotransmitter release, decreased free oxygen radical production, decreased posts ischemic edema,
and stabilized central nervous system blood flow. Hypothermia is achieved through passive cooling, fluid resuscitation, and titration of the extracorporeal circuit heat exchanger.

6. Pharmacologic agents. Mannitol (0.25 to 1.0 g/kg), high-dose barbiturates, methylprednisolone (30 mg/kg), calcium-channel blockers, adenosine 2A agonist, naloxone, and local anesthetic agents have a demonstrated efficacy in experimental models of spinal cord ischemia and multimorbidity clinical protocols. Methylprednisolone, naloxone, and mannitol have achieved variable clinical adoption. The proposed mechanism of spinal cord protection involves decreased spinal cord edema and improved free oxygen radical scavenging.

7. Minimizing aortic cross-clamp times. Debate persists regarding the effect of aortic cross-clamp time on rates of paralysis and paraplegia following thoracic and thoracoabdominal aortic aneurysm repair after the near-universal adoption of distal aortic perfusion. Despite these conflicting reports, the clamp-and-sew technique remains a foundational technical principle in the reconstruction of thoracoabdominal and descending thoracic aortic aneurysms.

Our institutional approach to spinal cord protection incorporates minimal clamp times, femorofemoral bypass, and CSF drainage for all extent I and II aneurysms and select extent III aneurysms or complex reconstructions. Special care is imperative in clamp application to avoid placement in segments with significant atheroma or mural thrombus to minimize the risk of embolization to the spinal cord and viscera. Distal aortic perfusion is maintained by femorofemoral bypass. Beveling of the anastomosis or revascularization with a branched aortic graft is performed at the T11 to L1 level when feasible and without a significant extension of total clamp time.

In patients with proximal extension or aortic calcification limiting proximal clamp application, femorofemoral bypass and hypothermic circulatory arrest provide support measures to allow completion of the proximal anastomosis. The graft is then cannulated to initiate warming to the great vessels, lower extremities, and viscera while the distal anastomosis is completed. Alternative cannulation strategies with the auxiliary artery may be utilized to minimize embolic stroke potential in patients with extensive atheroma.

AORTIC GRAFT SELECTION

Direct proximal and distal measurements or a sizing device should guide graft size selection. Zero-porosity polyethylene terephthalate (Dacron) grafts have eliminated the need for precollating or bleeding through the graft. Sidearm grafts may also be selected to achieve complex reconstruction or revascularization of visceral and intercostal vessels. Suture material should be selected and loaded prior to cross-clamp application. Our preferred suture is a long, double-armed 3-0 or 4-0 polypropylene suture for each aortic anastomosis with felt reinforcement of the aortic suture line.

TECHNIQUE FOR AORTIC ANASTOMOSES

Following application of the proximal and distal cross-clamps, the aneurysm is incised longitudinally with a large blade close to the site of the anastomosis. The aortotomy is extended proximally and distally with scissors to expose the lumen of the aneurysm and to allow evacuation of laminated thrombus. In extended aneurysms, the clamps should be placed in close proximity to minimize the potential for exclusion of dominant segmental arteries to the spinal cord. The distal clamp is transferred to the site of the distal anastomosis at the completion of the proximal anastomosis. Avoidance of distal clamp application with cell-saving suction may be utilized with the clamp-and-sew technique.

TUBE GRAFT PLACEMENT

The proximal aortotomy is fashioned to accommodate a transverse anastomosis. In chronic dissection, complete transection is recommended to identify each aortic layer for subsequent incorporation into the anastomosis. Complete transection may also be of benefit when feasible in the setting of chronic atherosclerotic aneurysm to facilitate the anastomosis.

Side towels cover retractors and clamps and the graft is placed onto the field. The proximal anastomosis is initiated on the graft and the aorta is picked-up for the first four sutures as a parachute stitch. The graft is approximated to the aorta and the anastomosis is completed expeditiously with large aortic bites to achieve hemostasis (Fig. 59.5). The suture line is completed sewing toward oneself beginning with the back wall until reaching the anterior suture line. The other arm is then brought from below. The aorta may be taken outside-in or inside-out as long as bites are both rapid and sufficient.

Following completion of the proximal anastomosis, the graft is clamped at 4 to 5 cm below the suture line and the proximal clamp is released to allow inspection and immediate repair of any sites of inadequate hemostasis (Fig. 59.5B). Repair is achieved with a standard-length 3-0 polypropylene suture as a mattress stitch, pledged with polytetrafluoroethylene. Branched visceral vessel and intercostal reconstructions are then performed prior to the distal aortic anastomosis.

Attention is directed to the distal suture line and retraction may be moved from the upper to lower incision when necessary. The aortotomy is extended down the aorta to the distal aneurysm neck and squared horizontally at the site of the proposed anastomosis. Complete transection of the aorta at the distal margin is favored only in the setting of a chronic dissection flap (Fig. 59.5C). In subacute dissection, a long tongue is fashioned away from the flap to allow a graft anastomosis to the outer aortic layer to maintain perfusion to both the true and false lumen distally. The anastomosis is then created in a similar manner. Notification to the anesthesia team upon nearing completion will allow preparation for cross-clamp release. As the distal clamp is removed, bypass flows are titrated and weaned to maintain optimal perfusion pressures. With this technique, minimal hemodynamic compromise should occur.

REIMPLANTATION OF INTERCOSTAL ARTERIES

Inspection for dominant, large intercostals is performed during the initial dissection, marking each for potential revascularization. Our preferred approach is to incorporate a 6-mm sidearm graft with 4-0 or 5-0 polypropylene suture to critical intercostal arteries rather than the island patch technique to minimize the potential for aneurysmal degeneration (Fig. 59.5C).

In the setting of extensive thoracoabdominal disease with visceral artery involvement, our preferred technique involves mobilization of the celiac axis, superior mesenteric artery (SMA), and right renal artery for reconstruction with a branched aortic graft (Fig. 59.6). During such complex reconstructions, distal aortic perfusion and progressive clamp advancement are performed to minimize visceral ischemic time. The proximal anastomosis is completed first and the graft clamped just below the anastomosis. The proximal
Section II: Adult Cardiac Surgery

Fig. 59.5. Transection of the aorta in cases of aortic dissection to ensure that all aortic layers are incorporated into the anastomosis. (A) Completion of the proximal aortic anastomosis. (B) Sequential clamping strategy with removal of an ellipse from the graft for reimplantation of dominant intercostal arteries. (C) Intercostal artery revascularization is completed prior to the distal anastomosis with 6 mm sidearm graft. The distal is then performed with complete transection of the aorta in the setting of concomitant dissection.

In many individuals, visceral vessels may neighbor the aneurysmal segment, yet their origins remain uninvolved. For these select patients, we favor an oblique distal anastomosis that preserves an anterior tongue of aorta from which the visceral vessels arise. This aortic tongue is subsequently incorporated in the aortic anastomosis, effectively maintaining visceral perfusion without the requirement for additional anastomoses.

Multiside-branched grafts have emerged as our preferred technique for branch vessel revascularization, with particular benefit for patients in which the origin of visceral vessels is splayed, occlusive, or aneurysmal. Multilimb perfusion catheters from the bypass arterial line are recommended with this technique to individually perfuse visceral arteries through coronary sinus balloon catheters during sequential revascularization as described.

Completion of the Operation

Hemostasis at all suture lines and adequate distal perfusion are confirmed following the achievement of all anastomoses. Extracorporeal support is weaned and the patient is adequately warmed. Adequate blood pressure and a satisfactory rhythm are confirmed. Protamine sulfate may be administered and cannulation sites are repaired. The graft is covered with the remnant aneurysm sac to prevent later fistula formation to the lung or intestine. The retroperitoneal tissue is approximated over the abdominal portion of the graft. If deficient, greater omentum may be used. 19- to 24-F small-diameter channel drains are placed into the pleural cavity at the apex and base. In addition, we routinely place a 19- to 24-F drain into the retroperitoneum. Topical hemostatic agents and anti-fibrinolytics may be used in the setting of persistent and generalized lack of adequate hemostasis, although the efficacy of antifibrinolytic therapy has not been demonstrated in retrospective analysis. The collapsed lung is reinfated and the operative field is irrigated. The ribs are approximated with multiple interrupted, heavy, absorbable sutures, taking care to avoid the neurovascular bundles. Intracostal sutures placed through holes that are drilled in the lower rib have been demonstrated to decrease postoperative neuralgia and are recommended. The soft tissues are approximated in layers. Postoperative mechanical ventilation is necessitated in all patients until acidosis is reversed and hemodynamic stability at normothermia is achieved.

Endovascular Repair Technique

Advancements in thoracic endovascular aneurysm repair (TEVAR) have inspired the clinical adoption of this treatment for many with distinct aortic pathologies or limited candidacy for open surgical repair.
reconstruction. The potential avoidance of thoracotomy, extracorporeal circulatory support, aortic cross-clamp time, and prolonged hospital length of stay support consideration of endovascular descending thoracic and thoracoabdominal aneurysm repair in patients with significant comorbid conditions (advanced age, cardiac, pulmonary, and renal dysfunction). Importantly, patients who are not candidates for open surgical repair have significantly poorer outcomes following TEVAR than TEVAR-treated patients that would have been open repair candidates. These data support further research advancement to define the potential expansion of treatment criteria for patients with asymptomatic descending and thoracoabdominal aneurysms.

Absolute contraindications to TEVAR include insufficient proximal and distal landing zones or an aortic diameter $<22$ mm. In the clinical translation of this guideline, off-labeled uses of non-FDA approved devices have been described. Extreme tortuosity of the thoracic aorta should be considered in operative planning as this may impair the ability to safely advance guide wires into the thoracic aorta. In the presence of laminated thrombus or significant atheromatous plaque, we carefully consider the application of endovascular therapy secondary to the significant risk of distal embolization. Relative and debated contraindications include a young age as long-term outcomes remain undefined, unstable patients requiring preoperative imaging, and patients with chronic renal insufficiency, although intravascular ultrasound (IVUS) may be performed with minimal contrast material.

At this time, three thoracic aortic stent platforms are approved by the U.S. Food and Drug Administration for the treatment of thoracic aortic aneurysms: the W.L. Gore TAG endograft platform (Flagstaff, AZ), the Cook Zenith TX2 (Bloomington, IN), and the Medtronic Talent (Santa Rosa, CA) thoracic endograft systems. Common design features of thoracic endograft systems include an elongated shaft for delivery to the proximal aorta from the groin, larger diameters and lengths, increased flexibility, and a tubular, nonbifurcated design. The selection of the appropriate endograft is determined by the individual patient anatomy. Endograft devices and approaches tailored to distinct pathologies are under current clinical investigation and development. The Talent (Medtronic) is available in larger diameters to 42 mm and incorporates a proximal bare metal stent for proximal fixation. The Zenith (Cook) device provides tapered graft options and an exposed distal stent for improved fixation. In addition to endograft system components, a stiff wire such as the Lunderquist (Cook) wire for tracking, a marker pigtail for length projection, and balloons for graft effacement provide intraprocedural adaptations to achieve satisfactory graft positioning within the thoracic aorta. All wires are to be at least 260 cm for access from the groin.

Thoracic endografting should be performed in an appropriately equipped specialized operating room with intraprocedural angiography capability. The patient is positioned supine on the operative table with exposure of the predetermined access vessels (femoral, iliac, terminal aorta) and upper extremity vascular access sites as necessary. General anesthesia is achieved with a single-lumen endotracheal tube; however, regional anesthesia may be utilized in select patients. Arterial pressure monitoring and pulse oximetry are established on the upper extremity. Large-bore peripheral intravenous access, Foley catheter placement, and temperature monitoring are achieved. CSF pressure monitoring and drainage and SSEP assessment are techniques to minimize the risk of paraplegia in patients requiring extensive coverage of the descending aorta or in patients with prior history of abdominal aortic aneurysm repair. Our general practice is to always place a lumbar drain in patients undergoing thoracoabdominal aneurysm repair. While recognizing the potential benefit of SSEP monitoring, we have not found that SSEP monitoring significantly alters intraoperative treatment. Thoracoabdominal aortic aneurysms may involve the ostia of the celiac axis or the SMA and inferior mesenteric artery (IMA), necessitating coverage upon endovascular repair. In these select patients, a first-stage debranching operation to achieve SMA-to-ceeliac artery, aorta-to-SMA, or aorta-to-ceeliac artery bypass grafting is performed. Branched, fenestrated endografts provide a promising innovation for future study and development. Additionally, snorkel or stove-pipe techniques are continuing to evolve and we have utilized each with some success in extent III aneurysms. When selecting an approach to bypass and reconstruction, it is important to consider that the ostia of the celiac artery axis may be covered without sequelae in the setting of documented and appropriate collateral flow through the SMA.

The common femoral or common iliac arteries are the principal sites for device access. Angiographic access may be obtained through the contralateral groin or the left brachial artery. Access through the upper extremity provides localization of the left subclavian artery and may facilitate true lumen cannulation in the setting of aortic dissection. In patients with insufficient femoral arteries, a retroperitoneal approach may be necessitated for infra-aortic or iliac artery access. The device is introduced and positioned prior to angiographic imaging at an oblique angle to splay the thoracic aorta and identify visceral vessels. Hemodynamic monitoring and control are imperative during device deployment, as balloon molding and pulse pressure may shift the graft. Overlap of at least 5 cm is recommended to avoid a junctional endoleak. Intussuction of the graft components may be necessary in the setting of aortic tapering. Compliance with device-specific guidelines is recommended for access diameter and deployment. Following deployment of the endograft, postreconstruction angiography is performed to confirm satisfactory localization and exclusion of the aneurysmal segment. Sheaths are removed and hemostasis is confirmed following either percutaneous device closure or direct surgical repair of access vessels. Immediate postoperative care and resuscitation parameters follow the presented guidelines for open repair.

Common iliac artery conduits or direct common iliac artery puncture provide alternative techniques for access in patients with size-limiting femoral arteries. While the most widely accepted approach to iliac artery access is to sew an 8 to 10 mm conduit onto the artery, direct access and primary closure are often sufficient. If the proximal landing zone is insufficient, extra-anatomic bypass may be performed to maintain perfusion to branch vessels. The most common indication for extra-anatomic bypass is the need to cover the ostia of the left common carotid or innominate arteries. The left subclavian artery is intentionally covered in approximately 50% of cases. In our experience, TEVAR exclusion of the origin of the left subclavian artery necessitated pre- or postoperative revascularization in 40.7% of patients. Exclusion of the left subclavian artery without revascularization may also increase the risk for perioperative stroke or spinal cord ischemia. In addition to selective revascularization, subclavian to carotid artery transposition is recommended when the aortic lesion is within 15 mm of the subclavian orifice. This technique is aimed at preventing type II endoleaks and perfusion of a dissected false lumen and is also recommended when the ipsilateral vertebral
artery is patent and dominant, when the ipsilateral internal mammary artery may be needed for future coronary revascularization, and when extensive coverage of intercostals contributing to spinal cord perfusion is anticipated. In patients who have absolute contraindications limiting their candidacy for open repair, extreme measures are possible to enable endovascular repair (Fig. 59.7). In each patient with the potential need for revascularization, transcranial Doppler angiography or CTA is recommended to confirm communication of the vertebral arteries at the basilar artery. Our preferred approach is to obtain a preoperative CTA of the head and neck with the performance of bypass in the setting of left vertebral artery dependence and anticipated stent graft coverage of the origin vessel from the aorta. Carotid to subclavian artery bypass is implemented in patients with a patent internal mammary artery conduit that is perfusing a coronary vessel and is combined with proximal subclavian artery ligation. With these considerations, endovascular therapy is emerging as an increasingly viable option for repair. However, further study and device design advancements are needed to define and address acceptable aortic diameters, landing zones, and treatment advantages for not only aneurysmal disease but also aortic dissection and transection.

THE HYBRID APPROACH

Hybrid techniques that incorporate open and endovascular repair techniques provide a promising approach to treatment in patients with complex thoracic aortic aneurysms with or without concomitant dissection. In patients with descending thoracic aortic aneurysms with proximal extension into the aortic arch, we have successfully performed open arch debranching and revascularization of branch vessels followed by TEVAR of the arch and descending thoracic aorta (Fig. 59.8). Such a technique has been demonstrated through a right anterior minithoracotomy at the third to fourth intercostal space, supporting further clinical advancement to provide patients with complex aortic pathologies the potential benefit of a minimally invasive approach to reconstruction. Additionally, our emerging treatment strategy for extent I and II aneurysms is to perform endovascular treatment of the proximal aneurysm extension, converting extent I or II disease into an extent III or IV aneurysm that is amenable to open surgical repair (Fig. 59.9). This approach provides the patient with a lower predicted mortality and paraplegia risk than that of an open extent I or II aneurysm repair. In patients with combined aortic arch and descending aorta involvement, endovascular treatment of the descending segment up to the subclavian artery enables open arch reconstruction through a median sternotomy, and reconstruction completion upon sewing the proximal graft to the descending
aortic stent and tapered aortic wall with felt reinforcement to the prosthetic graft (performed 2 days later at our institution) (Fig. 59.10). In addition to combined open and endovascular approaches, the simultaneous performance of TEVAR and EVAR for concomitant thoracic and abdominal aortic disease provides a feasible alternative to staged or hybrid repair.

**OUTCOMES**

An understanding of postoperative event chronology and preoperative risk stratification guides the selection of medical, open, or endovascular therapies for the treatment of descending thoracic and thoracoabdominal aortic aneurysms for patients across all risk stratifications.

Mortality following the open repair of thoracic aortic aneurysms has significantly decreased over the past 15 years with a current overall mortality of 18% to 21.4% (10% to 12% for intact aneurysms and 45% to 64% for ruptured aneurysms) and a 30-day mortality of 4.8%. Renal insufficiency, increasing age, symptomatic aneurysms, extent II aneurysms, FEV1 limitations, and the absence of CSF drainage are established predictors of increased operative mortality for open thoracic aortic aneurysm repair. Postoperative stroke is estimated to occur in 2% to 21% of patients following open repair and is dependent on the extent of the descending thoracic aorta replacement. In addition to stroke, paralysis and paraplegia are estimated to occur in 3% to 5% of patients following open repair. Additional predictors of paraplegia or paresis include total aortic clamp time, rupture, advanced age, proximal aortic aneurysm, renal dysfunction, and the application of distal
Section II: Adult Cardiac Surgery

Aortic perfusion and CSF drainage. Distal aortic perfusion and advanced techniques for revascularization target the prevention of postoperative renal dysfunction, with 13% of patients requiring temporary postoperative dialysis and 2% necessitating chronic renal replacement therapy. These primary postoperative outcomes remain the principal focus of surgical technique advancement and preoperative risk stratification for the open repair of descending thoracic and thoracoabdominal aortic aneurysms.

Adverse device-related postoperative events following TEVAR occur in 10% to 12% of patients in the initial 30-day postoperative period. The most common immediate intraoperative injury involves avulsion or tear of the external iliac and common femoral arteries upon sheath removal. Immediate arterial exposure and repair are performed with bypass from the common iliac to common femoral artery. Postoperative stroke is estimated to occur 2.5% to 5.8% of patients following TEVAR. Atheroemboli from the transverse aortic arch that are dislodged upon guide wire and device manipulation represent the principal etiology for stroke following TEVAR. Higher stroke rates are demonstrated in patients with a preoperative history of stroke undergoing proximal descending thoracic or complete descending thoracic aortic replacement. In addition to cerebral embolization, distal embolization following TEVAR results in acute mesenteric ischemia in 3% of patients.

Long-term complications include graft endoleak, continued aneurysm growth, metal fatigue, stent fracture and kinking, detachment, migration, perforation, and infection of the implanted device. Endoleaks are estimated to occur in 10% to 20% of patients and most commonly result from proximal attachment site failure, type IA. Endoleaks often warrant reintervention to prevent aneurysm enlargement and the associated increased risk of aortic rupture. For patients presenting with rupture post-TEVAR, complete endovascular relining is performed to provide proximal and distal landing zone extension.

Nationwide inpatient data from the United States demonstrate equivalent mortality, complication rates, and failure to rescue for TEVAR and open aortic repair with more frequent routine discharge for TEVAR. These data also suggested that TEVAR is an ideal alternative to open repair for ruptured thoracic aortic aneurysm in smaller hospitals where open expertise may be lacking. While clinical trials have suggested a reduction in 30-day cardiovascular morbidity and aneurysm-related mortality, superiority in neurologic and long-term outcome remains undefined. As our understanding of endovascular technology progresses, multidisciplinary collaborative decision-making is imperative to select the appropriate therapy for an individual patient based on underlying pathology, concomitant risk factors, and projected natural history of aneurysmal disease if medically treated.

**Follow-up Recommendations**

The potential for mid-term and long-term complication following descending thoracic and thoracoabdominal aneurysm
repair necessitates a commitment to dedicated surgical follow-up. The current standard for postoperative endovascular and open descending thoracic and thoracoabdominal aortic aneurysm repair involves physical examination and repeat imaging with CTA chest and chest radiography at 1, 6, and 12 months. The initial interval to postoperative evaluation may be modified as determined by the immediate in-hospital postoperative course.

CONCLUSIONS

The past two decades of open surgical technique refinement and the advent of endovascular technology have significantly advanced our capability to treat complex descending thoracic and thoracoabdominal aortic aneurysms in high-risk patients. We consider the factors most important in the determination of a safe operation to be careful assessment of the patient’s overall condition, especially noting chronic lung disease or coronary artery disease; planning of an operation that replaces in one setting the shortest possible segment of aorta; assessment before aortic cross-clamping of the likely complexity of the repair and planning for distal aortic perfusion if appropriate as well as CSF drainage; and rapid and precise anastomotic techniques that minimize cross-clamp times and allow precise management of hemodynamic stability.

SUGGESTED READINGS

This chapter on descending thoracic and thoracoabdominal aortic aneurysms by Drs. Stone and Kern has provided the comprehensive approach to descending thoracic aortic surgery at The University of Virginia. I would like to highlight a couple of comments. There is not a specialty that has changed as rapidly as this one has. The use of TEVAR for the majority of purely descending aortic aneurysms has revolutionized the field. One could argue about the issues with TEVAR but avoiding major thoracotomies certainly is worthwhile in the majority of patients. I think Dr. Kern has highlighted that the combination of TEVAR in addition to more limited repairs of the visceral vessels is an interesting one and probably will become a standard of practice. I also totally agree with the use of branch grafts for type 3 and 4 thoracoabdominal aneurysms where the visceral vessels are splayed to prevent recurrent aneurysms particularly in patients with Marfans Syndrome. I think that this field will continue to evolve. More improved branch grafts will allow percutaneous approaches to perhaps replace open surgery for even more complex situations.

ILK
INTRODUCTION

Since the first reported ascending aortic replacement by Cooley and DeBakey in 1956, operative technique refinement and critical care advancement have led to a significant improvement in survival for patients with ascending aortic aneurysmal disease. An improved understanding of distinct aortic pathologies and predisposing factors for aortic rupture and dissection has inspired a commitment to risk stratification and guidelines for elective surgical intervention. Improvements in diagnostic imaging and an increase in the incidental identification of aortic pathology on unrelated imaging have supported a significant increase in the incidence of thoracic aortic aneurysms to a projected rate of 10.4 cases per 100,000 person-years.

Isolated aneurysms of the ascending tubular aorta that taper to a normal diameter in the distal ascending aorta with a normal diameter at the sinuses of Valsalva are relatively uncommon and are estimated to occur in 13.5% of cases, with the majority of cases involving either the aortic annulus and the sinotubular junction or the aortic arch and branch vessels. Therefore, techniques for aortic valve conservation or replacement and branch vessel reconstruction are often needed in the operative reconstruction of the ascending aorta. The two surgical approaches to ascending aortic aneurysms involving the aortic root include aortic valve-sparing operations and composite replacement of the aortic valve and ascending aorta with a heart valve conduit. Aneurysms isolated to the ascending aorta without aortic root involvement are selectively approached by replacement of the aneurysmal segment with a composite ascending aortic graft.

In addition to anatomic principles for reconstruction, an understanding of distinct aortic pathologies and concomitant aortic valve disease is needed in the operative repair of ascending aortic aneurysms. Annuloaortic ectasia comprises a spectrum of aortic pathologies that involve dilation of the aortic annulus. This condition is predominately associated with an aneurysm of the aortic root; however, may occur independent of aneurysm formation and manifest as bicuspid or tricuspid aortic valve insufficiency or occur in patients with a subaortic ventricular septal defect. Importantly, ascending aortic aneurysms may also occur in the absence of annuloaortic ectasia. Dilation of the aortic sinuses results in aortic insufficiency when the aortic annulus and sinotubular junction dilate, resulting in poor leaflet apposition and central insufficiency. As the aortic root dilates, the aortic cusps become thinner, overstretched, and may develop stress fenestration in the commissural areas. This is an important consideration for the aortic valve repair at the time of ascending aortic aneurysm reconstruction.

The focus of this chapter is to review diagnostic standards and surgical principles for reconstruction in the treatment of aortic root and ascending aortic aneurysm with or without annuloaortic ectasia.

IMAGING

Aortic dimensions remain a principle consideration for intervention and reconstruction of the aortic valve, root, and proximal ascending aorta. Chest radiography may impart the initial diagnosis of ascending aortic aneurysm, with the findings of a convex contour to the right superior mediastinum or a loss of the retrosternal air space on lateral examination. Computed tomography (CT) and magnetic resonance imaging (MRI) provide detailed aortic wall assessment in addition to the capability for three-dimensional reconstruction, branch vessel evaluation, and aortic valve characterization. The reliability and reproducibility provided by these novel imaging techniques in coordination with transesophageal echocardiography (TEE) have largely replaced traditional aortography for the evaluation of the proximal ascending aorta, aortic valve, and aortic branch vessels, as aortography is limited in the determination of the presence of intraluminal hematoma. Aortography may be used selectively to localize the coronary ostia and to detect concomitant aortic regurgitation or coronary atherosclerotic disease. Measurements obtained with CT or MRI should be obtained perpendicular to the axis of blood flow and represent the external diameter of the aorta. Echocardiographic measurements are obtained in a similar plane; however, should be calculated for the internal aortic diameter. The dimension of the aortic root should be obtained at the segment of widest diameter, typically the mid-sinus level. In addition to dedicated aortic imaging, duplex carotid ultrasonography is indicated in patients older than 65 years of age or in younger patients with symptomatic presentation, physical exam findings, or additional atherosclerotic vascular disease consistent with an increased risk for cerebrovascular disease, as undetected carotid disease is a significant risk factor for stroke following ascending aortic replacement.

CT provides an estimated diagnostic accuracy of 92% for abnormalities of the thoracic aorta, with correct prediction of a requirement for circulatory arrest in 94% of patients. Electrocardiogram gating is required for ascending aortic disease to eliminate motion artifact that can resemble aortic dissection. In addition, CT provides a reliable method for the localization of calcification and evaluation of aortic valve morphology, function, and coronary artery anatomy. Axial CT introduces the potential for misinterpretation of the proximal aortic diameter, as ascending aortic elongation results in a C-shape of the aorta and resultant vertical plane orientation of the aortic valve.

MRI provides a comparable sensitivity and specificity for thoracic aortic pathology.
that may exceed that afforded by CT. The principle advantages to MRI include the identification of anatomic dissection variants and the enhanced diagnosis of branch vessel disease, aortic valve pathology, and left ventricular dysfunction in the absence of radiation or iodinated contrast. Clinical adoption has been limited by the time required for image acquisition, an inability to utilize gadolinium in patients with renal insufficiency, and a contraindication for use in patients with metallic implants including pacemakers.

Transthoracic echocardiography (TTE) provides an understanding of biventricular function while enabling visualization of the aortic valve and the proximal several centimeters of the ascending aorta to above the sinotubular junction. This capability supports the application of TTE in the evaluation of patients with proximal aortic aneurysms to determine the potential presence of concomitant valvular pathology or ventricular dysfunction. Importantly, TTE lacks reliability in mid-ascending aortic assessment. Thus, TTE is not recommended as the primary imaging modality for ascending aortic aneurysm surveillance. TTE may, however, be used to follow patients with aortic disease limited to the aortic root. TEE allows the assessment of biventricular function, segmental wall motion, and the potential for coronary artery ostial involvement in the setting of concomitant proximal aortic dissection. Intraoperative TEE provides a principle technique for the confirmation of preoperative diagnoses and the detection of pericardial or pleural effusions and aortic regurgitation. In addition, TEE enables the determination of the extent of aortic dissection and the identification of the intimal tear location, while providing characterization of aortic aneurysms and the confirmation of appropriate true lumen flow upon commencement of cardiopulmonary bypass.

**ETIOLOGY**

Aortic aneurysm formation is most commonly the result of medial degeneration, which is characterized by noninflammatory smooth cell loss, fragmentation of elastic fibers, and basophilic ground substance accumulation in the medial layer of the vessel wall. Debate persists regarding the pathogenesis of aortic medial degeneration and the resultant ascending aortic aneurysmal dilation; specifically, whether medial lesions are the result of primary connective tissue defects or arise secondary to hemodynamic forces, or both. Functional and structural asymmetry and decreased elastic performance of the aorta are proposed mechanisms for aneurysm formation, implicating advanced age, coronary artery disease, chronic smoking, and 17β-estradiol deficiency as primary predisposing factors to aneurysm formation. An increased incidence of ascending aortic aneurysm is also demonstrated in the setting of congenital or acquired aortic valve malformation, an aortic bicuspid or unicusp valve, and in hereditary connective tissue disorders including Marfan syndrome (fibrillin-1 gene mutation), Ehlers-Danlos syndrome type IV (deficiency in type III collagen), Loeys-Dietz syndrome, and familial thoracic aortic aneurysm and dissection. Medial degeneration may, therefore, be the result of damage and repair events in the aging aorta, abnormal postvalvular hemodynamics (excessive injury), and connective tissue disorders (impaired repair).

In addition to medial degeneration, established etiologies for thoracic aortic aneurysm formation include atherosclerosis, infection, inflammation, trauma, cardiopulmonary resuscitation, and chronic dissection. While atherosclerosis is considered a principal factor in the development of descending aortic aneurysms, dedicated study has demonstrated only a minor role for atherosclerosis in the pathogenesis of aneurysms of the ascending aorta. Inflammatory conditions include bacterial or fungal aortitis, Takayasu arteritis, and giant cell arteritis. Prior to improved diagnosis and the development of effective antibiotic therapies, syphilitic aortitis was the most common cause of ascending aortic aneurysmal enlargement, characterized by an obliterator end arteritis of the vasa vasorum. Risk factors associated with the development of thoracic aortic aneurysms include hypertension, smoking, and chronic obstructive pulmonary disease. Dedicated preoperative risk stratification and determination of underlying cardiopulmonary function, potential bleeding diatheses, and underlying connective tissue defects are critical in the operative planning for reconstruction of the ascending aorta.

**EPIDEMIOLOGY AND PATHOPHYSIOLOGY OF BICUSPID AORTIC VALVE DISEASE**

Bicuspid aortic valves (BAVs) represent the most common congenital heart anomaly, occurring in 0.9% to 2% of the population. Patients with a BAV demonstrate significantly increased wall stress, accounting for the increased propensity for aortic dilation, rupture, and dissection in this patient population. In addition to increased wall stress, patients with BAV disease have larger dimensions at the aortic annulus, sinus of Valsalva, the sinotubular junction, and the ascending aorta irrespective of the valve hemodynamic function. Microscopic studies and gene expression profiles for patients with BAV and concomitant ascending aortic aneurysm have demonstrated that the media of the aorta above the BAV is consistently abnormal and independent of both inflammatory response and the hemodynamic function of the valve. These data demonstrate that aortic root dilation is a morphological correlate of intrinsic structural aortic abnormalities in patients with BAV disease.

In retrospective study of patients with BAV disease, the aortic valve morphology was found not to be predictive of the pathologic anatomy of the thoracic aorta; however, patients with predominant aortic insufficiency demonstrated the highest incidence of aortic root dilation. In patients with a BAV and an absence of baseline aortic aneurysm, a 16-year mean follow-up (6,530 patient-years) has demonstrated an estimated age-adjusted relative risk of 86.2 for aneurysm formation in comparison to the general population. In patients with BAVs, aortic dissection incidences for patients 50 years and older at baseline was 17.4 per 10,000 patient-years and increased to 44.9 per 10,000 patient-years in individuals with concomitant aortic aneurysm. These epidemiologic data support a research commitment to risk-stratification modeling and selective preventative reconstruction in patients with BAV disease.

**ANATOMY OF THE AORTIC ROOT**

The aortic valve is described as the aortic root, given the anatomic and functional relationships of the aortic cusps and surrounding structures. The aortic root is defined by four distinct anatomic components: the aortic annulus, the aortic cusps, the aortic sinuses or sinuses of Valsalva, and the sinotubular junction. The aortic annulus is the attachment between the aortic root and the left ventricle. The aortic root is attached to the ventricular myocardium throughout 45% of its circumference and to the anterior leaflet of the mitral valve and the membranous septum in the remaining 55%. The aortic annulus forms a superior border to the three triangular structures of the left ventricular outflow
tract. The triangle below the right and left cusps consists of ventricular muscle and is rarely affected by connective tissue disorders of the aortic root. The additional two triangles are fibrous and flatten to acquire a broader base in patients with a dilated aortic annulus. The semilunar aortic cusps have a base and free margin extending from commissure to commissure. The sinotubular junction refers to the ridge above the commissures and is functionally important for the aortic root as it suspends the aortic cusps. Dilation at the sinotubular junction moves the free margins of the aortic cusps away from one another to result in central aortic insufficiency with ineffective coaptation. The aortic sinuses are anatomically described as the arterial walls contained within the aortic annulus and sinotubular junction (Fig. 60.1). Isolated dilation of the sinuses has no effect on valvular competence. The aortic sinuses maintain coronary artery blood flow during the cardiac cycle while maintaining eddies and currents to facilitate closure of the aortic cusps during diastole.

The aortic root contains a proportionally high content of elastin with a resultant compliance that diminishes with anatomic progression into the aortic arch and descending aorta. Systolic expansion of the ascending aorta represents the transfer of a portion of left ventricular kinetic energy into potential energy within the aortic wall. Diastolic recoil transfers this potential energy into kinetic energy for resultant forward flow. The transverse diameter of the aortic annulus is approximately 15% to 20% larger than the sinotubular junction diameter in young patients. The aging process results in a loss of elastic fibers within the arterial wall and the aortic root becomes less compliant, an effect that is associated with the presence of diastolic left ventricular dysfunction. An understanding of these dynamic physiologic and diseasespecific changes in the ascending aorta will guide the approach to reconstruction.

**PRESENTATION**

Acute rupture of the aneurysmal ascending aorta is manifested as severe anterior chest pain with sudden-onset of congestive symptoms resulting from associated cardiac tamponade. Patients with acute rupture or dissection necessitate emergent resuscitation and operative intervention. In the absence of rupture or dissection, ascending aortic aneurysms are primarily identified on unrelated imaging or during surveillance of associated anomalies. The predominant symptoms of aneurysmal enlargement result from distal arch involvement and impingement on nearby structures and may manifest as chest pain, back pain, dyspnea, hoarseness, or transient neurologic deficit. Ascending aortic enlargement may result in airway compression or superior vena cava obstruction. Heart failure symptoms may arise in the setting of aortic valve regurgitation secondary to aortic root or ascending aortic dilation. On physical examination, a widened pulse pressure or diastolic murmur signifying aortic insufficiency may be present in the setting of sinotubular ridge or aortic root enlargement. BAV disease may manifest as asymptomatic stenosis or regurgitation of the valve on physical examination.

**INDICATIONS FOR INTERVENTION**

A significant research commitment to define intervention criteria for the ascending aorta and aortic valve has provided disease-specific thresholds for operative reconstruction to prevent the life-threatening risks of rupture and acute dissection. The following recommendations are provided as evidence-based guidelines supported by the American Heart Association consensus statement:

- **Surgical repair** is recommended for asymptomatic patients with an acceptable physiologic status and a degenerative ascending aortic aneurysm, chronic aortic dissection, intramural hematoma, penetrating atherosclerotic ulcer, mycotic aneurysm, or pseudoaneurysm in the setting of an ascending aortic or aortic sinus diameter of 5.5 cm or greater.

- **Elective reconstruction** is recommended for patients with disorders of the ascending aorta (Marfan syndrome, Ehlers–Danlos syndrome, Loey–Dietz syndrome, Turner syndrome, BAV, or thoracic aortic aneurysm and dissection) at 4 to 5 cm to avoid acute dissection or rupture.

- **Operation should be considered for patients with a growth rate of 0.5 cm per year or greater in an aorta that is <5.5 cm in diameter.**

- **Concomitant repair of the aortic root or replacement of the ascending aorta is recommended for patients undergoing aortic valve repair or replacement with an ascending aortic or aortic root diameter of >4.5 cm.**

Ascending aortic replacement alone is performed in patients with normal sinuses of Valsalva and a nonaneurysmal sinotubular junction. Individuals with concomitant aortic valve disease should undergo separate valve and aortic replacements. Patients with Loey–Dietz syndrome and an internal aortic diameter of 4.2 cm by echocardiography or a 4.6-cm external aortic diameter by CT or MRI are considered candidates for operative repair. When contemplating pregnancy, women with

---

**Fig. 60.1.** Defined terminology for the aortic valve and aortic root components. (Adapted with permissions: Sievers et al. Eur J Cardiothoracic Surg 2012, 41(3):478-482.)
Marfan syndrome should be considered for aortic replacement when the aortic diameter exceeds 4.0 cm in diameter. In addition to this guideline, patients with Marfan syndrome or a BAV are recommended to undergo ascending aortic replacement when the maximal cross-sectional area (cm$^2$) of the ascending aorta or root divided by height (m) is $>$ 10. This guideline is applied to patients with Marfan syndrome to account for the 15% risk of aortic dissection at a diameter $<$ 5 cm. In addition, sinus conservation is not recommended in Marfan patients secondary to the requirement for reoperation.

Patients without significant aortic root dilation, elderly patients, or young patients with minimal dilation should be considered for separate valve and ascending aortic replacement in the presence of aortic valve disease. In the setting of concomitant aortic root and sinuses of Valsalva dilation, excision of the sinuses in combination with a modified David reimplantation operation should be performed. Aortic root reconstruction with reimplantation of the native valve provides an alternative to alloprosthetic composite replacement. With this technique, a level of coaptation within the tube graft is essential to achieve valve competence. If this operation is not considered technically feasible, a Bentall procedure is performed and involves a composite valve graft with mechanical or biologic components. This technique provides the capability to replace both the aortic root and ascending aorta in selected patients. In the setting of aortic regurgitation secondary to BAV disease, repair of the aortic valve is recommended in the absence of severe fibrosis or calcification and may necessitate root remodeling or tailoring of the sinotubular junction. Aortic allografts with coronary reimplantation may be considered in patients with endocarditis, women anticipating pregnancy, and young adults with active lifestyles or contraindications to anticoagulation. Pulmonary allografts are considered a congenital operation due to the proposed growth potential of the autograft.

While these guidelines represent accepted criteria for intervention, recent research efforts have established that aortic valve replacement alone may be sufficient in patients without connective tissue disorders with moderate poststenotic ascending aorta dilatation (50 to 59 mm), reserving aortic replacement for patients with a long-life expectancy. These data demonstrate that further long-term outcome research is needed in the evaluation of concomitant aortic valve and ascending aortic aneurysmal disease.

The selection of an appropriate valve substitute in patients with aortic valve stenosis requiring valve replacement should be determined by comorbid disease, risk of complications associated with anticoagulation and reoperation, and the projected life expectancy. In addition to aortic root replacement for valvular regurgitation, composite valve graft conduits provide the capability for the treatment of the stenotic aortic valve and ascending aorta.

Coronary artery bypass grafting may be performed at the time of ascending aortic reconstruction and is indicated in 25% of patients. In addition, patients with moderate-to-severe mitral regurgitation should undergo mitral valve replacement or repair concurrent with aortic replacement.

**OPERATIVE PREPARATION AND INITIAL EXPOSURE**

Central venous access is obtained through the internal jugular vein and hemodynamic pressure monitoring is placed into the radial artery. Pulmonary artery catheter monitoring is recommended to follow intraoperative filling pressures and cardiac output. Large-bore peripheral intravenous access is achieved for intraoperative resuscitation. In preparation for potential circulatory arrest, continuous pressure monitoring through the femoral artery is recommended as the radial artery waveform may be dampened. General endotracheal anesthesia is initiated and maintained through a single-lumen endotracheal tube. A nasopharyngeal temperature probe is recommended to monitor cooling and rewarming.

**Neurologic Protection and Cardiopulmonary Bypass**

A collaborative commitment to efficient and effective communication is essential between the anesthesiology and operative teams to minimize the duration of circulatory arrest and the potential for neurologic injury. Cardiopulmonary bypass and selective hypothermia are required for operations that involve replacement of the aortic arch. Cerebral protection may be achieved by profound hypothermia alone, direct antegrade perfusion of one or more brachiocephalic arteries, or retrograde perfusion with cold oxygenated blood infused into the superior vena cava during the arrest period. Following median sternotomy, pericardiectomy, and heparinization, the ascending aorta is cannulated in the region to be excised. Epiarterial ultrasound may aid cannulation in the setting of aortic calcification. Alternative to the ascending aorta, the axillary and femoral arteries provide potential sites for the arterial inflow of the cardiopulmonary bypass circuit. If the arch is involved and circulatory arrest is indicated, the right axillary artery, femoral artery, or aneurysmal aorta is cannulated. The right axillary artery enables a single arterial cannulation strategy for the entire operation, permitting selective antegrade cerebral perfusion.

Venous cannulation is achieved by a single two-stage cannula or bicaval cannulation strategy, if retrograde cerebral perfusion is to be performed (Fig. 60.2). A temporary period of retrograde perfusion is preferred when sustained cerebral perfusion is not planned to flush gaseous and embolic debris prior to the initiation of cardiopulmonary bypass. To support a period of retrograde cerebral perfusion, a connection is established between the arterial and superior vena cava cannulae. This connection is clamped during cardiopulmonary bypass and opened with alternative clamping of the arterial inflow and caval cannulae to provide retrograde cerebral perfusion.

Cardiopulmonary bypass is initiated upon achievement of an activated clotting time $>$ 480 seconds. A retrograde cardioplegia cannula is directed into the coronary sinus and a sump drain is placed into the left ventricle through the right superior pulmonary vein across the mitral valve. Cardiopulmonary bypass flows are increased and moderate systemic hypothermia (28°C) and hemodilution (Hct: 15% to 25%) are achieved. Cold blood hyperkalemic cardioplegia (4°C) is administered antegrade into the aortic root (300 ml/min) for 2 minutes followed by 2 minutes of retrograde flow (200 ml/min). Following the initiation of cooling, the ventricle is examined for distention to confirm appropriate sump placement. Cooling is advanced until the achievement of electroencephalogram (EEG) silence and the head is packed in ice. Proximal aortic reconstruction may begin during cooling following the administration of cardioplegia solution into the aorta proximal to a preplaced aortic cross-clamp. The patient is cooled for an additional 5 minutes following EEG silence to a core temperature that is typically below 18°C. Whole-body cardiopulmonary bypass is then discontinued and retrograde cerebral perfusion is initiated with the placement of a superior vena cava tourniquet. Retrograde cerebral perfusion should be maintained at a perfusion pressure of 20 to 40 mmHg at mild or profound hypothermic temperatures. Alternatively, antegrade perfusion techniques should maintain a perfusion pressure of 50 to 80 mmHg instituted through direct
cannulation of the brachiocephalic arteries, side-graft anastomosis to the axillary artery, or direct cannulation of the aortic graft.

The patient is transitioned to a Trendelenburg position. The aortotomy is then performed and cardioplegia solution is administered into the coronary ostia, and is to be repeated every 10 minutes into the ostia, coronary sinus, or both. The aneurysmal aorta is then excised through an incision down the lesser curvature with the preservation of all uninvolved vessels. When retrograde cerebral perfusion is utilized, a transition to whole body cardiopulmonary bypass is performed following completion of the distal anastomosis. If utilizing the ascending aorta as the site of initial arterial access, a sidearm graft may provide antegrade cerebral perfusion following completion of the distal anastomosis. If utilizing the ascending aorta as the site of initial anastomosis, deairing occurs when placed into the proximal unclamped graft as flow is slowly resumed. Following completion of the proximal anastomosis, arterial access is achieved through a catheter placed into the graft. The patient is then placed in deep Trendelenburg position, flows from the bypass circuit are reduced, and the core temperature is maintained. Sump suction allows decompression of the heart and flow from the bypass circuit is resumed. Rewarming is initiated and directed to achieve a difference in perfusate and core body temperature <10°C until a core body temperature of 27°C is achieved, upon which a perfusate temperature of 37°C is maintained. TEE is performed to confirm the absence of air bubbles prior to removal of the deairing needle. The retrograde cardioplegia cannula and sump drain are removed and the patient is weaned from cardiopulmonary bypass.

Independent risk factors for stroke in ascending aortic operations requiring hypothermic circulatory arrest include age >60 years, emergency operation, new preoperative neurologic symptoms, presence of clot or atheroma, concomitant cardiac procedures, and total cerebral protection time. Permanent neurologic injury is most commonly the result of thromboembolic event and is independent of the method of intraoperative cerebral protection. In retrospective review of ascending aortic-hemiarch replacement, comparable rates of permanent neurologic dysfunction were demonstrated between patients receiving deep hypothermic circulatory arrest (12.5%) or antegrade selective cerebral perfusion (7.6%; P = 0.075). The incidence of transient neurologic dysfunction increases linearly in relation to patient age and the duration of hypothermic circulatory arrest, with adequate cerebral protection afforded if the arrest period is kept < 60 minutes.

**Aortic Valve-Sparing Operations**

**Aortic Root Remodeling**

The David technique for aortic root remodeling and aortic valve-sparing ascending aortic reconstruction is described in a dedicated chapter of this text. In brief, aortic root remodeling is achieved through excision of the three aortic sinuses, preserving a remnant of arterial wall cusp attached to the aortic annulus and coronary artery ostia. A Dacron fabric strip is applied to the fibrous components of the left ventricular outflow tract and the commissures of the aortic valve are resuspended into the tailored graft. The neoaortic sinuses are sutured to the aortic annulus with a continuous 4-0 polypropylene suture and the coronary arteries are then re-implanted. The Cabrol technique involves the end-to-end anastomoses of a single 6- to 8-mm Dacron graft to the coronary arteries with subsequent side-to-side anastomosis of the graft to the reconstructed aorta in the setting of low-lying coronary ostia or prior scar. The distal aorta is clamped and cardioplegia solution is injected into the reconstructed aortic root to confirm aortic valve competence. The distal aortic graft is sutured to the ascending aorta to complete aortic continuity. In patients with a connective tissue disorder, the aortic annulus may dilate postreconstruction. It is, therefore, preferred to perform aortic valve reimplantation in patients with aortic root aneurysm with or without annuloaortic ectasia.

**Reimplantation of the Aortic Valve**

Reimplantation of the aortic valve into the reconstructed aortic root is similarly achieved through the excision of the three aortic sinuses. A triangular segment of the graft is excised that corresponds to the commissure between the right and left cusps. Horizontal mattress 4-0 polyester sutures are passed inside-to-out on the left ventricular outflow tract below the aortic annulus. These sutures are placed in the proximal intimal aorta. These preplaced sutures are then passed inside-out through the aortic graft. The aortic valve is placed within the graft and the left ventricular outflow tract sutures are tied on the outside. The distal end of the graft is cut to a length of 5 to 6 cm and the three commissures of the graft are pulled gently upward. The commissures are secured to the graft with transfixing 4-0 polypropylene sutures from the inside-to-out and left untied. The levels of coaptation and commissure alignment are evaluated with gentle traction applied to each of the sutures to ensure appropriate geometry and optimal function of the reconstructed aortic annulus.

The three commissural sutures are tied on the outside of the graft, and the remaining aortic sinuses and aortic
annulus are secured against the graft. The left and right coronary arteries are reimplanted into their corresponding neoaortic sinuses and hemostasis is confirmed. The distal end of the graft is sutured to the ascending aorta with a running 4-0 polypropylene suture. Neoaortic sinuses, as described in the modified David technique, provide improved accommodation to the resultant mechanical stress imposed on the aortic valve leaflets within a straight tubular graft.

**Repair of Aortic Cusp Prolapse**

Aortic cusp elongation at the free margin results in valvular prolapse. This condition is corrected by central plication of the cusp. The nodule of Aranti is folded to the aortic side and plicated with a 5-0 polypropylene suture. Additional sutures may be applied separate from the initial site of plication and toward the commissures of the prolapsing cusp to further shorten the free margin. Plication elevates the level of cusp coaptation and corrects excessive motion.

In addition to plication, the free margin may also be reinforced by weaving a 6-0 expanded polytetrafluoroethylene suture from commissure to commissure and anchoring the suture on the outside of the aorta or graft to correct fenestration in a commissural area or excessive free margin elongation.

**Aortic Root Replacement**

Aortic root aneurysms with damaged aortic cusps necessitate replacement of the ascending aorta with a conduit containing a valve. Options for ascending aorta and aortic valve replacement include mechanical valve containing Dacron grafts, biologic or bioprosthetic aortic root prostheses, and pulmonary autografts or aortic valve homografts. The Bentall procedure incorporates a valved-graft conduit for reconstruction and replacement of the aortic valve and is our preferred approach to the treatment of both an irreparable aortic valve or the reconstruction of the aortic root in a patient with concomitant acute aortic dissection and annuloaortic ectasia.

Following intraoperative evaluation of the aortic valve and confirmation of irreparable cusp damage, the aortic valve is excised and the annulus debrided of all calcium, scar, and any abnormality. Each sinus is excised with a remnant arterial cusp attached to the aortic annulus, and a 5-mm rim is preserved around each coronary artery. Mobilization of the coronary arteries should be performed to provide reimplantation without tension.

The selected replacement valve is secured to the aortic annulus with inverted horizontal mattress sutures of 2-0 polyester sutures with pledgets. Simple interrupted sutures may be applied in patients with a small aortic annulus size to body surface area to allow implantation of a larger valve. Round openings are fashioned in the aortic graft to allow reimplantation of the respective coronary arteries without tension or kinking. Particular attention is directed to the positioning of the right coronary artery, as right ventricular motion may induce kinking. The size of each coronary ostia should not exceed twice the value of the coronary artery diameter to reduce the risk of coronary button aneurysm formation, particularly in patients with Marfan syndrome. A continuous 5-0 polypropylene suture is utilized to secure the coronary buttons to the respective coronary ostia. Teflon felt is not recommended. 4-0 polypropylene suture is applied to fashion the distal graft-aorta anastomosis. The length of the graft should not exceed 6 to 7 cm.

Application of a stented bioprosthetic valve is achieved with concomitant graft and bioprosthesis fixation to the aortic annulus with multiple interrupted 2-0 polyester sutures on the ventricular side of the annulus. If concern is present for bioprosthetic valve failure, the valve may be sutured to the graft prior to fixation to the aortic annulus. This is our preference.

**Isolated Ascending Aorta Replacement**

Following the commencement of cardiopulmonary bypass, the aorta is cross-clamped proximal to the innominate artery. The heart is arrested with cold blood cardioplegia and the aorta is transected below the clamp, preserving a sufficient cold cardioplegia and the aorta is transected below the clamp, preserving a sufficient aortic cuff for the subsequent distal anastomosis. The proximal aorta is then transected superior to commissures. An appropriately sized Dacron graft is chosen and distally sewn to the aortic cuff with a 3-0 or 4-0 polypropylene suture. An aortic valve replacement may be performed at this time in the setting of a normal diameter aortic root. The graft is then fashioned to the desired length and the proximal anastomosis is completed with a continuous 3-0 or 4-0 polypropylene suture (Fig. 60.3). A catheter is inserted into the graft following completion of the proximal anastomosis to deair the graft. The patient is subsequently weaned from cardiopulmonary bypass.

**Open Distal Anastomosis Technique**

In the setting of significant atherosclerotic burden at the distal ascending aorta or concomitant aneurysmal aortic arch disease, an open distal anastomosis under circulatory arrest may be necessitated. Arterial inflow for cardiopulmonary bypass is maintained through the right axillary artery, femoral artery, or ascending aneurysmal aorta. The presented setup for retrograde cerebral perfusion and cardiopulmonary bypass is assumed. The patient is cooled to achieve EEG silence and a nasopharyngeal temperature of 15°C. Trendelenburg positioning is assumed and approximately one-fourth of the patient’s blood volume is drained into the venous reservoir. The aorta is transected distal to the furthest extent of aneurysmal disease. Beveling of the graft may be necessitated in the setting of hemi-arch involvement to preserve native branch vessels. Involvement of the brachiocephalic vessels supports aortic transection distal to the left subclavian artery. The distal anastomosis is completed as previously described. An ellipse of the graft may be removed to accommodate reimplantation of the brachiocephalic vessels, completed with a felt-enforced 3-0 polypropylene running suture. Selective antegrade cerebral perfusion or slow retrograde cerebral perfusion through the superior vena cava is maintained during the brachiocephalic
anastomosis to avoid embolization of air or debris. If selective antegrade perfusion is utilized throughout systemic circulatory arrest, a period of retrograde perfusion is recommended to similarly protect against induced embolic injury. Upon completion of the distal and potential brachiocephalic anastomoses, cardiopulmonary bypass is initiated through a preplaced 8-mm side-arm graft, direct cannulation of the ascending aortic graft, or initial axillary artery cannula utilized for continuous antegrade cerebral perfusion. The avoidance of femoral artery cannulation for resumption of bypass limits that potential for embolic injury. Additional cardiac procedures may now be performed as indicated for coronary revascularization or concomitant mitral valve disease. The proximal anastomosis is completed to the remnant proximal aorta above the sinotubular ridge. Deairing of the graft is performed through the direct insertion of a catheter into the graft and the patient is subsequently weaned from cardiopulmonary bypass.

OUTCOMES

Significant advancements in surgical technique have supported a reduction in operative mortality to approximately 1.2% to 3.7% for elective ascending aortic aneurysm resection, independent of etiology. Malperfusion resulting from acute aortic dissection is the primary determinant of early mortality for proximal aortic operations, supporting preventative reconstruction in the setting of at-risk aneurysmal disease. Predictors of mortality following elective ascending aortic reconstruction include: New York Heart Association class (III or IV), advanced age, preoperative dissection, reoperation status, prolonged cardiopulmonary bypass, and the requirement for concomitant coronary artery bypass grafting or arch reconstruction. Patients with connective tissue disorders such as Marfan syndrome demonstrate a low operative risk with an associated 30-day morality of 1.5% with prophylactic surgical replacement of the ascending aorta, supporting elective intervention to prevent aortic catastrophe. Aortic root replacement and distal aortic reconstruction may be approached with low operative mortality independent of the type of operation. As our understanding of valvular and aortic pathologies evolves, a commitment to patient-specific treatment promises to improve outcomes for patients with diverse pathologies and across all risk stratifications with ascending aortic aneurysmal disease.

Bleeding complications in the early postoperative period present the most common threat to immediate survival with indication for re-exploration in 4.5% to 17% of patients, particularly in the setting of prolonged cardiopulmonary bypass times and concomitant cardiac or aortic operations. As described, neurologic dysfunction represents a principle complication following aortic root and ascending aortic reconstruction. In retrospective review, transient neurologic dysfunction is noted in 9.8% of patients following ascending aortic and proximal aortic arch reconstruction, with a demonstrated increased incidence of permanent neurologic deficit, hospital stay, and a significantly impaired quality of life. Debate persists regarding the optimal strategy for cerebral protection. Deep hypothermic circulatory arrest provides a principle method for cerebral preservation, with a demonstrated effectiveness as the sole protection strategy. Retrograde cerebral perfusion has an established efficacy in the reduction of postoperative stroke that is most pronounced in patients receiving prolonged hypothermic circulatory arrest. The duration of deep hypothermic circulatory arrest is the primary predictor of transient neurologic dysfunction, regardless of the application of retrograde cerebral perfusion. These data support further research commitment to patient-specific strategies for preventative cerebral protection during aortic root and ascending aortic reconstruction.

The described David procedure affords a reliable technique for the reconstruction of the aortic root, with an estimated 4.8% of patients demonstrating relevant valve dysfunction. A 3-year survival of 95% and 89% is achieved with the David procedure for aortic root and ascending aortic aneurysmal disease, respectively. In patients with ascending aortic aneurysm and concomitant dilatation at the sinotubular junction, reduction in the sinotubular junction may be an alternative technique for the treatment of aortic insufficiency in the setting of normal aortic cusps with a 5-year freedom from aortic insufficiency of 91%. Long-term follow-up data at 10-years following the David reimplantation technique have demonstrated a 92% survival with a freedom from moderate or severe aortic insufficiency of 94%. From this study, 90% of patients achieved a New York Heart Association functional class I with the remaining 10% demonstrating class II presentation at 10 years.

In review of the presented Bentall procedure, mechanical and biologic valve conduits demonstrate comparable long-term survival supporting patient-specific selection. The presence of clot or atheroma is an independent predictor of both short- and long-term outcome following the Bentall procedure, with an associated eightfold increase in in-hospital mortality. Patients under the age of 50 years may select a mechanical aortic valve for the Bentall procedure, with consideration for the low incidence of long-term valve-related complication. Alternatively, patients above the age of 50 years may benefit from a biologic aortic valve with comparable long-term outcomes and the requirement for only a valve replacement rather than replacement of the composite root should postoperative valve dysfunction arise. Review of experience with a totally biological composite stentless aortic valve conduit implanted utilizing the Bentall technique has demonstrated a freedom from valve-conduit-related mortality of 88% over a 7-year follow-up period. In this study, >50% of patients achieved a New York Heart classification of I or II, with no reported valved conduit failures.

Reoperation following ascending aorta reconstruction is associated with an estimated mortality of 3% following elective intervention, with an incidence of 38% for emergent reoperations. In addition to indications for reoperation, distal thrombomelitis, prosthetic valve endocarditis, and aortic graft infection represent principle considerations in the long-term follow-up of patients following ascending aortic reconstruction.

CONCLUSIONS

The presented techniques for aortic root and ascending aortic reconstruction for aneurysmal disease provide a promising hope for cure for many with diverse aortic pathologies. Outcomes following ascending aortic and aortic root reconstruction provide reliable long-term survival and quality of life with the achievement of acute aortic event prevention. As we continue to advance our understanding of aortic disease, operative technique refinement will be founded on patient-specific reconstruction and an enhanced understanding of aortic fluid dynamics and disease-specific aneurysmal change.

ACKNOWLEDGMENT

The authors wish to acknowledge Dr. Tyrone E. David for his contributions within prior editions of this text regarding annuloaortic ectasia and the David re-implantation technique. In addition, Dr. Joseph S. Coselli and Dr. Scott A. LeMaire are recognized for authorship and contributions regarding aortic arch aneurysms within prior editions of this text. Their contributions provided a foundation for the presented discussions describing each respective technique.
Chapter 60: Ascending Aortic Aneurysms

SUGGESTED READINGS

ADDITIONAL CITATIONS

Posten et al.
This chapter is a complete and comprehensive summary of the issue of surgery for ascending aortic aneurysms. As noted by the authors, various types of aneurysms affect components of the aortic root and each type should be addressed based on its underlying pathologic and physiologic characteristics.

As greater information has been obtained about the relative risk of rupture or dissection for various sizes of aortic aneurysms, guidelines have been developed to suggest when surgical therapy should be undertaken. It is important to note that the guidelines are not absolute, but that the rate of progression of dilation may also be considered a primary indicator for operative therapy independent of aortic aneurysm size. It is particularly of concern that patients with Loeys-Dietz Syndrome have a high risk of aortic aneurysm rupture even at relatively smaller sizes. Therefore, the guidelines would suggest that operative intervention is appropriate in patients with Loeys-Dietz syndrome when the aortic root is only 3.5 to 4 cm in diameter. In children when the aortic root exceeds 3 cm in diameter, in a patient with Loeys-Dietz Syndrome, operative intervention should be undertaken. If these patients attain adulthood, as aortic root diameter > 4 cm is generally considered an indication for surgery. In addition, extensive searching for aneurysms in the rest of the vascular tree is recommended in this particular genetic abnormality.

The issue of root dilation in patients with conotruncal defects is a significant one. Most patients with tetralogy of Fallot will have some evidence of aortic root dilation over time, especially of the aorta above the sinotubular junction. In addition, patients who have had repair of hypoplastic left heart syndrome with patch augmentation of the aortic arch and patients with transposition of the great arteries who have had an arterial switch operation commonly have root dilation and aortic arch dilation. While it has been shown that the aortic roots dilate in patients with transposition after the arterial switch, at the present time there is a relatively low incidence of aortic insufficiency and dissection and rupture have not been reported. Nevertheless, these patients will need to be followed carefully as they age since progressive dilation may require intervention in some patients, preferably with preservation of aortic valve function with a David-type valve sparing root replacement.

The surgical techniques for aortic aneurysm resection and root replacement have been well described by the authors of this chapter. It is important in the David operation of valve sparing root replacement when the aortic leaflets are reimplemented into the Dacron graft to place interrupted sutures at the base of the sinuses and commissures of the aortic root through the graft, but not circumferentially. Placing mattress sutures circumferentially around the annulus and tying them to the graft can cause narrowing of the proximal graft anastomosis due to a Purse string effect and can create left ventricular outflow tract obstruction. The majority of the hemostasis in the David operation involves suturing the aortic wall containing the aortic commissures and leaflets inside the graft. Thus, the proximal suture line can be simply tacked with a few interrupted sutures to prevent migrations, but hemostasis is not critical at this site since the graft is actually outside the aortic root.
INTRODUCTION

The aorta is divided into two major segments: the proximal aorta and the distal aorta. The proximal aorta includes the aortic root, ascending aorta, and transverse aortic arch. The transverse aortic arch is anatomically defined as the segment of aorta that includes the origins of the brachiocephalic vessels: the innominate artery, left common carotid artery (LCCA), and left subclavian artery (LSCA) (Fig. 61.1). The descending thoracic aorta starts distal to the origin of the LSCA and continues to the diaphragmatic hiatus, where it joins the abdominal aorta. Criado and colleagues, as well as Ishimaru and associates, have each separately mapped the arch into five anatomic zones for endovascular procedures (Fig. 61.1). This schema has mostly been used to describe proximal landing zones for disease that involves the descending thoracic aorta, but it is becoming increasingly valuable in describing combined open and endovascular (hybrid) approaches to aortic arch repair.

Aortic aneurysm can occur anywhere along the aorta and is defined as a permanent, localized dilation that is at least 50% greater than the normal diameter at that anatomic level. Most arch aneurysms are contiguous with an aneurysm involving the adjacent ascending or descending thoracic aorta. Isolated arch aneurysms are less common and generally appear as localized, saccular outpouchings.

Aneurysms of the aortic arch can be caused by a variety of diseases but most commonly result from medial degenerative disease and chronic aortic dissection. Additional causative factors include genetically triggered disorders (such as Marfan, Ehlers-Danlos, and Loey-Dietz syndromes), infection, trauma, and aortopathy related to having a bicuspid aortic valve.

Surgical repair of the aortic arch remains one of the most difficult challenges in cardiothoracic surgery. This is largely because one must interrupt the natural flow of blood to both the brain and downstream organs. The first successful graft repair of a transverse aortic arch aneurysm was reported in 1957 by DeBakey, Crawford, Cooley, and Morris, who used an early form of antegrade cerebral perfusion (ACP).

For many years, aortic arch surgery was associated with high mortality and neurologic morbidity. Recently, dramatic advances in aortic arch surgery have improved outcomes. These advances include new or refined strategies for cerebral protection and arterial perfusion, revised reattachment strategies for the brachiocephalic vessels, and new options for treating extensive aortic disease. In addition, endovascular techniques that have recently revolutionized distal aortic repair are increasingly being applied to the aortic arch.

DIAGNOSIS AND PREOPERATIVE ASSESSMENT

Although most aneurysms are asymptomatic and are incidentally discovered through imaging studies performed for other reasons, some patients with aortic arch aneurysm present with symptoms, which are often related to the aneurysm's proximity to nearby structures. For example, patients may present with hoarseness because of stretching of the left recurrent laryngeal nerve. Patients may have dysphagia from esophageal compression, respiratory symptoms due to airway compression, or edema of the upper body from superior vena caval compression. Other problems that can arise from aneurysms involving the aortic arch and the adjacent segments include thromboembolic events such as stroke, and aortic valve regurgitation from associated root enlargement. Chest wall compression can cause chronic dull or aching retrosternal or mid-scaphular pain. New severe pain usually indicates aneurysm rupture or acute dissection. Arch aneurysms can rupture into the pleural cavity (usually on the left), mediastinum, esophagus, or tracheobronchial tree.

Dissection involving the arch can cause signs and symptoms of cerebral malperfusion, including syncope and neurologic deficits.

Whereas a chest radiograph may reveal a dilated aorta, definitive evaluation of an aortic arch aneurysm generally requires computed tomography or magnetic resonance imaging. These modalities can image the entire aorta and elucidate its relationship to surrounding structures and brachiocephalic vessels. Echocardiography is generally not useful in evaluating the aortic arch because of acoustic shadowing from the trachea. However, many patients with arch aneurysms have associated ascending aortic, valvular, or cardiac disease; therefore, echocardiography is useful for both planning the operation and assessing risk. Similarly, angiography is generally not used on a routine basis, but it is usually performed in patients who are already undergoing left heart catheterization to evaluate coronary artery disease.

Because there is a well-known association between aneurysmal aortic disease and carotid artery stenosis, it is useful to perform a screening ultrasound of the carotid arteries on patients with arch aneurysms. The risk of stroke is significant during aortic arch repair, and cannulation strategies may need to be revised in an individual patient on the basis of preoperative findings. Additional investigation may include pulmonary function testing, cardiac stress testing, nuclear imaging, and coronary catheterization.

INDICATIONS

Aortic aneurysms are repaired in order to prevent dissection, rupture, and death. Examining the natural history of aortic aneurysms has helped clarify the risk of these catastrophic complications. Elefteriades and his group at Yale found that aortic diameter is a strong predictor of rupture or dissection, especially when a "hinge point" is reached—a diameter of 6.0 cm in the
Landing Zone Classifications

Fig. 61.1. Illustration of the proximal aorta. The arch is the short segment that includes the origins of the three brachiocephalic arteries— the innominate artery, the left common carotid artery, and the left subclavian artery. The Criado and Ishimaru landing zones are used to describe aortic anatomy during endovascular repair. The landmarks for defining the proximal aorta are the same in both systems. Zone 0 includes the ascending aorta and the origin of the innominate artery. Zone 1 includes the origin of the left common carotid artery. Zone 2 includes the left subclavian artery origin. The systems differ in their description of the distal aorta. In the Criado system, Zone 3 is a short section of the aorta that comprises the 2 cm immediately distal to the origin of the left subclavian artery and Zone 4 begins where Zone 3 ends. In the Ishimaru system, Zone 3 is longer, extending to an imaginary border at the end of the arch curvature, whereupon Zone 4 begins. (Used with permission from Baylor College of Medicine, Houston, TX.)

ascending aorta or 7.0 cm in the descending aorta. Thus, the investigators recommended replacing the ascending aorta at a diameter of 5.5 cm and the descending aorta at 6.5 cm (5.0 and 6.0 cm, respectively, for patients with Marfan syndrome) or if an aneurysm of any size becomes symptomatic.

Current guidelines make several scenario-based Class Ila recommendations for the repair of aortic arch aneurysms, with the caveat that the approach to repair is generally dictated by adjacent disease of the ascending or descending aorta. For isolated arch aneurysms in low-risk, asymptomatic patients, it is reasonable to replace the arch when the aortic diameter exceeds 5.5 cm or is growing more than 0.5 cm per year. Saccular aneurysms tend to grow more rapidly than fusiform aneurysms and often warrant earlier intervention. For aneurysms limited to the ascending aorta and proximal arch, it is appropriate to perform a partial arch replacement along with the ascending aortic repair. Replacing the entire arch is reasonable in cases of chronic dissection and aneurysms that extend into the proximal descending thoracic aorta. Again, repair is indicated for symptomatic patients regardless of aortic diameter unless the patient has a limited life expectancy. Although the scenario of asymptomatic aortic arch aneurysm in patients with triggered disorders is not specifically addressed in these guidelines, patients with asymptomatic ascending aortic aneurysm in this circumstance may undergo elective repair at an aortic diameter of 4.0 to 5.0 cm, depending on the particular disorder.

PERFUSION AND CEREBRAL PROTECTION

There are several different surgical options for managing aneurysms that involve the transverse aortic arch. The surgical approach depends on the extent of involvement and the need for cardiac and cerebral protection. Repairs of the ascending aorta and arch are performed through a sternotomy with cardiopulmonary bypass (CPB), whereas aneurysms that involve the distal arch and descending/thoracoabdominal aorta are performed through a thoracotomy or thoracoabdominal incision.

Most aortic arch repairs necessitate a temporary period of systemic circulatory arrest combined with varying degrees of hypothermia to protect the brain and other vital organs. Over the last several years, advances in cerebral protection strategies and surgical techniques have been shown to improve outcomes in open arch repair; therefore, we have gradually incorporated these changes into our practice. Changes include the increasing use of ACP rather than retrograde cerebral perfusion (RCP), the use of the axillary or innominate artery instead of the femoral artery as a cannulation site for inflow, and refined hypothermic targets—mild (28.1 to 34°C) or moderate hypothermia (20.1 to 28°C)—rather than deep (14.1 to 20°C) or profound hypothermia (≤14°C).

The well-established role for hypothermia in cerebral protection stems from the fact that the cellular metabolic activity of the brain slows with cooling, reducing cerebral oxygen demand. However, the use of profound hypothermic circulatory arrest (HCA) during arch repair has important limitations; increasing rates of stroke and death have been associated with longer HCA times, especially those longer than 30 minutes. Nevertheless, for selected limited repairs of the aortic arch (i.e., those with an anticipated circulatory arrest time of <30 minutes), the use of HCA alone is considered a reasonable strategy for providing adequate brain...
protection. Because many aortic arch repairs are quite complex and require longer periods of HCA, two cerebral perfusion strategies—RCP and ACP—were developed to supplement HCA by delivering cold, oxygenated blood to the brain for the purpose of reducing the risk associated with repair. RCP involves directing blood from the CPB circuit into the head through the snared superior vena cava cannula. Although this approach still has some proponents, recent evidence suggests that RCP is less beneficial than ACP, and today, the use of RCP in aortic arch surgery is generally in decline.

Unlike RCP, ACP provides cerebral flow via the brachiocephalic arteries. Early on, the brachiocephalic vessels were cannulated directly, but this approach was soon abandoned because of the high rate of stroke associated with it. Renewed interest in ACP developed after Japanese surgeons showed improved outcomes with the use of flexible balloon-tipped catheters to deliver ACP during arch repair. Contemporary ACP techniques commonly involve cannulating either the right axillary artery (Fig. 61.2) or the innominate artery and subsequent connection to the arterial limb of the bypass circuit. This procedure carries an inherent risk, although small, of brachial plexus and vascular injury. Once systemic circulatory arrest is induced, the innominate artery is occluded proximally with either a Rumel tourniquet or a vascular clamp, and bypass flow is reduced to approximately 10 ml/kg/min. This allows either the axillary or the innominate artery cannula to deliver oxygenated blood to the brain via the right common carotid artery.

When the circle of Willis is intact, unilateral ACP via the right common carotid artery can deliver blood flow to the left side of the brain. Methods to help determine the adequacy of cerebral cross-circulation include preoperative imaging and intraoperative monitoring. Our preferred method of intraoperative monitoring is brain near-infrared spectroscopy (NIRS), which measures cerebral oxygenation; an additional perfusion catheter can be inserted into the LCCA if NIRS monitoring indicates inadequate perfusion. Antegrade cerebral protection via the right axillary artery or innominate artery has become our standard adjunct for cerebral perfusion during HCA and avoids the problems that can develop from cannulating the femoral artery. These problems include plaque embolization, which can result in stroke and other complications; also, in cases of aortic arch dissection, the retrograde pressurization of the false lumen can result in cerebral malperfusion.

Recently, there has been a trend toward using warmer temperatures during HCA with ACP. The primary advantage of mild (28.1 to 34°C) and moderate (20.1 to 28°C) HCA is a reduced risk of the severe and life-threatening coagulopathy that occasionally results from profound hypothermia. Potential drawbacks of warmer temperatures include the increased risk of neurologic deficit, including spinal cord ischemia. Because of the importance of temperature management in patients subjected to HCA, the decision regarding where to measure body temperature is important. The jugular venous bulb provides the best approximation of brain temperature, but few centers use this approach. Nasopharyngeal and esophageal temperatures lag behind the jugular venous bulb temperature but serve as reasonable, practical options. Bladder and rectal temperatures are poor indicators of brain temperature and are generally not reliable during HCA cases.

OPTIONS FOR REPAIR

There are many different options available for repairing aneurysms that extend into the transverse aortic arch: a brief overview of several approaches is presented below. It is important that the surgeon develop a consistent approach that allows the anesthesiologist, perfusionist, and nurses to function as a team with the goal of limiting circulatory arrest and cardiac ischemic times. The guiding principle should be economy of steps (i.e., avoiding unnecessary activities), especially during circulatory arrest. Aneurysms involving only a portion of the transverse aortic arch are usually treated with partial arch repair. For more extensive aneurysms, the entire arch is typically replaced. If the aneurysm extends into the descending thoracic aorta, the aneurysm can be repaired in either one or two stages. Additionally, the arch can be repaired by using open surgical techniques, experimental endovascular techniques, or a combination of both open surgical and endovascular approaches (i.e., hybrid arch procedures).

Partial Arch Repairs

Partial arch repairs, such as patch graft aortoplasty and hemiarch approaches, are less complex than other aortic arch repairs because repair does not directly involve the brachiocephalic vessels. Patch graft aortoplasty can be used to repair saccular aneurysms that originate from the lesser arch curvature and involve <50% of the aortic

![Image](https://example.com/image.png)
circumference. A fusiform ascending aortic aneurysm that extends into only the proximal portion of the arch (in a patient with a normal-sized distal arch) can be repaired with a hemiarch approach by using a beveled graft to replace a portion of the lower curvature of the arch (Fig. 61.3). Of note, for acute dissections that involve the arch (DeBakey I or II), we often use the hemiarch technique.

**Total Arch Repairs**

More extensive arch aneurysms often involve total replacement of the arch, with reattachment of the brachiocephalic vessels and a distal anastomosis at the proximal descending thoracic aorta. In the past, we reattached the brachiocephalic vessels to one or more openings made in the graft (“island patch technique”) (Fig. 61.4) or by using smaller, individual grafts to replace each vessel at its origin. There are two disadvantages to the island patch technique. First, this technique can result in difficult-to-control bleeding from the posterolateral aspect of the anastomosis. Second, the aortic tissue left behind can become aneurysmal, necessitating a second operation; this problem is most common in patients with connective tissue disorders.

**Y-Graft Techniques**

In 2002, Spielvogel and colleagues described the trifurcated graft technique (also called the double Y-graft technique) that they devised to simplify arch reconstruction by essentially “debranching” the aortic arch without strictly following its original anatomic structure. This technique appears to improve outcomes by reducing embolization and minimizing cerebral ischemia. In this technique, single or double Y-branched grafts are created by suturing one or two branch grafts (usually 8 mm in diameter) to a main trunk (usually 12 mm in diameter) at a 45-degree angle; commercially available, prefabricated Y-grafts can also be used. Each brachiocephalic branch vessel is typically sutured end-to-end to separate distal ends of the Y-graft (Fig. 61.5). To expedite repair, debranching can be performed during the cooling process before HCA is achieved. The double Y-graft can then be used to provide ACP while the aortic arch is replaced with a graft. The Y-graft approach is commonly used with the collared elephant trunk graft, and because the brachiocephalic vessels have been debranched, it is possible to move the distal anastomosis forward from its traditional location just distal to the LSCA to a position in line with the origins of the LCCA or innominate artery. These adjustments in technique are thought to promote a hemostatic distal anastomosis.

**Elephant Trunk**

For extensive aneurysms involving the entire thoracic aorta, repairs are generally performed in two stages, because the
Chapter 61: Arch Aneurysms

Fig. 61.5. Contemporary Y-graft arch repairs. These include (A) the single Y-graft approach, (B) the double Y-graft approach, (C) the elephant trunk approach with a single Y-graft, and (D) the elephant trunk approach with a double Y-graft.

surgical exposure needed to repair the proximal and distal aorta differs. The decision whether to address the proximal or distal aorta first is based on symptoms, aneurysm size, and cardiac disease; the symptomatic segment is addressed first. Borst’s elephant trunk procedure involves repairing the proximal aorta first, then performing a completion procedure to repair the distal portion of the aneurysm. During the first stage of the elephant trunk procedure, the distal anastomosis is constructed and a portion of the graft is left suspended within the proximal descending thoracic aorta (Fig. 61.4C). This “trunk” is then used during subsequent distal aortic reconstruction (Fig. 61.6) and offers many advantages, including easier dissection, shorter durations of aortic clamping, and safer clamping. Avoiding dissection around the distal arch reduces the chance of injury to the pulmonary artery and esophagus, which may be obscured by adhesions. Also, clamp times are usually shorter during the second stage because the proximal anastomosis is graft-to-graft, which makes hemostasis easier to achieve. Finally, because the aorta does not need to be clamped proximal to the LSCA, this technique reduces the risk of stroke from potential embolization of atherosclerotic debris.

An important change that improves the elephant trunk approach is the recent introduction of the collared or “skirted” aortic arch graft. The distal anastomosis of the aortic arch for the first stage of the elephant trunk procedure was traditionally done by invaginating the graft within itself,
mimicking an intussusception. One of the problems of this technique was the substantial size discrepancy between the graft and the remaining diseased distal aorta. This size discrepancy could create undue tension on the anastomosis and result in bleeding or pseudoaneurysm formation at a later time. The collared elephant trunk graft facilitates a tension-free distal anastomosis by providing a graft collar that can be easily cut to match the distal aortic diameter; this helps to simplify the repair.

In patients with extensive aneurysmal disease in which the thoracic or thoracoabdominal aorta is symptomatic or substantially larger than the proximal aorta, the distal repair is often performed first with the “reverse elephant trunk” and followed by the second-stage replacement of the proximal aorta (Fig. 61.7). The advantage of the reverse elephant trunk technique is that it eliminates the distal anastomosis during the second stage of the repair. A drawback of open elephant trunk approaches is the inherent between-stage recovery period, during which the un repaired portion of the aorta may rupture. In general, there is usually a 3- to 6-week interval between stages, although if the patient is symptomatic, this period may be shortened.

**Extensive Single-Stage Repair**

Alternatively, it is possible to replace the entire thoracic aorta during a single procedure. Kouchoukos and colleagues describe a single-stage repair for extensive disease involving the ascending aorta, the arch, and variable portions of the descending thoracic aorta; this repair involves performing a bilateral anterior thoracotomy with a transverse sternotomy (clamshell) incision. In this procedure, the arch anastomosis is done first during a short period of HCA in order to minimize the duration of cerebral ischemia.

**Hybrid Arch Repair**

The increasing interest in endovascular approaches to aortic arch repair has largely been driven by the need to reduce the high morbidity and mortality traditionally associated with open arch surgery and with the use of HCA. Such approaches are particularly attractive in high-risk patients with a poor likelihood of surviving a traditional open repair, either because of existing comorbidities (such as poor cardiac or pulmonary function) or emergent scenarios (such as rupture). Purely endovascular approaches to aortic arch repair are largely experimental and have limited applicability in day-to-day practice. Hybrid repairs, which are more accessible and increasingly widely used, involve “debranching” some or all of the brachiocephalic arteries, essentially lengthening the branchless aorta, and using an off-label application of standard “tube” stent grafts to exclude the diseased portion of the aortic arch.

The previously mentioned anatomic zones (Fig. 61.1) help to indicate the extent of hybrid arch repair. Zone 0 designates a repair that involves the entire aortic arch, necessitating the rerouting of all the brachiocephalic vessels because the stent graft will cover the origins of the innominate artery, LCCA, and LSCA (Fig. 61.8). When Zone 1 is planned as a landing zone, both the LCCA and the LSCA are rerouted, because their origins will be excluded by the stent graft.

These arch repairs are generally performed in specially designed hybrid operative suites that combine standard cardiothoracic operative equipment with specialty imaging devices. Hybrid arch repair typically involves performing a median sternotomy to provide sufficient exposure to reroute brachiocephalic vessels and to restore inflow from an anterolateral aspect of the ascending aorta, similar to the Y-graft techniques described previously. The debbranching procedure may be done off-pump and without HCA, although in practice, a period of CPB and even HCA is not uncommon. For saccular aneurysms, hybrid arch repair is particularly attractive because the disease is localized, and healthy aortic tissue is usually readily available for adjacent proximal and distal landing zones.

**Hybrid Elephant Trunk Repair**

Hybrid elephant trunk repairs combine a standard open arch repair with an extended, distal endovascular repair (Fig. 61.6B). These repairs can be performed simultaneously with the open arch repair or at a later time. The primary benefits of hybrid elephant trunk repairs are that they are less

---

Fig. 61.7. Postoperative drawing illustrating (A) the completed thoracoabdominal repair with the invaginated reversed elephant trunk graft suspended in the proximal portion of the graft. The completion repair may be done in the traditional manner (B) or by using the Y-graft technique. (Used with permission from Coselli JS, LeMaire SA, Carter SA, et al. The reversed elephant trunk technique used for treatment of complex aneurysms of the entire thoracic aorta. Ann Thorac Surg 2005;80:2166-2172; discussion 2172, figures 4 and 8. Copyright of The Society of Thoracic Surgeons.)
invasive than the traditional open elephant trunk completion procedure and that they can be performed sooner; by reducing or eliminating the interval between operations, the chance of between-stage death from rupture or other causes is reduced. Additionally, many patients are unwilling or unable to withstand a second open procedure, and a combined strategy allows for extended descending thoracic aortic coverage without requiring a second open procedure that involves a thoracotomy. Hybrid elephant trunk repairs are not suitable for patients with extensive distal aortic disease because endovascular approaches require secure landing zones, and it may not be possible to identify a suitable distal landing zone for the stent graft.

A modification of this approach is the frozen elephant trunk, in which the stent graft is deployed antegrade during the initial repair procedure. In the United States, this approach generally involves direct suturing to affix the stent graft to both the aortic wall and the replacement graft; this approach should minimize the risk of device migration by securing the endograft. Outside the United States, the frozen elephant trunk is a specialty device that has a Dacron-only section sutured to a stent graft. Spinal cord injury, as a result of ischemia, has been reported as an occasional complication of the frozen elephant trunk approach.

**Surgical Techniques**

**Contemporary Approach to Aortic Arch Repair**

Preparation for open repair of the transverse aortic arch includes placing a central line, a Swan–Ganz catheter, a left radial arterial line, and NIRS optodes for cerebral oxygenation monitoring. A standard median sternotomy is performed, and arterial inflow is established through the axillary or innominate artery. If the axillary artery is to be used, an incision is made in the deltopectoral groove. The pectoralis major muscle is spread along its fibers to expose the pectoralis minor muscle, which is then divided to expose the axillary artery. Care is taken to avoid the lateral and medial cords of the brachial plexus. A 3- to 4-cm segment of artery is freed, and a vessel loop is placed around it. A partial occluding clamp is placed on the artery after 5,000 units of heparin are given intravenously. An 8-mm Dacron graft is then anastomosed to the axillary artery with a running 6-0 polypropylene suture. The graft is clamped, the partially occluding clamp is removed, and the graft is attached to the arterial arm of the bypass circuit. Alternatively, the arterial cannulation can be achieved through an 8-mm graft anastomosed to the innominate artery by a similar process. Full-dose heparin is given before the cannula is attached to the CPB circuit. Venous drainage is achieved by placing a dual-stage venous cannula in the right atrium with its tip in the inferior vena cava. We routinely place a retrograde cardioplegia cannula in the coronary sinus and a sump drain in the left ventricle via the right superior pulmonary vein.

CPB is initiated and ventilation is discontinued once an adequate activated clotting time (>480 seconds) is achieved. The innominate artery is encircled with a tourniquet in preparation for snaring when CPB is discontinued. Once CPB has been initiated and the heart is fully decompressed, cooling can safely begin; the target temperature is 24°C (as measured with a nasopharyngeal probe). The head is packed in ice to enhance cerebral protection and prevent topical rewarming. During cooling, we give mannitol for cerebral protection, and we administer magnesium, lidocaine, and amiodarone to help maintain a sinus rhythm for as long as possible. Immediately after fibrillation (which usually occurs at approximately 30 to 32°C), retrograde cardioplegia is delivered into the coronary sinus. This induces diastolic arrest that is maintained by hypothermic conditions. Alternatively, if the aorta can be safely cross-clamped and the aortic valve is competent, cardioplegia can be given antegrade into the aortic root. Cardioplegia can also be administered directly into the coronary ostia once the aorta is opened under circulatory arrest. Cardioplegia is given about every 6 minutes thereafter.
If a hemiarch procedure is going to be performed, the patient is cooled to the target temperature before HCA is initiated. We now cool to a moderate temperature of 24°C; subsequently, CPB pump flows are brought down to about 10 ml/kg/min. Simultaneously, the Rumel tourniquet around the innominate artery is cinched down to allow perfusion of the brain through the right common carotid artery and to the right arm via the distal innominate or right axillary artery. The aorta is opened, and the arch vessels are visualized from within the opened arch. During this procedure, if NIRS monitoring indicates a significant drop in cerebral oxygenation from baseline, a perfusion catheter can be inserted directly into the LCCA. To incorporate the lesser curve of the arch, a beveled anastomosis is made with a running 3-0 or 4-0 polypropylene suture. The anastomosis may be reinforced with a second layer of running polypropylene suture or interrupted, pledgeted mattress sutures. After the distal anastomosis is completed, the innominate snare is released, CPB flows are increased, and the graft is deaired and then clamped. The proximal aspect of the repair is then performed as the patient is slowly rewarmed while receiving full CPB flows.

If the entire arch is to be repaired, we now generally use a Y-graft approach (Fig. 61.9). While the patient is being cooled

---

Fig. 61.9. Drawings illustrating the Y-graft technique. (A) The proximal portions of the brachiocephalic arteries are exposed, and a double Y-graft is created by suturing two side grafts to a main graft at 45-degree angles. (B) The first two branches of the graft are sewn end-to-end to the transected left subclavian and left common carotid arteries. The proximal ends of the transected brachiocephalic arteries are ligated. (C) A balloon-tipped perfusion cannula is placed inside the double Y-graft and used to deliver antegrade cerebral perfusion. After systemic circulatory arrest is initiated, the innominate artery is clamped, transected, and sewn to the distal end of the main graft. (D) A clamp is placed on the proximal aspect of the Y-graft, thereby directing flow from the axillary artery to all three brachiocephalic arteries. The arch is then replaced with a collared elephant trunk graft. (E) The distal anastomosis between the elephant trunk graft and the aorta is created between the innominate and left common carotid arteries. (F) The aortic graft is clamped, and a second limb from the arterial inflow tubing of the cardiopulmonary bypass circuit is used to deliver systemic perfusion through a side branch of the arch graft while the proximal portion of the ascending aorta is replaced. Once the proximal aortic anastomosis is finished, the main trunk of the double Y-graft is cut to an appropriate length, and the beveled end is then sewn to an oval opening created in the right anterolateral aspect of the ascending aortic graft, which completes the repair (G). (Used with permission from LeMaire SA, Price MD, Parenti JL, et al. Early outcomes after aortic arch replacement by using the Y-graft technique. Ann Thorac Surg 2011;91:700-707; discussion 707-708, figure 2. Copyright of The Society of Thoracic Surgeons.)
to a moderate target of 24°C, the Y-graft debranching process is begun. The proximal aspects of the brachiocephalic vessels are exposed. Next, the LSCA is ligated near its origin with a heavy silk tie and transected. One of the branches of the Y-graft is then swnn end-to-end to the LSCA with a 5-0 or 6-0 polypropylene suture. In the same manner, the LCCA is ligated and transected, and the distal end is swnn end-to-end to another side branch of the Y-graft. A single Y-graft approach may be used if the distal portion of the arch is not aneurysmal; in this case, only the LCCA is anastomosed to the Y-graft. The graft is then deaired and clamped. Once HCA is achieved, the arch is opened, the proximal portion of the innominate artery is ligated, and the distal end of the innominate artery is anastomosed end-to-end to the main trunk of the Y-graft. During the innominate artery anastomosis, if NIRS monitoring shows a significant drop in cerebral oxygenation from baseline, a perfusion catheter can be inserted directly into the Y-graft to perfuse the LCCA. Once the innominate anastomosis has been performed, the Rumel tourniquet around the innominate artery is removed. The Y-graft is deaired and clamped proximally to maintain flow from the axillary artery to the two or three previously anastomosed brachiocephalic arteries while the aortic graft is placed.

Next, the distal aortic anastomosis is performed. When the descending thoracic aorta is not aneurysmal, a straight or curved graft may be used to complete an end-to-end distal anastomosis. More commonly, the aneurysmal disease extends into the descending thoracic aorta, and a collared elephant trunk graft is used to perform the distal anastomosis. Because the aortic arch has already been debranched, this distal aortic anastomosis can be performed more proximally within the boundaries of the transverse aortic arch (proximal to the original anatomic location of the LSCA or LCCA), rather than at the traditional location just beyond the LSCA. This anastomosis is performed with either a 3-0 or a 4-0 polypropylene suture in a continuous manner. Often, this distal anastomosis is then reinforced with either another layer of running suture or pledged mattress sutures. If it appears that the residual descending thoracic aortic aneurysm is amenable to subsequent endovascular repair, metallic clips are placed on the distal edge of the elephant trunk graft to facilitate later stent-graft delivery by aiding fluoroscopic visualization. Once the distal anastomosis is complete, the graft is deaired, a clamp is applied to the proximal portion of the graft, and distal systemic perfusion is reestablished via a side branch (usually 8 mm) of the collared elephant trunk graft. Full CPB is reestablished via the axillary artery perfusion cannula and the side branch of the elephant trunk graft.

Rewarming to 36.5°C can be initiated immediately after CPB is restarted, but it is occasionally prudent to delay rewarming if extensive reconstruction is required proximally, such as repair involving the aortic valve or root. The difference between perfusate and core body temperature is kept to <10°C until a core body temperature of 27°C is achieved, after which the perfusate is kept at 37°C for the remainder of rewarming.

During rewarming, the proximal aortic anastomosis is completed, often near the level of the sinotubular junction. After the main trunk of the Y-graft is cut to an appropriate length, the proximal end is anastomosed to a small opening made on the right anterolateral aspect of the ascending aortic graft (proximal to the aortic cross-clamp) in an end-to-side manner with a 4-0 or 5-0 polypropylene suture. The length and orientation of the Y-graft are carefully planned to prevent any kinking of the graft when it is pressurized and compressed by the closed sternum.

The graft is deaired and the aortic cross-clamp is removed. The retrograde cardioplegia catheter is removed. Temporary pacing wires are placed. The patient is separated from bypass as soon as the physiologic temperature is reached and appropriate criteria are met. When it is time to remove the arterial cannula, the side arm of the graft is clamped and divided. A heavy silk suture is used to tie off the side arm graft flush with the aortic graft, and a suture ligature is used to definitively obliterate the side arm lumen. If the side arm is not tied flush with the graft, contrast may enter the residual side arm during future computed tomography scans, and this leakage might be interpreted as an anastomotic leak or rupture.

**Elephant Trunk Completion**

The second portion of the elephant trunk procedure may be performed with open or endovascular techniques (see section Hybrid Elephant Trunk) (Fig. 61.6). Our technique for distal aortic repair is more fully described elsewhere. In brief, our approach is based on the distal extent of repair, and additional surgical adjuncts are used for more extensive repairs (such as Crawford extent I and II thoracoabdominal aortic repairs). We begin by placing a double-lumen endobronchial tube and monitoring arterial pressure with right radial and femoral arterial lines. For extensive distal aortic repairs, a cerebrospinal drain is placed in the intervertebral space at L3-L4 or L4-L5. The patient is then positioned on the right side with the thorax at a 75-degree angle to the bed and the hips at a 45-degree angle to allow the exposure of the vessels in the groin in the event that they are needed to establish CPB.

A posterolateral thoracotomy incision is made in the fifth or sixth interspace. If the aneurysm extends below the diaphragm, the incision is extended toward the umbilicus in a curvilinear manner. We do not remove a rib, and we only occasionally need to divide the posterior aspect of a rib to complete an elephant trunk procedure. The costal margin and rectus abdominis muscle are divided, connecting the thoracotomy to the abdominal incisions. The retroperitoneal reflection is dissected with electrocautery; this mobilizes the spleen, descending colon, and left kidney, thereby exposing the abdominal aorta. An arcuate incision is made in the diaphragm, staying approximately 1 to 2 cm from the tendinous portion, where the neurovascular bundle runs, and leaving a 3- to 4-cm margin attached to the chest wall to facilitate later closure with No. 1 polypropylene suture. Self-retaining retractors on the upper and lower ribs, and gentle reflection of the abdominal contents to the right by the surgical assistant, provide stable exposure of the thoracoabdominal aorta.

If the aneurysm is less extensive and a short cross-clamp time is anticipated, an expeditious clamp-and-sew technique can be performed. Otherwise, left heart bypass is used with outflow from the left pulmonary vein and inflow to the distal descending thoracic aorta. A heparin dose of 1 mg/kg is given, and the pericardium overlying the left inferior pulmonary artery is opened. A pledgeted 4-0 polypropylene purse-string suture is placed in the pulmonary vein, which is then cannulated. The aorta is cannulated distally in the descending thoracic portion, or in the abdominal portion in the case of thoracoabdominal aneurysms. Flow is initially run at 500 ml/min until the cross-clamp is applied, after which flows are adjusted (usually to 1.5 to 2.0 L/min) to maintain a right radial mean arterial pressure of 60 to 70 mmHg. The aorta is clamped in a place that includes the free-floating arm of the elephant trunk graft. Because the graft should extend some distance into the descending aorta, the clamp does not have to be applied flush against the arch.
A second clamp is placed on the aorta proximal to the arterial cannula. The isolated segment of aneurysmal aorta is opened, and the free-floating portion of the graft is retrieved and clamped. The first clamp is removed, which allows the graft to be stretched inferiorly because its corrugated structure gives it a tendency to shorten.

An appropriately sized graft is anastomosed to the free-floating arm of the elephant trunk graft with 2-0 or 3-0 polypropylene suture. It is not necessary to routinely reinforce this anastomosis because the graft-to-graft connection is quite hemostatic. Left heart bypass is discontinued, and the arterial cannula is removed. The distal clamp is also removed, and back-bleeding from the aorta is dealt with by suctioning blood to a cell-saver system. The remainder of the aneurysmal aortic segment is opened. Intercostal vessels with vigorous back-bleeding are oversewn. Depending on the extent of the aneurysm, one may need to reattach the intercostal arteries, visceral branches, or both to the graft in addition to performing the distal anastomosis.

The graft is then cut to size, and the distal anastomosis is performed with running 3-0 or 4-0 polypropylene suture. During this time, the anesthesiologist is alerted a few minutes before the clamp is removed so that appropriate adjustments can be made to preload, afterload, contractility, and acid–base status. The patient is placed head-down, and the aortic clamp is slowly removed. The cannula in the pulmonary vein is removed, protamine is given, and meticulous care is taken to achieve a hemostatic field, after which the wound is closed.

**Reverse Elephant Trunk**

In the first stage of the repair, the descending thoracic or thoracoabdominal aorta is replaced by using our standard techniques, with one important difference: the proximal anastomosis is constructed with approximately 10 cm of graft invaginated within itself (Fig. 61.7). This folded edge of the invaginated graft is sewn end-to-end to the aorta with 3-0 or 4-0 polypropylene.

The second portion of the repair is performed after an appropriate convalescence (ideally about 4 weeks) in a manner similar to that described above for aortic arch repair. This is done via a median sternotomy after HCA and ACP are established. The Y-graft technique is used to anastomose the brachiocephalic vessels. Forceps are then used to reach into the aorta beyond the arch to pull the invaginated portion of the previously placed graft from within itself. The proximal portion of the graft is then anastomosed to the ascending aorta. Finally, the main trunk of the Y-graft is sutured to an oval opening in the ascending aortic graft.

**Hybrid Arch Repair—Zone 0**

This repair can be performed without CPB. The chest is entered through a median sternotomy, and heparin (1 mg/kg) is administered. With a side-biting, partially occluding clamp, a small anterolateral portion of the ascending aorta is isolated; care is taken to ensure that this site is proximal to the proposed endovascular landing zone. The main branch of a Y-graft is anastomosed end-to-side to a small opening in the isolated portion of the ascending aorta with continuous 4-0 polypropylene suture. The side-biting clamp is then removed, and a straight clamp is placed on a proximal section of the Y-graft trunk. The innominate artery is clamped and divided, and its proximal aspect is then oversewn near its origin with 3-0 polypropylene suture; the artery is then anastomosed to the distal aspect of the Y-graft main trunk with continuous 5-0 polypropylene suture in an end-to-end fashion. The LSCA is then divided and oversewn at its origin with 3-0 polypropylene suture; subsequently, its distal transected end is anastomosed end-to-end to one of the side branches of the Y-graft with continuous 5-0 polypropylene suture. Similarly, the LCCA is divided and oversewn at its origin with 3-0 polypropylene suture, and its distal transected end is anastomosed end-to-end to the remaining side branch of the Y-graft with continuous 5-0 polypropylene suture. As each brachiocephalic artery is rerouted, clamps are repositioned to restore circulation expeditiously.

After the aortic arch has been debranched, a 10-mm graft is anastomosed with continuous 4-0 polypropylene suture in an end-to-side manner to an anterolateral portion of the ascending aorta isolated by a side-biting, partially occluding clamp. This graft will serve as a conduit for antegrade deployment of one or more stent grafts, depending on the extent of the aneurysm. Through this conduit, a pigtail catheter is inserted through a guide wire so that the adequacy of the arch debranching process can be assessed angiographically. Then, a 24-F sheath is inserted through the conduit over a stiff guide wire, and one or more stent grafts (the number depends on the extent of aortic disease) are advanced into the aortic arch and descending thoracic aorta. Care is taken to ensure that the Y-graft inflow from the proximal ascending aorta is not occluded by the proximal stent (Fig. 61.8).

The stent grafts are often balloononed to ensure an adequate seal at the proximal and distal landing zones, as well as at any overlapping sections; ballooning is not performed if there is an aortic dissection. A completion arteriogram is then performed to ensure that the aneurysm has been excluded, that there are no endoleaks, and that no suture lines have been disrupted during this process. The 10-mm graft is oversewn at its base with 3-0 polypropylene suture, because leaving any stump could confound later imaging studies or cause thrombus formation with the potential for distal embolization. Protamine sulfate is then given to reverse the effects of heparin, tubes are placed for drainage, and the chest is closed.

**Hybrid Elephant Trunk**

The first part of the procedure is similar to our method of total aortic arch replacement with the Y-graft technique and the collared elephant trunk graft approach (see sections Options for Repair and Y-Graft Techniques). During the cooling phase of CPB (to 24°C), the brachiocephalic arteries are debranched in an end-to-end manner onto a Y-graft (a 10- or 12-mm main trunk and two 8- or 10-mm side branches), which is then used to provide ACP. The aortic arch is transected at the level of the LCCA, and a collared elephant trunk graft is distally anastomosed with 2-0 polypropylene suture in a running, continuous manner. A second suture of 3-0 polypropylene is run around the anastomosis for reinforcement. Under direct vision, the stent graft is deployed antegrade through this graft over a stiff Amplatz wire to cover the proximal aspect of the descending thoracic aorta. One or more stent grafts may be deployed at this time, and if necessary, these stent grafts are overlapped by at least 2 cm. Often, the endograft is then balloononed to create an adequate seal (this step may be omitted in cases of aortic dissection) and may be secured at the proximal landing zone to both the collared elephant trunk graft and the aortic wall by placing pledged 3-0 polypropylene sutures in a mattress manner. The collared elephant trunk graft is then deaired, and the cross-clamp is applied to its proximal portion. Full CPB is reestablished via the 8-mm perfusion graft in the right axillary or innominate artery and the 8-mm side branch of the collared elephant trunk graft.

The proximal portion of the aortic repair is then carried out while the patient is rewarmed back to physiologic temperature. The main trunk of the Y-graft is anastomosed to an opening in the right anterolateral section of the ascending aortic graft in an end-to-side manner with continuous 4-0 polypropylene suture (Fig. 61.6B). Deairing is done through the anastomosis and subsequently via a 19-gauge needle placed in the ascending aortic graft before the aortic cross-clamp is released. The retrograde cardioplegia cannula is removed, a temporary right ventricular pacing wire is...
placed, and once the appropriate temperature is reached (36.5°C) and deairing is completed, the patient is weaned from CPB.

Alternative two-stage approaches involve advancing the stent graft in an antegrade manner from a brachial artery or advancing the wire in a traditional retrograde manner from the femoral artery into the existing elephant trunk. Often, metallic clips are placed on the distal edge of the elephant trunk graft to facilitate radiographic visualization during the second-stage repair.

OUTCOMES

Aortic arch repair carries substantial risks—primarily the risks of operative death or stroke. The prolonged use of CPB and HCA has been long associated with increased mortality, neurologic morbidity, and other complications. Furthermore, certain patient-specific characteristics (such as acute aortic dissection, previous median sternotomy, urgency of repair, an incomplete circle of Willis, and a history of stroke) may enhance operative risk. Although it is difficult to interpret outcomes across these various approaches, results appear to be generally improving, particularly for elective repair of the aortic arch in patients without aortic dissection. In general, less extensive open aortic arch repair (such as the hemiarch approach) tends to carry less risk than extended arch repair (such as elephant trunk approaches). In very high-risk patients, a hybrid approach has been advocated as an effective alternative to open repair, because this approach is believed to cause fewer cardiac, pulmonary, and other complications, as well as less short-term mortality and morbidity. The primary drawbacks of hybrid approaches appear to be the increased risk of stroke (due to endovascular manipulation within the aortic arch) and the increased risk of spinal cord ischemia (when repairs extend into the descending thoracic aorta), as well as uncertain durability.

Our contemporary experience regarding aortic arch repair in 243 patients is presented in Table 61.1 and includes outcomes for traditional partial-arch approaches (such as the hemiarch approach), traditional full-arch approaches, and our initial use of the Y-graft approach. Many of the patients had conditions that tend to enhance operative risk: 83 patients (34%) had a prior median sternotomy and 91 (37%) had acute dissection of the ascending aorta. Many of these arch repairs involved concomitant repair of the aortic valve (148 patients, 61%). We have been gradually shifting toward more moderate HCA temperatures, and in this series, the median lowest nasopharyngeal temperature was 22.0°C for patients who underwent the arch repair with the Y-graft approach, 19.4°C for the traditional partial-arch approach, and 16.3°C for the traditional full-arch approach.

Renal failure is defined as the need for dialysis at time of hospital discharge.

F I N A L C O M M E N T S

Approaches to transverse aortic arch repair are becoming increasingly diverse, and over the past several years, our approach to these operations has gradually changed, largely through the introduction of various techniques aimed at reducing the risk of neurologic complications. The selection of one approach over another should be based on the extent of aortic disease, as well as patient-specific comorbidities such as advanced age, severe atherosclerosis, chronic renal dysfunction, and preexisting cardiac dysfunction. Regardless of the approach used for transverse aortic arch repair, postoperatively, all patients should be routinely assessed for late complications, including the development of pseudoaneurysms, patch aneurysms, and new aneurysms in other sections of the aorta. This is particularly important in hybrid arch repairs, because these are off-label applications of endovascular devices, and the durability of these repairs is unknown.

ACKNOWLEDGMENTS

The authors gratefully acknowledge Susan Y. Green, MPH, and Stephen N. Palmer, PhD, ELS, for providing editorial support, and Scott A. Weldon, MA, CMI, for creating illustrations and assisting with image selection. Portions of this chapter were adapted from our chapter in the 2nd edition of this textbook; we acknowledge John Bozinovski, MD, for his contributions as a coauthor on the previous chapter.

SUGGESTED READINGS

The combination of hybrid approaches, including direct revascularization of the arch vessels through a sternotomy followed by TEVAR, is a very attractive approach in much more complex or difficult situations. I believe that this technology is continuing to change, and a procedure that used to be greatly feared now can be done electively with relatively low risk of mortality or stroke.
Acute traumatic aortic transection (TAT) remains a devastating complication of blunt trauma with a mortality of 80% at the scene and is the second leading cause of death from blunt injuries. Further, up to half of the patients surviving to hospital admission perish within the first 4 hours. Due to the mechanism of injury, TAT is rarely an isolated finding and confounding extrathoracic injuries complicate both the diagnosis and management strategy. A multidisciplinary approach including trauma services, critical care management, radiology, and the cardiovascular surgeon is critical to assessing the spectrum of injuries and decisively executing a therapeutic plan.

Increasing sophistication of trauma systems and the introduction of multi-detector computed tomographic angiography (CTA) have led to the increase in both the initial survival of TAT patients to hospital admission and diagnosis of aortic pathology. The ability to obtain quick, high-resolution imaging with multiplane reconstruction through CTA has replaced traditional angiography in the diagnosis of TAT. In addition, the liberal application of computed tomography scanning has allowed for better assessment of concurrent injuries and allowed for appropriate planning of either an open or endovascular surgical approach. Further, documented decrease in rupture rates with the administration of anti-impulse therapy has allowed for more patients to reach the operating room and a small subset of patients to be treated without surgery.

Despite these advances, TAT continues to be a highly lethal entity. Operative mortality approaches 25% in recent American Association for the Surgery of Trauma (AAST) prospective trials on management of TAT. Data are promising for the ability of thoracic endovascular aortic repair (TEVAR) to improve outcomes in this population; however, the applicability of this technology to all patients is controversial and still limited by anatomic and device-specific constraints. Continued experience in open surgical repair (OSR) for TAT is critical in approaching these complex patients. The most efficacious approach to management will be appropriate selection of both the timing and technique of intervention.

**NATURAL HISTORY AND PATHOLOGIC CONSIDERATIONS**

Eighty percent of acute TAT occur as a result of motor vehicle collisions. Other causes include kicks, falls from heights, and crush injuries. Most series report that 20% of motor vehicular accident fatalities are a result of TAT. The incidence is higher in the young adult population and has an increased male-to-female ratio. More than one half of the transections occur at the aortic isthmus, 25% can occur in the arch and great vessels, and the remaining throughout the descending and abdominal aorta. Recent pooled data of OSR only trials for meta-analysis reported the need for open arch reconstruction in TAT at 4.1%. This was associated with significantly elevated mortality. Similarly, concomitant repair of injury at the isthmus and abdominal aortic branches has increased mortality and morbidity, likely due to the greater force and associated injuries needed to create this spectrum of disease.

Multiple mechanisms of injury have been reported by autopsy study and ex vivo mechanical testing of the tensile strength of the aorta. The most commonly accepted theory is the sudden movement of the heart and arch against the fixed position of the descending thoracic aorta. In this deceleration model, the greatest tension point is the aortic isthmus, resulting in the spectrum of injuries in TAT. Other proposed mechanisms include a sudden rise in blood pressure, high-pressure reflected wave from sudden occlusion of the aorta at the diaphragmatic hiatus, and stretching or “pinching” of the aorta by the osseous structures in the thorax. Regardless of mechanism, the natural history of TAT is such that immediate death was historically reported in 80% to 90% of cases. In a contemporary autopsy study of 242 cases of fatal TAT, Burkhart et al. (*J Trauma 2001*) published immediate mortality in 57%, 37% within 4 hours of admission, and only 6% who died >4 hours after hospital arrival.

A basic understanding of the underlying pathology can also greatly aid in diagnosis and decision making regarding surgical timing. TAT is a continuum of disease spanning from subintimal hemorrhage to complete transection, and extent of injury likely plays the ultimate role in survival. Parmley et al. (*Circulation 1958*) classified the injuries as intimal hemorrhage only, intimal hemorrhage with laceration, medial laceration, complete laceration of all layers, pseudoaneurysm formation, and free aortic hemorrhage. The fine detail provided by CTA allows for classification of these injuries along this spectrum at diagnosis.

**DIAGNOSIS**

With a history of any deceleration injury, there should be a suspicion for possible acute aortic transection. Symptoms on arrival at the emergency room in a conscious patient range from nonspecific complaints to those of chest pain, intrascapular pain, hoarseness, dyspnea, dysphasia, and frank paralysis. Physical examination findings include rib fractures, sternal fractures, and even imprints of the steering wheel on the chest. The cervical and thoracic spines are also vulnerable, and these should be carefully examined. Hypertension in the arms, so-called coarctation syndrome, has been reported. It is important to carefully examine the pulses in the upper and lower extremities and check for any differences. A baseline neurologic examination is extremely important in these patients because paraplegia may be present preoperatively and may be due to other causes such as spinal fractures and dislocations.

In the era of liberal CT scanning, chest roentogram has a less important role, but diligent examination is still warranted,
especially in patients with otherwise underwhelming presentation. An initial chest radiograph should be obtained as soon as the patient’s cervical spine is cleared. An upright posteroanterior (PA) film is desirable; however, the most upright anterior-posterior (AP) film possible is the best alternative. Supine chest radiographs usually reveal a widened mediastinum. Any abnormality seen in the mediastinum on an upright PA chest film should raise the suspicion for aortic transection and prompt further investigation. Various specific radiographic findings associated with aortic transection include mediastinal widening, obscuration of the aortic knob, obliteration of the AP window, tracheal deviation, depression of the left mainstem bronchus, widening of the paravertebral stripe, deviation of the esophagus (seen most commonly as deviation of the nasogastric tube), and a left hemotorax. Fractures of the first rib and/or scapula should raise the suspicion of an aortic injury due to the extreme force required to fracture these bones. A history of a deceleration injury in conjunction with an abnormal mediastinum seen on the chest radiograph should prompt further investigation.

CTA has replaced arch angiography as the modality of choice in investigating blunt aortic injury (Fig. 62.1). Magnetic resonance imaging (MRI) has also been advocated, especially considering the physiologic information which can be gained from functional MRI; however, it is often too cumbersome to obtain in the acute trauma situation. Transesophageal echocardiography (TEE) has been shown to be a useful diagnostic tool, but this test may not be readily available in all institutions, and its accuracy is operator anatomy dependent. With TEE, there is also a risk of free aortic rupture due to patient gagging or Valsalva from inadequate sedation causing increase in intrathoracic pressure. In our experience, TEE has been most useful when the patient was sent to the operating room emergently for other life-threatening injuries and there remains a question regarding the diagnosis of acute TAT. Intraoperatively, TEE is useful in helping to rule in or out aortic injury. Operative exploration is now justified without the use of arteriography in the acute setting with a suggestive clinical picture along with other diagnostic radiologic findings such as that seen on plain radiographs, CT scans, and intraoperative TEE findings. Associated injuries are common, and acute TAT is rarely seen as an isolated entity. Injuries to other organ systems (intracranial, intra-abdominal), including major fractures (spine, pelvis), must be considered and treated if a successful outcome is to be obtained. When associated injuries are present, the cardiovascular surgeon should be involved with the treatment and prioritization of these injuries.

Three recent papers have attempted to grade CT findings of TAT along the lines of pathologic injury. The Simplest of these is the Vancouver simplified grading systems described by Lamarche et al. (/ Thorac Cardiovasc Surg 2011). In order from least to most severe: Grade I is defined as an intimal flap/thrombus/hematoma <1 cm in length; Grade II as intimal flap/thrombus/hematoma >1 cm; Grade III pseudoaneurysm formation; and Grade IV free contrast extravasation. Furthermore, the authors correlated these findings to outcomes in a small subset of patients, advocating observation for all Grade I and some Grade II injuries with no mortality. Grade III injuries were treated with intervention and hospital survival in 90% and Grade IV with only 33% survival despite intervention. These favorable data can be used to guide operative decision making.

CTA can be both diagnostic and used for planning of operative intervention. Sizing of landing zones for TEVAR, presence of anomalous great vessel anatomy, patency of vertebral circulation, evidence of prior coronary grafting from internal mammary, angulation of aortic arch, and presence of other injuries can all be assessed with appropriate CTA. When CTA is being performed for suspected TAT, it is advantageous to scan the entire vascular tree from neck to femoral vessels. This allows for assessment of access vessels
in the event of possible TEVAR without adding to the contrast administration. One must consider that in younger patients with compliant vessels, intake CT scans may underestimate the actual size of the aorta and iliac system. Several millimeters of variance have been described in the under-resuscitated state. Furthermore, the more dynamic pulsation of the aorta in a young patient can be misrepresented on a static scan. This can lead to inappropriate oversizing of an endograft as will be described later. In patients with a documented anaphylactic reaction to iodine, or concern for renal failure, a noncontrasted thin cut CT scan can still be a useful adjunct in evaluating TAT and for operative planning and can be augmented by other modalities such as TEE and intravascular ultrasound (IVUS).

**MEDICAL THERAPY**

The use of anti-impulse therapy was first applied in the management of descending thoracic dissection and has expanded to use in the management of acute traumatic aortic injuries. This therapy decreases the wall stress tension in the aorta by means of beta-blockade and, if necessary, vaso-dilating agents. Prospective studies have demonstrated a decrease in the incidence of spontaneous rupture with the institution of appropriate anti-impulse therapy. This is an important aspect in the management of multiply injured patients where other life-threatening injuries need to be addressed first, prior to aortic repair.

The goals of therapy are to reduce systolic blood pressure to <100 mmHg. This is best achieved with a combination of pain control, inotropic/chronotropic blockade, and afterload reduction. Often overlooked is the importance of adequate analgesia. The contribution of acute pain to the cascade of catecholamine release is significant and appropriate treatment with intravenous opiates is warranted. One of the most feared complications of TAT is paraplegia from spinal cord infarction either spontaneously or from treatment. As such, the use of intrathecal analgesia is contraindicated.

Initiation of therapy with beta-blockade is the standard of care. The goal heart rate is <80 bpm. By initiating beta-blockade early, reflex tachycardia and catecholamine release are blunted with the initiation of afterload reducing agents. Choice of a beta-blocker, for example labetalol, with α and β adrenergic effects may achieve appropriate cardiac and peripheral effects with a single agent. However, this may precipitate pulmonary complications in at-risk patients and thus initiation of therapy with a short acting agent, for example esmolol, may be more prudent in selected cases. Initiation of sodium nitroprusside infusion after beta-blockade has been an effective agent. However, recent data have shown similar efficacy of nicardipine infusion in treatment of acute type B dissection without the risk of cyanide toxicity and may be applied to TAT.

**TIMING OF REPAIR**

While expectant management of a potentially fatal injury pattern can be anxiety provoking, the scope of injuries in the TAT patient often makes this management advantageous. Perceived advantages of delayed repair include allowing for appropriate resuscitation, time for full evaluation and treatment of other life-threatening injuries, stabilization of intracranial or solid-organ injuries, which may potentially hemorrhage with heparinization, improvement in pulmonary mechanics in patients requiring significant ventilator support, correction of hypothermia and coagulopathy, and allow for proper sizing and acquisition of endografts if TEVAR is planned.

An inherent bias exists in the literature regarding this issue. Intuitively, the patients with the most severe grade of TAT will necessarily require a more immediate operation and have expected worse outcomes. The AAST evaluated this issue in a prospective manner. Two major groups were examined—those with and without major extrathoracic injuries. In the group with major extrathoracic injuries, the mortality in the early repair group was 21.6% versus 3.2% in the delayed repair group. Even when adjusting for severity of injuries and modality of repair in a regression analysis, this trend toward improved overall survival in delayed repair was evident. A similar trend was described in patients with no other associated injuries. The authors in the AAST advocate delayed repair when feasible in all comers, although it is more difficult to justify observation of a potentially fatal injury in an otherwise stable patient based on these data alone. Conversely, a recent consensus statement from the Society of Vascular Surgery states that most patients should be repaired within 24 hours when feasible. Careful consideration of the entire clinical picture combined with appropriate grading of the injury on CTA will lead to the most judicious timing of intervention.

**CHOICE OF MODALITY**

TEVAR for TAT has rapidly gained acceptance as an alternative to OSR. In fact, in a recent meta-analysis of OSR versus TEVAR for TAT, TEVAR was performed in the majority of cases (60%). There are currently several device-specific trials attempting to gain Federal Drug Administration (FDA) indication for TAT; however, it must be mentioned that this remains an off-label therapy for commercially available grafts in the United States at this time.

The perceived advantages of TEVAR in other aortic pathologies also make it an attractive option in TAT as well. The devices can be delivered from remote sites without the need for a major cavity operation in patients who may have associate injuries in these areas. In addition, heparin administration is significantly less than that needed for cardiopulmonary bypass, and TEVAR can be performed under regional anesthesia in many cases. No aortic cross-clamping is needed attenuating the hemodynamic effects on both the heart and distal vasculature. Reported rates of spinal cord infarction are significantly less with TEVAR than OSR, and paraplegia can often be managed expectantly without the need of prophylactic spinal drainage.

However, as with any new technology, TEVAR has developed a new set of complications. Rupture of access vessels due to the large-bore devices was common in early experiences and still remains an important consideration in operative planning. Careful attention to evidence of anomalous arch anatomy or prior coronary bypass is crucial to prevent coverage of vital branch vessels. Proper oversizing of the endograft is difficult in the young trauma patient, and angulation of the distal arch can make delivery and seal of the proximal aspect of the stent difficult, both of which may lead to proximal type I endoleak or collapse of the endograft. Type I and Type II endoleaks are present in up to 20% of cases necessitating repeat intervention.

Similar to evaluating delayed versus immediate intervention, bias exists in evaluating the literature regarding OSR versus TEVAR. In five of six meta-analyses comparing the two modalities, operative mortality was in favor of TEVAR, but in those studies reporting timing or severity of injury, OSR was more often the modality chosen. However, in more contemporary series, the perioperative mortality and paraplegia rate have favored TEVAR. In the same cohort of patients from the prior study, the AAST investigators evaluated OSR versus TEVAR in a prospective manner. In patients
with and without other associated injuries, the mortality was significantly lower with TEVAR as was paraplegia (2.9% OSR, 0.8% TEVAR). There was no associated difference in ICU stay, systemic complications, or days of ventilator dependence.

The pooled data on TEVAR are limited by a mean follow up of only 18 months. Similar to evaluation OSR versus TEVAR for aneurysm disease, it appears that the survival benefit of TEVAR is lost after 1 year, likely due to the not insignificant morbidity and mortality of subsequent interventions required in patients treated with TEVAR. Perhaps, the most important factor limiting application of TEVAR to all cases of TAT is the lack of long-term data regarding performance of the grafts in young patients. Concern exists regarding potential for migration as the aorta dilates with age. Further, it is unknown whether these devices will suffer material fatigue when implanted for extended periods of time. Several reports describe successful salvage of failed endografts with open repair.

No clear data exist to definitively favor one modality over the other. A strong trend toward decreased perioperative mortality and paraplegia in patients treated with TEVAR for TAT. This technique can expand therapy to patients who are not candidates for open repair. Evaluation of anatomy, associated injuries, urgency of repair, and patient age will lead to proper operative decision making.

**OPEN SURGICAL MANAGEMENT**

The surgical preparation of a patient with an acute TAT should be done in an orderly manner. Every attempt to approach this problem as elective surgery should be made if the patient is stable. It is of paramount importance that the patient and the family be thoroughly counseled about the procedure and specifically about the perioperative risks of paraplegia. This is a lethal injury, and the possibility of death from other injuries or from the transected aorta should be thoroughly discussed with the family. The other major risks of the operation should be discussed. These include the possibility of infection, renal failure, respiratory distress syndrome, vocal cord paralysis, and complications from other associated injuries.

If at all possible, a double-lumen endotracheal tube should be placed for the procedure because this will greatly facilitate exposure of the injury. If there is a question of a cervical spine injury, it should be ruled out before the patient is taken to the operating room. A cervical collar makes anesthetic intubation difficult and limits access to the neck, should the placement of additional intravenous lines be necessary. Appropriate monitoring and resuscitative lines should be placed. A cardiopulmonary perfusionist should be available. The blood pressure in the upper extremities should be monitored through a right radial artery catheter, because during the repair the left subclavian artery (LSCA) will need to be occluded and inaccurate readings will be obtained from a left radial artery catheter.

The left groin is left free in case access is needed for bypass procedures or for other lines. Our preference is to place a Swan sheath for its size and to use a true Swan–Ganz catheter only when hemodynamic questions arise. We do not routinely monitor cerebral spinal fluid (CSF) pressure, because this adds time and complexity to the procedure with little known benefit in the acute trauma setting. All patients receive prophylactic antibiotic therapy mainly aimed at prevention of *Staphylococcus aureus* infection in anticipation of potentially placing a prosthetic graft in the aortic position. Several sizes of aortic grafts should be in the room and made available. Our routine is to size the aorta intraoperatively, either visually or with sizers, which generally gives us an accurate idea of what size of graft to use. Our graft preference is a pretreated woven graft, which does not require preclotting.

After all the preoperative plans have been made, the patient is taken to the operating room, placed in the supine position, and anesthetized. The induction of anesthesia and intubation is a very critical point in the procedure. Every attempt should be made to avoid severe blood pressure fluctuations, because any hypertension can precipitate a rupture. The patient is then placed in the right lateral decubitus position. Positioning and padding of the extremities are to be performed at this juncture. In addition, we like to position the patient so the left groin is available in case the femoral artery or femoral vein needs to be exposed during the procedure. The patient is prepared and draped. Our preference is to use an anti-septic-impregnated plastic drape to keep as much skin covered as possible considering the probability of a prosthetic graft being used during the procedure.

A full posterolateral thoracotomy incision is made from just below the left nipple. Both the latissimus dorsi and serratus anterior are divided, and the fourth intercostal space should be chosen for entering the pleural cavity as a fifth interspace incision can make the exposure difficult. It is usually not necessary to excise a rib. However, if exposure is inadequate on opening of the chest cavity, our procedure has been to resect 1 cm of rib (posteriorly, behind the paraspinal ligament) below our initial incision to allow additional exposure.

Once the pleura is entered, the left lung is deflated and adequate ventilation ensured. After the lung is deflated, often a formidable, large pulsating hematoma will be seen in the mediastinum. The surgeon should proceed deliberately to obtain proximal and distal control. Distal control is usually obtained first, because this is easiest to perform and avoids precipitating free rupture. It is important when dissecting around the distal aorta to avoid the intercostal artery branches, which are paired and come off each side. It is preferable not to sacrifice any intercostals but to go between the intercostals and encircle the aorta with an umbilical tape.
vascular clamp s. It is much easier to pull without exsanguination occurring first). When the clamp is placed, it is completely around the aorta. Attention is then turned superiorly. The subclavian artery can be palpated easily and often is involved in the periaortic hematoma. Control of the subclavian artery is important and should be obtained even when the angiogram suggests that the injury is distal to its takeoff. We prefer a Rommel tourniquet on the subclavian artery, because it takes up very little space in the surgical field and is more than adequate to provide hemostasis during the repair. Placement of the proximal aortic clamp is one of the most important technical parts of the operation. It is preferable to place this clamp distal to the left carotid, but well proximal to the takeoff of the LSCA. Although aortic transections are usually distal to the takeoff of the LSCA, this extra portion of aorta is often necessary to obtain a good repair. In addition, intimal tears may extend further proximally than can be appreciated by preoperative imaging. Attempts to obtain control distal to the takeoff of the LSCA are often met with rupture of the pseudoaneurysm, because, invariably, the hematoma is entered or friable aortic tissue is encountered in this region. When a clamp is placed distal to the left subclavian, the tear will often extend into the clamp, and it may be necessary to obtain more proximal control (which may not be possible without exsanguination occurring first). The vagus nerve runs in this area, with the recurrent branch as well. The recurrent branch is almost never seen because of the hematoma, but the vagus can usually be seen stretched by the hematoma. By staying anterior to this nerve, one should easily be able to obtain proximal control of the aorta. A finger can usually be placed gingerly between the left carotid and the left subclavian around the aorta in this area to create a proximal clamp site. At this point, an umbilical tape is passed to provide a handle to place the clamp at a later time.

One should be aware that multiple aortic tears are possible. The tear at the isthmus is sometimes associated with a tear in the arch, the ascending aorta, or the great vessels, and this should be anticipated as well and preferably ascertained on preoperative imaging. On rare occasions, the clamp will have to be placed between the innominate and left carotid to gain adequate proximal control.

When proceeding with partial left heart bypass, it is necessary to establish a drainage line and a return line to the patient (Fig. 62.3). Many sites are available for this. Our preference is to use the junction of the left atrium with the superior pulmonary vein (or, alternatively, via the left atrial appendage) for drainage and the descending aorta distal to our distal clamp for return. The lung should be retracted laterally and the pericardium opened with care to avoid injury to the phrenic nerve. We usually open the pericardium posterior to the phrenic nerve immediately anterior to the pulmonary veins, but occasionally have opened it anterior to the phrenic nerve. The surgeon should inspect the pericardium before deciding on which side of the phrenic nerve to incise the pericardium. Usually, the left atrial appendage can be identified easily because it beats within the pericardium. In the decubitus position, there is almost an up-and-down motion of the appendage. When the pericardium is opened, the left atrial appendage almost “pops” up into the wound. On occasion, the pericardium can be ruptured from the blunt trauma, and access can be obtained through the rupture. The tip of the appendage may appear friable, it is for this reason that we have occasionally obtained venous drainage at the confluence of the left superior pulmonary vein and the left atrium. This area takes sutures well. To avoid tears in the left atrial appendage, we place a purse string of 2-0 braided polyester suture in the best appearing tissue. The tip of the appendage is amputated, and a venous drainage catheter is placed into the left atrium. Depending on the size of the patient, a 26-, 28-, or 30-F wire-reinforced venous cannula is selected. With a 28-F drainage catheter, flows can be obtained in the 3- to 4-liter range without difficulty. During the placement of this catheter in the atrium, communication between the anesthesiologist and the surgeon is important as the clamp is removed from the appendage. A Valsalva maneuver is performed to prevent entry of air into the left side of the heart as the cannula is placed, and a Rommel tourniquet is secured and tied to the cannula. The connection to the inlet tubing of the pump is freed of air.

Distal perfusion can be obtained in several areas. If it appears reasonable, the descending aorta well away from the injury is cannulated through the thoracotomy wound. An 18- to 20-F flexible cannula is usually sufficient for adequate flow. Alternatively, if descending aortic cannulation is not feasible, an incision is made in the left groin. The femoral artery is dissected and a femoral artery cannula inserted. In patients with multiple injuries or fractures with possible delayed or remote bleeding, this circuit can be used without heparin or a very minimal amount of heparin, such as 5,000 units.

At this point, a graft is chosen. We have used both knitted and preclotted woven grafts. The knitted grafts are easier to sew, but must be preclotted before heparinization.
Section II: Adult Cardiac Surgery

Fig. 62.4. The proximal aortic clamp is placed on the transverse arch as the left heart bypass circuit is initiated. Pump flows are adjusted as the clamp is placed to ensure adequate proximal and distal aortic perfusion pressures.

Appropriate vascular clamps are chosen to be used for the proximal and distal control. Before the clamps are placed for repair of the transection, mannitol (12.5 to 25 g [0.25 to 0.5 mg/kg]) is administered to maximize renal perfusion.

Once all the above steps are accomplished, the proximal aortic clamp is applied (Fig. 62.4). Proximal hypertension is alleviated by increasing left heart assist to unload the left heart as the clamp is secured. The distal clamp is applied, and then the snare on the subclavian artery is secured. The operation should proceed expeditiously but in an orderly manner. The hematoma is opened, usually met with a disconcerting amount of blood that should be anticipated. With the clamps properly placed, active bleeding should not be seen from any of the clamp sites. Bleeding from intercostal collaterals is expected; however, this should not be a cumbersome amount. If the clamps are not placed all the way across the aorta, time will be wasted in obtaining proximal or distal control, and a large amount of blood will be lost. Once the hematoma is entered, the site of the tear will be obvious. In the case of complete transection, the stumps may be retracted and separated by several centimeters. Once the free ends are identified, the edges of both sides should be freshened, excising to good tissue (Fig. 62.5). Sometimes, a primary repair may be possible. However, in the majority of cases a graft will be needed to bridge the gap without undue tension. Sometimes, bleeding from intercostals can be problematic, and these can be controlled with bulldog clamps, hemoclips, or silk ligatures as needed. We try not to sacrifice any intercostals unless they are involved directly in the tear and cannot be salvaged.

We prefer to address the proximal aorta first because this is typically the more difficult anastomosis as a result of relatively limited exposure around the ligamentum and the friable and unpredictable nature of the tissue in this area. Our preference is to use a double-arm 4-0 polypropylene suture without pledgets and to perform the anastomosis in a simple running manner. Care should be taken not to place the sutures blindly and deep in this area because the esophagus and recurrent laryngeal nerve are immediately adjacent and posterioromedical to this area. After the proximal anastomosis is completed, the graft is stretched and cut to length. An important point is to cut the graft appropriately. Too long a graft will lead to kinking; too short a graft will create tension and tearing of the aorta as sutures are placed. The distal suture line is then done with a running 4-0 Prolene suture. Just before the anastomosis is completed, the distal clamp is removed to check for hemostasis and to deair the aorta (Fig. 62.6). The anastomosis is completed and the proximal clamp removed after deairing. Weaning from left heart assist is done simultaneously with the removal of the proximal clamp. Sometimes, hypotension will develop, which requires reapplication of a clamp either partially or totally to restore the proximal blood pressure; then, as volume is added, an adequate pressure proximally and distally can be maintained.

At this point, the proximal and distal suture lines can be further examined. Sometimes bleeding is seen and can be controlled with simple sutures. However, bleeding from needle holes or just oozing

Fig. 62.5. The hematoma is opened after left heart assist is achieved. The friable aortic edges are carefully debrided to good tissue, any intercostal bleeders are controlled, and the recurrent nerve is avoided.
from distal suture lines should be watched; if heparin has been administered, it should be reversed with protamine to allow these sites to clot. Usually, packing the area and waiting 5 to 10 minutes will reveal complete hemostasis. At this point, the bypass circuit, if used, can be removed and the previously placed purse strings tied to ensure hemostasis. Before the thoracotomy is closed, we cover the graft, especially the suture lines, with mediastinal pleura using absorbable sutures to exclude the graft site from the lung.

Over the years, our technique for repair has evolved from one in which all cases were done in a clamp-and-sew manner to one in which we nearly routinely use left heart bypass from the left atrium to the descending aorta or to the left femoral artery using a centrifugal pump with very little heparinization. However, when this is not technically feasible, or in cases of free rupture, we do not hesitate to perform the clamp-and-sew technique. We do not use passive shunts because flow cannot be regulated. The other advantage of using a centrifugal type of left heart assist is the ability to warm or cool the blood as a heat exchanger can be easily added to the circuit.

We do not believe that any one technique has been conclusively proven to prevent paraplegia. It is our opinion that expeditious and timely repair of this lesion is the most important aspect in preventing this complication. Much has been made of the 30-minute ischemia period as a contributing factor to paraplegia. However, there have been many cases reported of clamp times much longer than this with no evidence of paraplegia. The complication of paraplegia is probably multifactorial, and time represents only one factor. However, partial left heart assist may benefit in other ways, because it does maintain distal perfusion pressure and allows us to unload the left heart and avoid hypertension proximal to the clamp. It, therefore, may help to avoid the use of vasodilating agents such as nitroprusside, which have been known to cause decreased blood flow to the spinal cord. Most importantly, it maintains perfusion to the lower body and kidneys during the period of cross-clamping. It also allows the opportunity to either cool or warm the patient in an expeditious manner. Although it does add complexity to the operation, we believe that its benefits are well worth the effort.

**ENDOVASCULAR MANAGEMENT**

Operative preparation, monitoring, and blood availability for TEVAR should proceed similar to that for open repair. Anesthetic technique can be either general or sedation with local anesthetic if femoral access is evaluated on CT. Most new generation thoracic endografts are engineered to withstand the unique pressures and hemodynamics present in the distal arch and have improved delivery systems for this area. When at all possible, a thoracic device should be used for TEVAR in TAT (Fig. 62.7).

In choosing an appropriate access site, the diameter and nature of the iliac vessels is evaluated on CT. Most new generation thoracic endografts can be delivered through 20- to 22-F outer diameter sheaths. An access vessel of 7 mm should be more than adequate. In the younger patient and those without atherosclerosis on CTA, the external iliac arteries are often compliant
and can still receive the device. Again, IVUS can be critical in evaluating the true size and presence of atherosclerosis when performing TEVAR. In pooled analyses of over 25 experiences with TEVAR in TAT, the need for iliac or aortic conduit was only 8.7%.

Once the patient is properly prepared, an oblique incision is made over the femoral artery and an appropriate length of common femoral artery is dissected and controlled with a Potts vessel loop. Unless bulky atherosclerosis is encountered in the femoral, dissection of the bifurcation is not warranted. Access is gained to the exposed artery and a 9-F sheath is placed. Diagnostic access is then gained percutaneously in the contralateral femoral or right brachial artery (the left brachial is avoided due to the involvement, and possible need to cover, the left subclavian). A guidewire is then placed from the 9-F sheath into the ascending aorta. Over this, the IVUS catheter is introduced and evaluation of the iliac and aorta commences. If any question exists regarding access vessels, this is the appropriate time to change to a conduit. A 10-mm Dacron conduit is then sewn end to side on the common iliac or distal aorta and then accessed with a 9-F sheath. Sizing of the aorta in systole allows for precise oversizing of the endograft. In TAT, we recommend oversizing of only 10% to 15% to decrease the incidence of endocollapse and decrease the “stretch” of the graft on the aorta, which may precipitate further propagation of dissection either proximally or distally. Newer devices now have tapered configurations to aid in appropriate sizing as the aorta is often significantly larger at the distal arch than mid-thoracic region. Pull back measurements are made to ensure 15 mm of seal on either side of the injury and the shortest component chosen that covers the injured site to limit the number of intercostal arteries sacrificed. At this point, the endograft can be opened and prepared on the back table, along with an appropriate compliant aortic occlusion balloon.

A marking flush catheter is then placed in the ascending aorta and diagnostic aortogram performed. A left oblique position of the type II should be utilized to open up the arch, usually around 40 degrees. A 30-cm³ injection is usually adequate. Confirmation of arch anatomy, vertebral anatomy, site of injury, and presence of internal mammary grafts is made at this juncture. Selection of the vertebral arteries is not routine unless definitive coverage of the left subclavian is planned, and any question exists regarding vertebral anatomy or fetal posterior circulation from preoperative imaging. The proposed landing sites are marked on the imaging screen and length measurements confirmed. At this point, the patient should be heparinized as above.

Working over the stiff guidewire, the device sheath (or device itself depending on manufacturer) and then the device are advanced to the area of intended delivery. The flush catheter is positioned just proximal to the proximal landing zone and a magnified aortogram is performed. The
critical anatomy is marked and the device is then advanced past the landing zone to remove any energy built up in the delivery shaft and then slowly pulled back to the intended mark. This is often the most critical step in deployment. The angulation of the arch at the isthmus can be severe, especially in young patients. A major limitation is the ability to track the device over the curve of the distal arch. Significant force is placed on the outer curve of the aorta and this can precipitate rupture in a tenuous injury. The newer generation devices have improved tips for trackability; however, this can still be a challenge. Occasionally, right brachial access is needed. A snare system is used to create a “floss” of the patient where the wire is tethered both outside the right brachial sheath and in the access sheath. The “floss” should be performed using a floppy glidewire and then exchanged for a stiff wire through a catheter. This technique will greatly improve the trackability of the device over the arch and decrease the stress on the outer curve of the aorta. Conversely, we have had to convert to a sternotomy and antegrade access in this situation when the device cannot pass.

Once in proper position, the graft is deployed via the specific manufacturer’s recommendation. We routinely leave the flush catheter behind the device to preserve access behind the graft in case of inadvertent coverage of a branch vessel. It can then be retracted over a wire and replaced through the graft after deployment. The device is removed and gentle molding with a compliant balloon is recommended for any areas that do not fully conform to the aortic wall. This is not mandatory, however, is often helpful in eliminating the “bird-beak” effect in the proximal landing zone. A completion angiography is performed, and repeat IVUS can confirm apposition of the stent to the aortic wall.

The catheters and balloon are removed. Final removal of the large-bore access sheath is the last critical component of the case. It is during this step that the external iliac artery can be sheared from the iliac bifurcation (the so-called “iliac on a stick”). This will precipitate exanguinating hemorrhage. We, therefore, advocate removal of the sheath over a guidewire left in the aorta. This facilitates rapid placement of an occlusion balloon into the aorta for proximal control and then expeditious open or endovascular repair of the iliac injury.

Once the device is removed and pulsatile infow confirmed, the femoral arteriotomy is closed, or conduit is oversewn. Routine angiography of the iliac is not necessary, but if any question exists regarding iliac injury, the diagnostic catheter from either the contralateral femoral or brachial can be used for diagnostic purposes. Pulses in the feet and wrist are confirmed to be the same as preoperative and protamine is administered. After removal of all devices, the patient can be transferred back to the ICU for further management of his injuries. If necessary, blood pressure can now be liberalized and we recommend maintaining a systolic pressure of at least 110 mmHg to aid in spinal cord perfusion. Neuromotor checks are performed frequently and expectant management of paraplegia is appropriate. A follow-up CTA is recommended before discharge. Any signs of lower extremity malperfusion, sudden drop in urine output, and severe right arm hypertension should alert the intensive care team to the potential for endograft collapse which is a life-threatening emergency. Emergent CTA angiography is warranted, although if the necessary personnel are in the hospital, proceeding directly to the angiography suite is appropriate as well.

The management of the LSCA warrants special consideration. Due to the relatively low risk of paraplegia with coverage of subclavian collaterals in patients with TEVAR for TAT, the Society for Vascular Surgery recently released guidelines recommending elective revascularization of the LSCA. In the majority of cases, coverage is well tolerated and upper arm arterial insufficiency or vertebralbasilar symptoms can be managed with delayed revascularization. With the exception of hypoplastic right vertebral artery and patent left internal mammary artery (LIMA) grafts, traumatic TEVAR can proceed without this step as delay in aortic repair and additional operation with heparin administration is not warranted in most cases.

**CONCLUSION**

Improvements in trauma systems, critical care, and imaging of the injured patients have greatly altered the landscape of this lethal injury. Managing the spectrum of aortic transection and other associated injuries in these complex patients remains a challenge. Advances in both the medical management of the TAT patient and a careful selection of patients appropriate for delayed repair have improved overall outcomes. Application of both precise surgical technique and mastery of endovascular skills allows for appropriate selection of modality to best treat the individual patient.

**SUGGESTED READINGS**

Mattox KL, Holzman M, Laurens R. Clamp repair: a safe technique for treatment of blunt injury

Chapter 62: Acute Traumatic Aortic Transection

619

CT angiography, then there is suspicion of injury. The patients are often treated electively particularly if multiple other injuries are present. There have been a very few cases of a rupture occurring during the waiting period. Repair has pretty much all switched over to TEVAR. It is very rare to do an open repair for this injury anymore. This has been done without any significant comparative data of open repair versus TEVAR.

There are several issues that need to be discussed. I am in full agreement with elective subclavian artery revascularization following TEVAR repair. I think this is an appropriate technique and can easily be done with a carotid subclavian bypass. I am in full agreement with TEVAR but the long-term results are not clear. These are young patients with normal sized aortas, and what will happen to repairs in the long run is not certain.

Having said all this, we now can avoid rushing patients having multiple organ injuries to the operating room. I believe this has been a huge advance and believe we salvage more patients than we used to.

ILK
INTRODUCTION

The techniques developed by Norman Shumway and Richard Lower at Stanford University set the stage for heart transplantation to become the therapy of choice for patients with end-stage heart failure. The introduction of transvenous endomyocardial biopsy and the advent of cyclosporine immunosuppression dramatically increased patient survival and marked the beginning of the modern era of successful cardiac transplantation. Heart transplantation is now a widely accepted therapeutic option for end-stage cardiac failure, with more than 3,300 procedures performed annually.

RECIPIENT SELECTION

Patients with end-stage heart disease who are being considered as potential candidates for cardiac transplantation should be evaluated by a multidisciplinary committee to ensure an equitable, objective, and medically justified allocation of the limited donor organs. This process should select patients with the greatest chance of postoperative survival and rehabilitation. The primary objective of the recipient selection process is to identify patients with irreversible cardiac disease not amenable to other therapy (optimization of medical therapy, revascularization, ventricular remodeling, valve repair/replacement, biventricular pacing). In our center, the evaluation for a ventricular device is part of the transplant selection process. It is desirable to identify patients who will most likely resume a normal active life and be compliant with the rigorous postoperative medical regimen. Recent successes and the introduction of improved immunosuppression have significantly expanded the eligibility criteria. Patients with New York Heart Association class III or IV symptoms despite optimal medical therapy should be considered for cardiac transplantation. Most patients present with end-stage heart failure due to ischemic heart disease or idiopathic dilated cardiomyopathy. However, the spectrum of known causes of end-stage cardiomyopathy includes infectious (viral), inflammatory, toxic, metabolic, and familial etiologies. Patients selected for cardiac transplantation should have a predicted 2-year survival of <50%. Other less common indications for cardiac transplant include refractory angina, life-threatening arrhythmias, and chronic cardiac allograft rejection. Contraindications to cardiac transplant are primarily based on comorbid illnesses. Examples of widely accepted contraindications include active infection, irreversible hepatic dysfunction, and fixed pulmonary hypertension (pulmonary artery systolic pressure >60 mmHg, transpulmonary gradient >15 mmHg, pulmonary vascular resistance >6 Wood units). Many centers have demonstrated that a left ventricular assist device (LVAD) can be used to reverse fixed pulmonary hypertension and allow patients to become transplant patients. Age in no longer considered to be a contraindication to cardiac transplant.

Preoperative Recipient Evaluation

Evaluation for cardiac transplantation begins with a comprehensive history and physical examination, chest roentgenogram, and lab work including complete blood count, coagulation screen, erythrocyte sedimentation rate, uric acid level, liver function tests, fasting lipid panel, and infectious disease serologies (hepatitis A, B, and C, herpes simplex virus, human immunodeficiency virus, rapid plasma regain, rubella, measles, Toxoplasma). All patients should undergo an exercise test with peak exercise oxygen consumption (peak VO₂) measurement. Available studies suggest that patients with peak VO₂ <14 ml/min/kg have improved survival and significant functional benefit with transplantation. A right heart cardiac catheterization study should be performed to rule out irreversible pulmonary hypertension. For patients with ischemic cardiomyopathy, coronary angiography should be reviewed or repeated to confirm the inoperability of coronary artery disease. For patients with non-ischemic cardiomyopathies and prolonged or atypical symptoms, endomyocardial biopsy should be performed to rule out the possibility of a medically treatable illness.

Most centers also include nutritional labs, thyroid function studies, fasting and post-prandial blood sugar, creatinine clearance, 12-lead electrocardiogram, echocardiogram, pulmonary function tests, panel reactive antibody screen, HLA typing, vascular screening exams (abdominal ultrasound, carotid and lower extremity Doppler flow studies), esophagastroduodenoscopy, psychosocial evaluation, dental evaluation, financial analysis, and screening studies for malignancy (stool guaiac, prostate-specific antigen, mammogram, Papanicolaou smear).

Patients listed for transplantation should be examined routinely for re-evaluation of recipient status. Repeat right heart catheterization is indicated when follow-up echo studies suggest worsening or persistent pulmonary hypertension. Actively listed patients should undergo a repeat right heart catheterization at least twice annually.

DONOR AVAILABILITY AND ALLOCATION

Donor organ availability is the primary factor limiting the application of heart transplantation.
transplantation. As a result, 20% to 40% of patients on the waiting list may die before transplantation. Organ allocation is based on recipient priority status, time on the waiting list, and proximity. Highest priority is given to local status IA patients with the longest accrued waiting time. The allocation system is designed to provide the most critically ill patient with a heart while minimizing allograft ischemic time. Although only 25% of patients are classified as status 1 at the time of listing, 48% progress to status 1 by the time of transplantation. The mean waiting period for a status 2 candidate is currently >1 year, whereas status 1 patients wait a mean of 60 days. There is significant variation in waiting times from region to region. Due to this variability, many more patients require an LVAD as a bridge to transplant, in some regions as many as 85% of blood type 0 patients require an LVAD bridge.

**Donor Selection**

Potential cardiac donors undergo a rigorous screening evaluation. The local organ procurement agency should provide the implanting program with patient’s age, height, weight, gender, blood type, hospital course, cause of death, routine laboratory data, and viral serologies. Additional required data include electrocardiogram, chest roentgenogram, arterial blood gas, and echocardiogram. Coronary angiogram is indicated in a selective manner. The presence of advance donor age (male donors >45 years of age, female donors >50 years of age), risk factors for atherosclerotic coronary artery disease (tobacco abuse, diabetes, significant family history), and occasionally the mechanism of death should be evaluated to determine the need for coronary angiogram. When a member of the transplant team arrives for organ procurement, a secondary screening is performed. This secondary screening allows the recovering surgeon to confirm and review the data presented by the procurement agency. The most important donor screening occurs in the operating room at the time of organ procurement. The heart is examined to identify ventricular or valvular dysfunction previous infarction, coronary atherosclerosis, or myocardial contusion. If direct examination of the heart is unremarkable, the procurement surgeons proceed with donor cardiectomy.

Matching potential recipients with the appropriate donor is based primarily on blood group compatibility and patient size. As a rule, ABO barriers should not be crossed in heart transplantation because incompatibility frequently results in fatal hyperacute rejection. Donor weight should ideally be within 30% of recipient weight except in pediatric patients, where closer size matching is required. If the recipient has elevated pulmonary vascular resistance (>4 Wood units), a larger donor is preferred to reduce the risk of right ventricular failure in the early postoperative period. When the recipient has an LVAD, special consideration should be given to the location of the donor; in these cases, the variable time required to explant the device mandates that the implanting surgeon be able to control the cross-clamp time and organ arrival times. When the percentage (or the panel) reactive antibody (PRA) is >10% to 15%, a prospective negative T-cell cross-match between recipient and donor sera is recommended before transplantation. Some centers also insist on a negative B-cell cross-match before transplantation. A positive cross-match is an absolute contraindication to transplantation. A cross-match is always performed retrospectively, even if the PRA is absent or low. Retrospective studies have also demonstrated that better matching at the HLA-DR locus results in fewer episodes of rejection and infection and an overall improved survival. Because of current allocation criteria and limits on ischemic time of the cardiac allograft, prospective HLA matching is not always logistically possible. Many centers have begun to selectively use virtual cross-matching in cases where recipient serum is not available.

There have been recent reports that “extended” donors can be safely used to obtain similar short-term results observed with standard donors. The term “extended” refers to patients with advanced age, high-risk social behavior, limited coronary artery disease, or positive viral serologies. When used, the extended donors are matched to high-risk recipients in which increased risks are acceptable.

**DONOR HEART PROCUREMENT**

During the secondary donor screening, the location of central and arterial lines should be noted. The location of these lines may affect the conduct of the organ harvest. It is important to continually monitor the donor's volume status and urine output during the harvest to maintain organ function. The donor is positioned in the supine position and widely prepped from chin to knees. To facilitate both thoracic and abdominal organ recovery, the harvest is begun with a midline incision from sternal notch to pubis, including a median sternotomy. The pericardium is incised and a pericardial well is created. The heart is examined to assure no previously unidentified anomalies exist. After this inspection, the harvesting surgeon should notify the implanting surgeon regarding the suitability of the heart for transplantation.

The heart is then mobilized for cardiectomy. It is important for the harvesting surgeon to know whether any extended lengths of vessels will be necessary to facilitate implantation. For our preferred method of implantation, the bicaval technique, an extended length of superior vena cava (SVC) is required. The SVC is mobilized from the right atrium to the innominate vein. SVC mobilization usually includes dissection of the right pulmonary artery and ligation of theazygous vein. If additional caval length is required, the innominate vein can be harvested en bloc. The inferior vena cava (IVC) is dissected and mobilized circumferentially. Encircling the SVC and IVC with umbilical tapes or heavy suture may assist with retraction during cardiectomy. The aorta is dissected from the pulmonary artery and then isolated with umbilical tape. If hemodynamic instability is encountered during the harvest, clamping of the abdominal aorta at the iliac bifurcation may be helpful. Once the mobilization of the abdominal organs is complete, the donor is given 30,000 units of heparin intravenously. A purse-string suture is placed in the ascending aorta, through which an antegrade cardioplegia catheter is placed. The central venous pressure line is pulled back to beyond the caval-innominate junction. After assurance is given that the abdominal team is ready to proceed, the SVC is clamped or ligated distal to theazygous vein (this avoids sinoatrial nodal injury) (Fig. 63.1).

If the abdominal IVC is vented, the IVC is clamped at the level of the diaphragm. The heart is vented by transecting the left inferior pulmonary vein (or left atrial appendage if the lungs are being concomitantly harvested) and incising the anterior IVC proximal to the clamp. The aortic cross-clamp is applied, and the heart is arrested with cold cardioplegic solution. Adequate perfusion pressure is assessed by palpating the aortic root. The left ventricle should also be monitored to assure that it does not become dilated. Rapid cooling of the heart is achieved with 10 L of topical cold saline (4°C). After a successful arrest, cardiectomy is initiated by completing the transaction of the IVC (Fig. 63.2). The heart is wrapped in an ice-soaked lap pad, and the apex of the heart is elevated. Proceeding from inferior to superior, first on one side and then the other, one divides the remaining intact pulmonary veins and branch pulmonary arteries. When the lungs are being procured for transplantation, the procedure is modified to retain adequate left atrial cuffs and pulmonary arteries for both the heart and
lungs. The ascending aorta and SVC are transected last. The underlying disease of the recipient should be taken into account when determining the required length of aorta and SVC.

After explanation, the allograft is carefully taken to the back table and placed in a basin of cold saline for inspection and final preparation. The heart is examined for evidence of patent foramen ovale, vascular injuries (or inadequate length), and valvular abnormalities. Any positive findings should be disclosed to the implanting surgeon. The donor heart is then sequentially placed in two sterile bowel bags, each filled with cold saline, a sterile saline-filled air-tight container, and finally a standard cooler of ice for transport.

Several common pitfalls have been identified. Avoiding the following mistakes is vital to successful organ harvest:

1. Failure to monitor the heart closely during multiorgan dissection.
2. Failure to heparinize.
3. Right or left ventricular distension.
4. Failure to adequately cool the heart during harvest and transport.

ORGAN PRESERVATION

Most preservation techniques of the cardiac allografts permit a "safe" ischemic period of 4 to 6 hours, because ischemia times >4 hours have traditionally been associated with poorer outcomes. Multiple factors contribute to postoperative myocardial dysfunction including insults associated with suboptimal donor management, hypothermia, ischemia–reperfusion, and depletion of energy stores. The preservation method used by >90% of transplant centers is a single flush of a cold crystalloid cardioplegic solution followed by hypothermic storage. No single preservation regimen has demonstrated consistently significant superior myocardial protection. Hypothermia is the cornerstone of organ preservation, and some experimental evidence suggests that 4°C provides the best protection. Perfusion of the donor heart with cardioplegic solution to achieve electromechanical arrest is an invaluable adjunct to topical hypothermia. Crystalloid solutions are classified as "intracellular" or "extracellular." Intracellular solutions, characterized by moderate-to-high concentrations of potassium and low concentrations of sodium, purportedly reduce hypothermia-induced cellular edema by mimicking the intracellular milieu. Examples of commonly used intracellular solutions include University of Wisconsin, Euro-Collins and Bretschneider (HTK). Extracellular solutions...
solutions, which are characterized by low-to-moderate potassium and high sodium concentrations, avoid the theoretical potential for cellular damage and increased vascular resistance associated with hyperkalemic solutions. Celsior, Hopkins, and St. Thomas Hospital solutions are representative extracellular cardioplegic solutions. Some centers choose to augment their solution with highly oncotic additives (mannitol, lactobionate, raffinose, and histidine), which theoretically counteract intracellular osmotic pressure to reduce hypothermia-induced cellular edema in the allograft. Several other groups have reported using other additives, including Krebs-cycle substrates and free radical scavengers. Recent developments include the investigation of continuous hypothermic perfusion using portable machines. In animal models, this technology appears to safely extend cold ischemia time up to 24 hours. During graft implantation, myocardial preservation can be augmented with continued use of topical cold saline and retrograde blood cardioplegia.

ORTHOTOPIC HEART TRANSPLANTATION

Nearly all heart transplants are performed in an orthotopic manner. The technique has changed little what was originally described by Shumway and Lower in the 1960s. The transplant surgeon must be well organized to avoid any technical or nontechnical mishaps. Special attention should be paid to assuring that an ABO mismatch does not occur. At our center, the operative surgeon must confirm the donor and recipient blood type prior to incision and again upon arrival of the donor organ. Patients who have been fully anticoagulated preoperatively should be corrected with a combination of vitamin K and fresh-frozen plasma. After the organ procurement team has confirmed that the donor allograft is acceptable, the recipient is taken to the operating room and placed under general anesthesia. Preferentially, central line placement should avoid the right internal jugular to minimize difficulties with future myocardial biopsies. High-dose narcotics are usually the primary agents for induction and maintenance of anesthesia. Inotropic and vasoactive agents should be readily accessible for the rapid management of induction-induced hypotension. Inhaled agents may be added, but their potential myocardial depressant effects limit widespread use in this patient population. Antibiotics should be given at least 30 minutes before skin incision. At our center, we routinely use aminocaproic acid therapy to minimize perioperative blood loss.

Operative Preparation of the Recipient

The heart is exposed via a medium sternotomy and vertical pericardiotomy. If the patient has had prior cardiac surgery, a femoral arterial line may be placed in case cardiac decompensation requires the emergent placement of an intra-aortic balloon pump or the initiation of peripheral cardiopulmonary bypass. In a patient with an LVAD, peripheral arterial cannulation may be preferential, because this often facilitates the aortic anastomosis. The patient is heparinized and prepared for cardiopulmonary bypass. In most cases, the aortic cannula is inserted just proximal to the origin of the innominate artery. Bicaval cannulation is performed with venous cannulae placed at the IVC-atrial junction and directly into the SVC. Umbilical tape snare s are passed around the SVC and IVC. Bypass is initiated, the caval snares are tightened, and any additional cardiac mobilization is performed. After the donor heart has arrived, the ascending aorta is cross-clamped and the cardiectomy is performed. The aorta and main pulmonary artery are transected above the semilunar valves. Most centers now perform bicaval atrial anastomosis, and hence the SVC and IVC are transected at the caval-atrial junction. The left atrium is entered anterior to the right pulmonary veins and then incised along the atroventricular groove to leave an adequate cuff for allograft implantation. Great care should be taken to avoid injury to the left superior pulmonary vein when excising the left atrial appendage. If a bialtral anastomosis is required, a right atrial cuff can be preserved.

To facilitate implantation, the proximal 1 to 2 cm of aorta and pulmonary artery are separated from one another with electrocautery. A weighted sucker placed in the left atrial remnant will keep the field free of blood and augments donor heart myocardial protection. Some centers routinely flood the operative field with CO₂ to assist with graft deairing. Timing of donor and recipient cardiectomies is critical to minimize allograft ischemic time and recipient bypass time. Frequent communication between the procurement and transplant teams permits optimal coordination of the procedures. Ideally, the recipient cardiectomy is completed at the time of cardiac allograft arrival. At our institution, we have a protocol that mandates five telephone calls: first, when the recovery team arrives at the harvest site and assesses the donor, next after visualization of the organ in the operating room, then before cross-clamp at the harvest site, next on leaving the remote site, and finally when arriving locally. At any time, implantation team should be allowed to slow down the harvest process as needed to minimize organ ischemia time. In an era when many recipients have an LVAD at the time of transplant, this is especially crucial, preferably the harvesting surgeon should not cross-clamp the donor heart until given approval by the transplanting surgeon.

Implantation

The donor heart is removed from the transport cooler and placed in a basin of cold saline. The aorta and pulmonary artery are separated using electrocautery or sharp dissection. The left atrial cuff is prepared by connecting the pulmonary vein orifices and excising excess atrial tissue (Fig. 63.3). The cuff is tailored to the size of the recipient’s left atrium. The tricuspid apparatus and intra-atrial septum are inspected. There have been several recent reports suggesting that there should be a low threshold for performing a donor tricuspid annuoplasty at the time of transplantation. Recipients are predisposed to increased right-sided heart pressures in the early postoperative period owing to pre-existing pulmonary hypertension and volume overload. Both the conditions are poorly tolerated by the recovering right ventricle. To avoid refractory arterial desaturation associated with right-to-left shunting, if present, patent foramen ovale is over sewn.

Implantation begins with an end-to-end left atrial anastomosis (Fig. 63.4). A 54-inch, double-arm 4-0 polypropylene suture is passed through the recipient left atrial cuff at the level of the left superior pulmonary vein and then through the donor left atrial cuff near the base of the atrial appendage. The allograft is lowered into the recipient mediastinum, and the suture is continued in a running manner caudally and medi ally to the inferior aspect of the intra-atrial septum. The second arm of the suture is run along the roof of the left atrium and down the intra-atrial septum. Any size discrepancy between donor and recipient atria should be continually assessed and corrected. At our center, we often leave a weighted sucker in the left atrium (as a vent) at the completion of the suture line. The suture line is temporarily controlled with a Rummel tourniquet. After completion of all of the anastomosis, the heart is deaired, the vent is removed, and the suture line is secured. Some centers introduce a bubble-free cold line into the left atrial appendage for continuous hypothermic
Fig. 63.3. Allograft preparation for orthotopic transplant. The pulmonary vein orifices are joined to form a left atrial cuff.

saline lavage (50 to 75 ml/min) and evacuation of intracardiac air.

After completing the left atrial anastomosis, attention is turned to the IVC anastomosis. An end-to-end donor-to-recipient anastomosis should be performed using a 4-0 polypropylene suture. Again, great care should be taken to correctly manage any size discrepancy. This is often the most difficult of the five anastomoses and often is more easily performed from the right side of the table. Next, an end-to-end SVC-to-SVC anastomosis is constructed using a 5-0 polypropylene suture. We prefer to lock the posterior row of the anastomosis to minimize the risk of purse-stringing. When prolonged ischemia is expected after the completion of the two caval anastomoses, a dose of cardioplegia can be administered in either an antegrade or retrograde manner.

Next, an end-to-end pulmonary artery anastomosis is performed. It is crucial that the pulmonary artery ends be trimmed to eliminate any redundancy that might cause kinking and lead to right heart dysfunction. Using a 4-0 polypropylene, one starts the anastomosis at approximately 3 o'clock on the recipient pulmonary artery from outside to inside. The posterior wall of the anastomosis is then performed from the inside of the vessel, whereas the anterior wall is completed from the outside. If adjunctive hypothermia was used, the patient is rewarmed at this time. Finally, an end-to-end aortic anastomosis is performed in a similar manner. If a significant donor-recipient size mismatch is encountered when performing the aortic anastomosis, this may be handled by either beveling the aorta or creating a vertical aortotomy. In cases where prolonged ischemia times are encountered, the aortic anastomosis can be performed directly after the left atrial cuff anastomosis while the pulmonary artery and caval anastomosis can be performed with the cross-clamp off. The caval tapes are then released and the heart is filled with blood. Before the aortic anastomosis is secured, the lungs are ventilated and the heart is manipulated to facilitate deairing through the anastomosis. An aortic root vent/cardioplegia needle is then placed. If desired, a dose of warm cardioplegia can be administered before removal of the cross-clamp. Lidocaine is given, and the patient is placed in a steep Trendelenburg position. The aortic cross-clamp is removed, and deairing is continued via the root vent until no air is visible on transesophageal echocardiography.

Several maneuvers are performed during the resuscitation phase. Atrial and ventricular pacing wires are placed, pleural and mediastinal chest tubes are placed, the pulmonary artery catheter is advanced into proper position, and a thorough exploration for bleeding is undertaken. In patients with an implanted AICD or pacemaker, the device is removed at the time of transplant. The leads are transected during the
recipient cardiectomy and the generator is removed while the heart is being resuscitated. The patient is then weaned from cardiopulmonary bypass with the assistance of inotropes and nitric oxide as indicated. After removal of the cannulae and assurance of hemostasis, the wound is closed in the standard manner.

To assure excellent results, it is crucial to be hypervigilant during the early resuscitation period. This is especially important in cases with recipient pulmonary hypertension, prolonged organ ischemia, or when using a slightly undersized donor heart. In these cases, right ventricular failure may be potentiated by subtle changes in cardiac volume, acid–base status, or pulmonary artery pressure. The cardiac surgeon should work closely with the anesthesiologist to assure that all metabolic derangements are promptly corrected (e.g., hyperglycemia, hyper- or hypokalemia, respiratory or metabolic acidosis, hypocalcemia). Volume resuscitation should be closely monitored, especially when blood products are required to correct a coagulopathy. Pulmonary hypertension can be mitigated with rational use of inotropes, nitric oxide, and ventilator management. Finally, per the local protocol, immunosuppressive therapy should be started in the operating room.

**ALTERNATIVE TECHNIQUES FOR ORTHOTOPIC HEART TRANSPLANTATION**

Although most centers now perform the bicaval anastomosis, the original biventricular technique described by Shumway and Lower and revised by Barnard can often prove useful. We prefer the bicaval technique due to the associated increase in 5-year survival (81% vs. 62%), decreased risk of tricuspid regurgitation, reduced postoperative dependence on diuretics and inotropes, and lower incidences of atrial dysrhythmias, conduction disturbances, mitral and tricuspid valve incompetence, and right ventricular failure. To perform a right atrial cuff anastomosis, a curvilinear incision is made from the inferior vena caval orifice toward the right atrial appendage of the allograft (Fig. 63.5). The right atrial anastomosis is performed in a running manner similar to the left with initial suture placed at the most superior aspect of the intra-atrial septum.

Some centers have advocated total heart transplantation, which involves complete excision of the recipient heart with bicaval end-to-end anastomosis and bilateral pulmonary venous anastomosis.

**RECIPIENTS WITH CONGENITAL ANOMALIES**

Transplantation in adults with previous palliative procedures for congenital anomalies is uncommon; however, it is critical that a generous donor cardiectomy be performed so that sufficient tissue is available for optimal reconstruction. Several authors have described techniques detailing heart transplantation in recipients with “L” transposition, hypoplastic left heart, previous Fontan procedure, and situs inversus. In most situations, an allograft cardiectomy that includes the branch pulmonary arteries, aortic arch, and innominate vein is required. The details of these specific reconstructions are well described in the literature and beyond the scope of this text.

**REDO STERNOTOMY**

At least 30% of heart transplant recipients will have had a previous median sternotomy. The use of preoperative chest X-rays or computed tomographic imaging may help to determine whether a potential space exists posterior to the sternum. External defibrillation pads should be placed before making an incision. In patients with previous coronary artery bypass surgery, an angiogram should be reviewed to determine which, if any, grafts are still open. If the proximal aorta must be retained, the stumps of any existing bypass grafts must be oversewn to minimize the risk of pseudoaneurysm formation. In patients who have had multiple previous median sternotomies or are redo transplants, it may help to expose the femoral vessels. If emergent bypass is required, it may help to start with a single venous cannula and transition to bicaval cannulation after the control of the situation has been achieved.

After completing a substernal dissection, the sternum is divided with oscillating saw (anterior table) and Mayo scissors (posterior table). The right atrium, SVC and IVC, and aorta are then mobilized to facilitate cannulation. The reminder of the heart is then mobilized and a low threshold for early use of cardiopulmonary bypass is observed. The implantation is performed in the standard manner.

**TRANSPLANT AFTER VENTRICULAR ASSIST DEVICE**

A growing number of patients will have a ventricular assist device (VAD) in place at the time of transplantation. These patients can provide many additional challenges. Femoral arterial cannulation is often preferred in these patients due to the risk of re-entry injury and to facilitate the

---

*Fig. 63.5. Biventricular orthotopic heart transplant. After completion of the left atrial anastomosis, full-thickness bites are taken through the interatrial septum. Note the curvilinear incision made in the right atrium.*
aorta–aorta anastomosis. If one chooses to primarily cannulate centrally, the outflow graft from the VAD often provides a flexible site for temporary arterial cannulation. After the initiation of cardiopulmonary bypass, the VAD is turned off, the aorta is cross-clamped, and the native cardiectomy is performed. It is often advantageous to amputate the left ventricular apex to facilitate cardiectomy and remove the VAD after reperfusion of the allograft. The extensive dissection required to remove the device predisposes these patients to bleeding. In addition, the current generation of LVADs requires that the patients be on anticoagulation; despite efforts to normalize the coagulation profile preoperatively, the patients often remain coagulopathic in the early postoperative period. Aggressive use of targeted diagnostics (thromboelastogram, platelet functional assays, fibrinogen, PT, PTT) followed by directed transfusion is the basis of managing this potential problem. Some centers have advocated delayed primary closure in patients with uncontrollable posttransplant bleeding.

HETEROTOPIC HEART TRANSPLANTATION

Heterotopic cardiac transplantation, the intrathoracic placement of an allograft in series with patient’s heart, is rarely performed today. The procedure was first used clinically by Barnard in 1974. Today, the procedure may be indicated in cases with marked elevated pulmonary vascular resistance (pulmonary artery systolic pressure >60 mmHg and no pulmonary vasoreactivity) or when a donor heart is too small to sustain the recipient. Even in these selected cases, results have not been equivalent to orthotopic heart transplantation, with reported 1- and 5-year survival rates of 83% and 66%, respectively.

Similar to the cardiectomy performed for patients with congenital disease, the maximal lengths of aorta, SVC, and pulmonary arteries are procured. The IVC and the right pulmonary veins are oversewn, and a common left pulmonary vein orifice is created (Fig. 63.6). A linear incision is made along the long axis of the posterior right atrium extending 3 to 4 cm into the SVC. The recipient is cannulated in a bicaval manner as described, and the pericardium and right pleura are incised to permit placement of the allograft in the right chest. The sequence of anastomosis is as follows: donor to recipient left atrium, donor SVC to recipient right atrium, end-to-side aortic–aortic anastomosis, finally, end-to-side anastomosis joining the pulmonary arteries of donor and recipient (Fig. 63.7). The pulmonary artery anastomosis often requires the use of an aortic homograft of synthetic graft conduit permitting the donor heart to reside within the right pleural space.

POSTOPERATIVE MANAGEMENT

Postoperatively, the transplant recipient is usually admitted to a private room in the intensive care unit. Traditional “protective isolation” with elaborate positive-pressure air filtration systems has been abandoned by most centers because recent studies demonstrate no benefit over mask and hand-washing regimens. Contact with individuals with communicable diseases should be avoided.

Intensive care monitoring is analogous to that of any patient who has undergone cardiac surgery. A radial artery catheter, left internal jugular venous catheter, continuous telemetry, pulse dosimeter, oxygenography, and Foley catheter are essential components for optimal postoperative care. Occasionally, a Swan–Ganz catheter is indicated in patients with increased pulmonary vascular resistance or if donor allograft dysfunction is anticipated. If the patient remains hemodynamically stable, all invasive monitoring lines and Foley catheter should be removed by 48 to 72 hours to minimize the risk of nosocomial infection. Chest tubes are removed on the first postoperative day if drainage is <25 ml/h.

Donor myocardial performance is transiently depressed in the immediate postoperative period. Allograft injury associated with donor hemodynamic instability and the hypothermic, ischemic insult of preservation contributes to the reduced ventricular compliance and contractility characteristic of the newly transplanted heart. With a biatrial anastomosis, abnormal atrial dynamic owing to the mid-atrial dynamics exacerbates the reduction in ventricular diastolic loading. An infusion of isoproterenol or dobutamine is initiated routinely in the operating room to provide temporary isotropic support. The positive chronotropic effect of isoproterenol is also therapeutic for the bradyarrhythmias that frequently complicate the early posttransplant period.

In patients with high pulmonary artery pressures or right heart failure, inhaled pressures nitric oxide is a therapeutic alternative. Intra-aortic or pulmonary artery balloon counterpulsation and right VADs have been utilized in patients unresponsive to medical therapy. Restoration of normal myocardial function usually permits the cautious weaning of isotropic support within 2 to 4 days.

Sinus or junctional bradycardia occurs in more than half of transplant recipients. The primary risk factor for sinus node dysfunction is prolonged organ ischemia. Adequate heart rate is achieved with isoproterenol infusion and/or temporary dual chamber epicardial pacing. Most bradycardiac rhythms resolve over 1 to 2 weeks, although placement of a permanent pacemaker is necessary in 2% to 25% of patients; few are still paced dependent at 6 months.

Most patients undergo an endomyocardial biopsy on approximately day 7 and are discharged shortly thereafter. All patients have close outpatient follow-up with intensive monitoring of their immunosuppression, antibiotic prophylaxis, and endomyocardial biopsies.

RESULTS

Cardiac transplantation continues to have operative mortality of approximately 5% due to primary graft nonfunction, acute rejection, sepsis, and pre-existing recipient comorbidities. Most patients will have an acute rejection episode during the first posttransplant, which is most often treated with corticosteroids. Patients with recurrent or refractory rejection are often treated with polyclonal antibodies, alternate immunosuppression, or antimitabolites. Chronic rejection is manifested by allograft coronary artery disease, for which the only available therapy is re-transplant. The use of calcineurin inhibitors (cyclosporine, FK506) is associated with a 3% to 10% incidence of chronic renal failure. The overall 1-year patient survival is now approximately 90%, with a 3-year survival of >75%. Similar outcomes should be expected in patients that are bridged to transplant with an LVAD. There is every reason to believe that, with continued improvements in immunosuppression and treatment of transplant-related illnesses, these data will improve.

SUGGESTED READINGS

Gamel AE, Yonan NA, Grant S, et al. Orthotopic heart transplantation: a comparison of standard and bivacual pulmonary hypertension that would affect an majority of patients, the left ventricle is working but often there is some preexisting pulmonary hypertension that would affect an unconditioned right ventricle. One must be very careful with administration of clotting factors to avoid RV distention and failure. It is critically important to get outstanding results. Programs are being very carefully monitored by CMS and I think the stakes are high for both the patient and the program.
INTRODUCTION

Heart–lung transplantation represents the last hope for a small group of patients with severe combined end-stage disease. It was performed successfully at Stanford University in 1981, and these patients were the first to be completely supported by transplanted lung grafts. The Registry of the International Society for Heart and Lung Transplantation reports that >3,000 heart–lung transplants have been performed worldwide. In the earlier years, this included patients with primarily lung disease, such as emphysema or cystic fibrosis; more recently, it has been restricted to end-stage disease of both organs, such as patients with congenital heart disease and pulmonary vascular disease (Eisenmenger syndrome), or severe primary pulmonary vascular disease with end-stage right heart failure (Cor pulmonale). In addition, at our center, we have successfully transplanted patients with primary lung dysfunction in the setting of end-stage ischemic heart disease. About 20 to 30 heart–lung transplant procedures are performed yearly in the United States, with an additional 30 to 50 performed in the rest of the world.

RECIPIENT SELECTION

The primary objective in recipient selection is to identify individuals with progressively disabling cardiopulmonary or pulmonary disease who still possess the capacity for full rehabilitation after transplantation. Heart–lung transplantation has a greater potential for technical complications than either heart transplant or lung transplant alone, so that it is particularly important to have stricter recipient selection criteria to assure a reasonable chance of a successful outcome. To this end, older recipients (>60 years of age) have not usually been selected for heart–lung transplantation, whereas they are frequently candidates for heart transplant. Significant multisystem disease is a contraindication, although combined heart–lung and liver, or combined heart–lung and kidney, transplantation has been successfully performed. Contraindications include renal dysfunction, active malignancy, infection with HIV, hepatitis B or hepatitis C, severe liver disease, cachexia or obesity, drug or alcohol abuse, and inability to cooperate with treatment programs. Patients who have had previous thoracic surgery are evaluated on a case-by-case basis. Multiple previous thoracotomies or pleurodesis are not absolute contraindications, although they might represent higher risk for surgical teams without significant experience in performing the operation. A patient who is acutely ill in the intensive care unit and specifically on mechanical ventilation is generally considered to be too ill to undergo heart–lung transplantation.

Patients accepted for transplantation are listed on the National Transplant Registry on the basis of diagnosis, time on the waiting list, and ABO blood group. Because heart–lung transplant recipients are in competition with critically ill heart recipients who may have a more urgent status, the number of potential donors offered is low. The additional requirement for lung volumes of approximately equal or slightly smaller size further limits the potential donor pool. Like lung transplantation alone, patient height is a reasonable predictor for lung volume, and donors of significantly greater height should be avoided. The presence of preformed reactive antibodies (PRA) at a level of >25% requires a prospective specific cross-match between the donor and recipient. The presence of a significantly elevated PRA will require specific measures, either pretransplant or posttransplant, to reduce the likelihood of hyperacute rejection of the donor organs, such as plasmapheresis and alternative immunosuppression. Diligent surveillance is also mandated in these patients to avoid the sequelae of late humoral rejection.

ORGAN PROCUREMENT AND PRESERVATION

Currently, all heart–lung block donors have sustained irreversible brain death but retain near-normal heart and lung function. Standard donor evaluation is performed, including physical examination, chest X-ray, 12-lead electrocardiogram, arterial blood gases, and serologic screening. A donor age of <50 years is preferred. Coronary angiography may be indicated in donors >40 years of age or with cardiac risk factors. Meticulous fluid management prevents excessive pulmonary edema and improves pulmonary and myocardial function. The last decade has seen significant progress toward better donor management, such that initially poor lung and heart function can be improved with aggressive treatment. Because of the already greater technical complexity of the heart–lung transplant operation, good donor organ function is extremely important. The criteria for donor selection are listed in Table 64.1.

The donor operation is performed via a median sternotomy, as shown in Figure 64.1. Some harvests may also be done with a bilateral transverse thoracotomy as shown, depending on the requirements of the abdominal organ teams. Both pleural spaces are immediately opened with inspection of both lungs carried out. The heart is inspected, to rule out significant contusions and anatomic anomalies. This is followed by palpation of the coronary arteries to rule out significant coronary artery calcifications. The lungs are briefly deflated, and the pulmonary ligaments are divided using electrocautery. After completely dissecting and removing the thymic remnant, the pericardium is removed to within about 2 cm of the phrenic nerves bilaterally. Umbilical tapes are placed around the ascending aorta and both venae cavae. The pericardium overlying the trachea is incised vertically, and the trachea is encircled in the superior part of the mediastinum at least five or six...

Complete tracheal rings above the carina. This maneuver can be facilitated by ligating and dividing the innominate vein.

An infusion of prostaglandin E₇ is started approximately 15 minutes before applying the aortic cross-clamp, beginning at a rate of 20 ng/kg/min, followed by incremental increases, to a target rate of 100 ng/kg/min. Careful monitoring of the mean arterial blood pressure should assure that it remains above 50 mmHg. Ventilation continues with a fraction of inspired oxygen (FiO₂) of 40% and a small amount of positive end-expiratory pressure (PEEP) (3 to 5 cm of water). Infusion lines are placed in the ascending aorta and the main pulmonary artery, as shown in Figure 64.2. The donor is then heparinized, the superior vena cava is ligated, and a straight Potts clamp is placed across the inferior vena cava. After the heart empties, the aortic cross-clamp is applied, and 10 ml/kg of cold crystalloid cardioplegia is rapidly infused into the aortic root. We prefer the Stanford formulation, but several other cardioplegia solutions are available. The inferior vena cava is then incised, and the tip of the left atrial appendage is amputated (Fig. 64.2), to avoid cardiac and lung distention from the return of the pulmonary perfusion. While antegrade cardioplegia is being delivered, a separate pulmonoplegia is flushed through the main pulmonary artery at a rate of 15 ml/kg/min for a period of 4 to 5 minutes. Ice-cold saline or Physiosol solution (Abbott Laboratories, North Chicago, IL) is immediately poured over the heart and lungs. During the cardioplegia and pulmonoplegia infusions, ventilation...
is maintained with half-normal tidal volumes of room air. On completion of these infusions and topical cold application, all solutions are aspirated from the thoracic cavity, and the lungs are fully deflated.

The heart–lung block is dissected free from the esophagus, commencing at the level of the diaphragm and continuing cephalad to the level of the carina. Dissection is kept close to the esophagus, and care is taken to avoid injury to the trachea, lung, and great vessels. The posterior hilar attachments are divided and the lungs inflated to a half-normal tidal volume, and the trachea is stapled at the highest point possible with a TA-55 stapler (United States Surgical, Norwalk, CT) at least four rings above the carina. The trachea is then divided above the staple line, and the entire heart–lung block is removed from the chest. After the heart–lung block is removed from the donor, it is wrapped in sterile gauze pads and immersed in ice-cold saline between 2°C and 4°C, placed in several sterile plastic bags, and then placed in a sterile plastic container. This is placed in an ice-filled insulated box and transported to the transplant center. Because nonpressurized aircraft might be employed, we believe it is important to avoid overdistention of the lung before stapling of the trachea, to prevent overexpansion during transport, especially if air transport is required.

With current preservation techniques and careful andatraumatic excision of the heart–lung block, procurements from as far as 1,000 miles from the transplant center and ischemic times up to 6 hours are reasonably well tolerated. The additional use of corticosteroids in the donor and white cell filtration before lung reperfusion in the recipient are also measures that contribute to improved preservation.

**RECIPIENT OPERATION**

The heart–lung transplant operation is composed of two phases of equal importance. The first is safe excision of the native organs with excellent hemostasis, followed by implantation of the donor organs and continued attention to excellent hemostasis.

Anesthetic monitoring includes arterial pressure, pulse oximetry, continuous electrocardiography, temperature, and urine output. A standard endotracheal tube is used, and transesophageal echocardiography may be helpful during the early stages of the operation, but should be removed during the time of recipient organ excision. This helps to prevent injury to the esophagus while dissecting in the posterior mediastinum. A median sternotomy is employed for the majority of recipients, with transverse thoracotomy (clam-shell) helpful for patients who have had extensive previous thoracotomies or pleurodesis (Fig. 64.1). In that situation, the bilateral thoracotomies offer better access to the posterior mediastinum and the apical areas of the thoracic cavity for a more meticulous dissection and better hemostasis. Otherwise, the median sternotomy is preferable for better chest wall mechanics postoperatively.

After sternotomy, both pleural spaces are opened widely just below the sternal edges. Anterior mediastinal thymic remnants and the anterior pericardium are carefully dissected and removed. The ascending aorta is dissected free and encircled with umbilical tape, followed by the superior vena cava and the inferior vena cava, as shown in Figure 64.3. Cannulation for cardiopulmonary bypass consists of a cannula in the high ascending aorta and separate vena caval cannulas, as seen in Figure 64.4. Once cardiopulmonary bypass has been initiated, the aorta is cross-clamped and tapes are placed down around the vena cava. The heart is then excised by dividing the great vessels just above the aortic and pulmonary valves in a manner quite similar to cardiectomy for heart transplantation (Fig. 64.5). When bicaval anastomoses will be used, we do like to leave a portion of the right atrium that connects the superior and inferior vena cavae to prevent them from retracting once the cardiectomy has been performed. The left atrium is divided across its mid-portion, leaving the pulmonary veins intact. Mobilization of the lungs is begun with separation of the pulmonary ligaments bilaterally. The pleural reflections over the anterior mediastinum are carefully opened, and dissection of the pulmonary veins is begun. As much as possible of the dissection of the hila can be performed before cardiopulmonary bypass, but cardiopulmonary bypass should be started if hemodynamic instability develops. Any pleural adhesions are divided using electrocautery with meticulous hemostasis. A useful adjunct helpful in maintaining hemostasis is the Argon Beam Coagulator (ConMed Corp., Utica, NY) for the control of diffuse bleeding from chest wall adhesions.

After cardiectomy, bilateral pneumonectomy is performed. The pulmonary veins and pulmonary artery are divided by stapling, as shown in Figure 64.6. In some particularly scarred hila, the electrocautery can also be used to divide the pulmonary veins and arteries.

In some patients, there may be significant bronchial artery collaterals, as well as other mediastinal vessels in the lymphatic and peribronchial tissue. All of these have to be carefully controlled with either the electrocautery or ligaclips. The right and left mainstem bronchi are stapled using the TA-30 (United States Surgical, Norwalk,
Section II: Adult Cardiac Surgery

Fig. 64.4. After the median sternotomy, both pleural spaces are opened widely just below the sternal table. The ascending aorta and both vena cavae are dissected free and encircled with umbilical tapes. Cannulation for cardiopulmonary bypass includes a typical arterial return line in the high ascending aorta and a right-angled venous cannula in the superior vena cava and the inferior vena cava.

CT), dividing distally and then removing the lungs. At this point, very careful control of any bleeding in the posterior mediastinum is essential.

The next steps in preparing the recipient for implantation consist in creating openings for both the right and left hila in the lateral pericardial walls and dissecting the main bronchi back to the distal trachea, to divide the trachea and prepare it for the implantation.

Anterior to the pulmonary veins bilaterally, the left and right pericardium are opened and enlarged superiorly and inferiorly to provide enough room for the donor lungs. Careful identification of the right and left phrenic nerves should provide adequate protection against injury. By grasping the stapled ends of the right and left bronchus and using the electrocautery, careful dissection right against the bronchus can separate it from the posterior mediastinum and dissect it back into the central posterior mediastinum, where they meet at the carina (Fig. 64.7). Dividing the right pulmonary artery remnant just anterior to the trachea will help facilitate this exposure. We believe it is important to leave a portion of the left pulmonary artery intact adjacent to the underside of the aorta near the ligamentum arteriosum to preserve the left recurrent laryngeal nerve. It is also important to stay right on the bronchus and not to injure the tissue immediately posterior to the carina, where the right and left vagus nerves will be passing anterior to the esophagus. A common error is to divide or traumatize the vagii at this location, causing a high vagotomy with gastric paresis post transplant. Again, multiple bronchial vessels must be identified and carefully ligated using ligacips or controlled with the electrocautery. Patients with Eisenmenger syndrome have fairly large bronchial collaterals, which are identified and ligated. Once perfect hemostasis has been obtained, the trachea is divided at the carina with a No. 15 blade. The surgeon should keep in mind that the membranous trachea should not be pulled down excessively and then divided, because this may remove a fair amount of the recipient posterior wall unnecessarily. Additional tracheal collaterals should be controlled at this point. The chest is now prepared to receive the heart–lung graft.

The donor heart–lung block is removed from its transport container and prepared by opening the trachea just below the staple line and carefully obtaining a swab culture, irrigating, and then aspirating the retained mucus. The suction used for this purpose should be kept separate from the

Fig. 64.5. Cardiectomy is performed in a manner quite similar to that for isolated heart transplantation. We prefer to leave an intact portion of posterior and medial right atrial wall that will connect the superior and inferior vena cavae and prevent their retraction, facilitating the anastomosis.
suctions used for the recipient operation. The cultures obtained are sent for fungal and bacterial examinations. The donor trachea is then trimmed down to leave just one cartilaginous ring intact above the carina. All of the peritracheal tissue should be retained as much as possible to facilitate post transplant vascularization of the anastomosis. Excessive dissection of this tissue will lead to possible necrosis or stricture, especially if a long left bronchial remnant remains with extensive skeletonization. Care should be taken to leave adequate tracheal tissue in the membranous portion posteriorly when transecting the donor trachea.

The heart–lung graft is then lowered into the chest, passing the right lung beneath the right phrenic nerve pedicle. The left lung is gently manipulated under the left phrenic nerve pedicle. An alternative technique that leaves one or both lungs anterior to the phrenic nerves has been described by Copeland’s group. This maneuver facilitates rotation of the heart–lung block for better exposure during the post-bypass phase of the operation to inspect the posterior mediastinum for bleeding points.

Positioning of the donor organs before beginning the anastomosis is shown in Figure 64.8. The implantation begins with anastomosis of the trachea. In the adult patient, this is performed using continuous 3-0 polypropylene suture, as shown in Figure 64.9A. For children or neonates, appropriately smaller polypropylene suture is used. The posterior membranous portion is sutured first from the inside and from the left to the right, followed by completion of the anastomosis anteriorly, as shown in Figure 64.9B. The heart is wrapped with a sterile gauze pad, and topical myocardial hypothermia is initiated for the heart, with secondary topical cooling of both lungs.

Next, the bicaval venous anastomosis is performed beginning with the inferior vena cava, as seen in Figure 64.10. The donor interatrial septum should be looked at through the opening of the inferior vena cava to see whether a patent foramen ovale is present and needs closure. The inferior vena cava–right atrial junction is joined with a continuous 4-0 polypropylene suture. This is performed along the back wall of the right atrium, where the posterior atrial wall is intact, between the superior vena cava and inferior vena cava of the recipient. It is then continued along the free edge of the recipient inferior vena cava anteriorly. When this is completed, we usually proceed with anastomosis of the ascending aorta in a standard manner using 4-0 polypropylene suture. Finally, the superior vena cava is appropriately trimmed and sutured to the recipient vena cava using 5-0 polypropylene, with care to prevent purse-stringing of this anastomosis by leaving it intentionally looser. Excessive tension in this suture line will cause some stricture and possible later thrombosis.

Before release of the aortic cross-clamp, the amputated left atrial appendage is oversewn, and the pulmonoplegia site in the pulmonary artery is also repaired. A bubble vent in the anterior aorta is put to coronary suction as the tapes are removed from the vena cava, and blood is allowed to return into the heart and lung block. Just before this maneuver, we initiate white cell...
filtration of the cardiopulmonary bypass circuit to reduce the exposure of recipient white blood cells to the donor lungs. The aortic cross-clamp is then removed so the heart will be reperfused.

The reperfusion and resuscitation of the heart–lung may require 30 to 45 minutes. Deairing and complete dilution of the pulmonoplegia solution are essential. Gentle ventilation with room air is performed prior to coming off of cardiopulmonary bypass. Weaning is initiated with an FiO₂ of 50% and adjusted based on the oxygen saturation measured peripherally.

Some low-dose dopamine or isoproterenol may be helpful to maintain heart rate and improve renal perfusion. Methylprednisolone (500 mg intravenously) is given after protamine is administered. The appearance of the completed transplant is shown in Figure 64.11. Drains are left in both chest cavities and the mediastinum, and closure is routine.

**CLINICAL MANAGEMENT IN THE EARLY POSTOPERATIVE PERIOD**

The early postoperative management for heart–lung transplant recipients includes careful fluid and ventilatory management. The primary objective is to maintain adequate perfusion and gas exchange while minimizing intravenous fluid, cardiac work, and barotrauma. Careful and gentle pulmonary and endotracheal suctioning should be used to remove mucus and prevent atelectasis. Standard ventilatory weaning is initiated after the patient is deemed to be stable, awake, and alert. Typically, extubation is feasible within the first 24 hours after transplantation. As with all heart transplant recipients, some degree of transient sinus node dysfunction may be present in about 10% to 20% of patients. The use of isoproterenol or temporary cardiac pacing will usually lead to resolution within 1 week.

If pulmonary dysfunction develops, as manifested by an increasing requirement for FiO₂ with the development of a diffuse interstitial infiltrate on chest roentgenogram,
then the presence of a reperfusion injury should be considered. In addition, some element of obstruction of a pulmonary vein should be considered, because it has been reported after heart–lung transplantation. This is a particular risk when the heart–lung block is placed anterior to the phrenic nerves. This can be detected by transesophageal echocardiography. If primary graft dysfunction continues, the use of inhaled nitric oxide may be indicated. Temporary extracorporeal membrane oxygenation may be considered if iNO is not effective. Postoperative hemorrhage and the need for excessive blood product replacement will magnify any pulmonary dysfunction, again pointing out the importance of careful intraoperative hemostasis.

**IMMUNOSUPPRESSIVE MANAGEMENT**

The immunosuppression for heart–lung transplant recipients begins intraoperatively and continues for the patient’s lifetime. The drug protocols used are similar to those for other lung transplant recipients. We have seen benefits from the use of induction therapy using rabbit anti-thymocyte globulin, with delay in the use of maintenance steroids for 2 weeks post transplant. However, for most patients we do not currently use induction therapy. During the early post transplant period, cyclosporine is initiated and switched to oral administration when extubation has occurred. Methylprednisolone is administered intraoperatively at graft reperfusion and continued for the first 24 hours at 125 mg intravenously every 8 hours. After 2 weeks, prednisone is started at a daily oral dose of 0.6 mg/kg and gradually tapered over the next month to 0.2 mg/kg/day.

**INFECTION PROPHYLAXIS**

In heart–lung transplantation, as in lung transplantation, very meticulous antiviral and antifungal prophylaxis are important components of postoperative management. Cytomegalovirus (CMV) prophylaxis with ganciclovir is used by most centers in any CMV-negative recipient receiving an allograft from a CMV-positive donor. Fungal prophylaxis against mucosal *Candida* infection includes the use of daily Nystatin mouthwash. *Pneumocystis carinii* prophylaxis consists of trimethoprim-sulfamethoxazole or aerosolized pentamidine. *Aspergillus* colonization is inhibited by the use of aerosolized amphotericin B early postoperatively. Recipients who are toxoplasma-negative and receive grafts from

*Fig. 64.10.* The inferior vena cava anastomosis is started along the posterior wall and sutured from left to right. It is continued anteriorly, with care to avoid severe purse-stringing. Usually, this opening is large enough that this is not as much of a concern as with the superior vena cava.

*Fig. 64.11.* The completed implantation of the heart–lung transplant. The tracheal anastomosis lies in the space between the superior vena cava and posterior to the ascending aorta. Angled chest drains are placed bilaterally and a straight drain in the anterior mediastinum. The chest closure is routine.
toxoplasma-positive donors receive pyrimethamine prophylaxis for at least the first 6 months after transplantation.

**GRAFT SURVEILLANCE**

Routine clinical follow-up to monitor and modify the need for immunosuppressive drugs requires regular surveillance. This consists of serial pulmonary function tests, arterial blood gases, and bronchoscopic evaluation beginning at 2 weeks post transplant. Further surveillance bronchoscopies and biopsies are obtained on a regular schedule.

**POSTOPERATIVE COMPLICATIONS**

The importance of a meticulous and atraumatic operative procedure is highlighted by the fact that most of the early morbidity and mortality can be directly related to the quality of the donor organs and the need for excessive blood product administration due to postoperative hemorrhage. The most common cause of early death is due to primary graft failure or infection, together with multisystem organ failure due to poor primary graft function or excessive bleeding. This leads to a relatively high early postoperative mortality of 16% in our series of more than 200 heart–lung transplants.

If present, pulmonary dysfunction and multisystem organ failure are managed in a conventional manner, as for all critically ill postoperative patients. Careful attention to preservation of the graft, judicious fluid administration, and minimizing the need for excessive blood products postoperatively will reduce the incidence of this syndrome. Fortunately, as in heart or lung transplant-only recipients, acute rejection episodes and graft failure due to rejection are extremely unusual. The lung is more likely to experience rejection than is the heart, with about 67% of heart–lung patients having pulmonary rejection within the first year and only approximately 15% experiencing heart graft rejection.

**CHRONIC REJECTION OR LATE COMPLICATIONS**

The major long-term limitation of heart–lung transplantation, similar to isolated lung transplants, is the presence of chronic lung rejection presenting as obliterative bronchiolitis (OB). The diagnosis is confirmed with lung histology obtained by bronchoscopy, characterized by a dense eosinophilic submucosal scar, which partially or totally obliterates the lumen of small airways, accompanied by a decrease in arterial oxygen pressure, a decrease in the forced expiratory volume in 1 second, and a decrease in the forced expiratory rate between 25% and 75% of forced vital capacity. The only therapy is an augmentation of immunosuppression, which may be helpful in reducing the ongoing progression but usually does not reverse the disease.

**RETRANSPLANTATION**

When terminal respiratory failure develops secondary to OB or when chronic coronary artery disease develops (rarely) in long-term recipients, retransplantation of the heart–lung block, the lung alone, or of the heart alone has been performed. These operations represent technical challenges but have been reported to be successful in recipients who are otherwise in reasonably good physiologic condition. The same principles of meticulous donor procurement and preservation, attention to hemostasis, and careful perioperative management are essential. The major cause of death after retransplantation procedures remains multisystem organ failure.

**AIRWAY COMPLICATIONS**

Fortunately, the heart–lung graft facilitates revascularization of the tracheal anastomosis through the early development of coronary-to-bronchial collaterals. This has resulted in a very low rate of primary tracheal dehiscence, as well as a low rate of tracheal stenosis, which is usually due to ischemia. In fact, tracheal complications have tended to develop only in patients who required extended postoperative ventilation and increased PEEP. When complications develop, the diagnosis is made by bronchoscopy and can be treated by reoperation or bronchoscopy with dilation or airway stenting.

**DOMINO-DONOR PROCEDURES**

In patients who require a double-lung transplant, the strategy of performing a heart–lung transplant with donation of the recipient heart has been described as the “domino-donor transplant,” with good results for both the heart–lung recipient and the heart recipient. These operations must be done with complete bicaval anastomosis so that an adequate donor heart is procured. Otherwise, the procedures are as already described.

**HEART–SINGLE-LUNG TRANSPLANT**

A small number of patients with congenital heart disease have been reported who have unilateral pulmonary vascular disease or severe developmental changes in one lung, which have been successfully transplanted with a heart–single-lung block. This strategy has also been used when severe scarring of one thoracic cavity has made it impossible to safely remove one of the recipient’s lungs. A single bronchial anastomosis with appropriate pulmonary vein and pulmonary artery anastomosis are then performed. Good long-term results can be obtained.

**LONG-TERM RESULTS**

The long-term survival for heart–lung patients has gradually improved with better operative and postoperative management. Newer immunosuppressive drugs and better antimicrobial prophylaxis, particularly for CMV, have been major factors. In the last 10 years at Stanford, the 1-, 5-, 10-, and 15-year survival rates were 75%, 55%, 40%, and 30%, respectively, in 217 patients. The currently longest-living heart–lung transplant recipient is 23 years post transplant, with normal heart and lung function.

**CONCLUSION**

The evolution of heart–lung transplantation for end-stage cardiopulmonary disease has depended on careful operative technique. It can be a very straightforward operation in some patients and a very demanding and difficult procedure in others. The importance of appropriate donor organ procurement and preservation cannot be overemphasized. Meticulous hemostasis and the use of all possible measures to reduce postoperative hemorrhage are essential to good outcomes. Patients who experience successful procedures can look forward to long-term survival equivalent to any recipient of a bilateral lung graft, with very satisfactory and rewarding return to normal activities. Future improvements in immunosuppression and the ability to induce immunologic tolerance will continue the evolutionary improvement of heart–lung transplantation therapy.

**SUGGESTED READINGS**

Hardesty RL, Griffith BP. Procurement for combined heart–lung transplantation. Bilateral thoracotomy with sternal transection,

Heart–lung transplantation was developed at Stanford University under the leadership of Dr. Bruce Reitz. It has been a very exciting procedure and we have had the opportunity to do several of these procedures here at The University of Virginia. The difficult is getting heart–lung blocks. Double-lung transplantation has now been used for Eisenmenger’s syndrome and certainly single-lung transplantation is available for other kinds of primary lung disease. We have also performed intercardiac repairs in addition to lung transplantation in patients with ventricular septal defects that resulted in Eisenmenger’s syndrome. At present, the only major indication for heart–lung transplantation is cardiomyopathy in addition to end-stage lung disease. I think we will become much more clever as time goes on in terms of other application of lung transplantation. I believe heart–lung transplantation should be in every major transplant center’s skill set but will be infrequently used. 

**ARRHYTHMIAS**

**Surgical Treatment of Atrial Fibrillation**

Sameh M. Said and Hartzell V. Schaff

---

**BACKGROUND**

Atrial fibrillation (AF) is by far the most common cardiac arrhythmia, and the prevalence increases with age, from 0.5% for patients in their 1950s to almost 9% among patients 80 years of age and older. It is estimated that approximately 2.3 million people in the United States have AF, and the incidence will continue to increase with increasing age in the population.

AF has three main serious sequelae: (1) patient anxiety due to rapid heart rate, (2) deterioration of cardiac hemodynamics related to loss of synchronous atrioventricular contraction, and (3) increased risk of thromboembolic complications and stroke. The basis of AF management is directed toward these complications and includes control of heart rate, prevention of thromboembolism, and, when possible, reestablishing and maintaining sinus rhythm. There is continued controversy regarding the efficacy of rhythm control versus rate control strategies. Unfortunately, long-term success of medical treatment of AF is poor. Five years after entry into the AFFIRM trial, only 63% of patients assigned to the rhythm control group were in sinus rhythm. Furthermore, chronic medical therapy has a number of unwanted side effects.

For these and other reasons, there has been considerable interest in novel strategies for control and treatment of AF over the last three decades. One of the earliest approaches to control AF was “ablate and pace strategy” with atrioventricular nodal ablation and permanent pacemaker implantation. Although atrioventricular node ablation controls the heart rate, the patient remains in AF, is pacemaker dependent, and still incurs the risks of thromboembolic stroke. Compared with patients with AF managed medically, patients who undergo atrioventricular node ablation and permanent transvenous pacing exhibit similar exercise performance and ventricular function. In patients with diminished left ventricular function, atrioventricular nodal ablation and permanent pacing result in a small but significant improvement in left ventricular function compared with medical therapy alone.

Through the work of Cox and associates, surgical and catheter techniques for ablating AF have been developed and are highly refined. Patients with AF who come to surgical attention fall into two general groups. First, are patients with isolated (lone) AF who are symptomatic despite medical treatment and/or attempts at catheter ablation. In the second, larger group, are patients with AF and associated structural heart disease that requires operative treatment. Selection of a surgical ablative method differs depending on the indication for operation, the disability caused by the arrhythmia, and the anticipated morbidity of the procedure for AF and any additional necessary surgery. For example, the standard “cut-and-sew” maze procedure may be the most effective and appropriate treatment for a highly symptomatic patient with isolated AF, but the technique would not be appropriate for an elderly patient undergoing double-valve replacement who has few symptoms from AF and whose heart rate is easily controlled medically.

**SURGICAL ABLATION**

**The Cox-Maze Procedure**

The prototype for all current surgical procedures for AF is the maze procedure developed by Cox and coworkers, and we consider the standard “cut-and-sew” maze procedure to be the most reliable and effective method in creating complete transmural atrial lesions for AF ablation. We continue to use the “cut-and-sew” maze (Figs. 65.1–65.6) procedure in selected patients with only two modifications from the original description of the procedure. First, we have replaced the incision on the medial aspect of the right atrium from the cut edge of the right atrial appendage to the tricuspid valve annulus with a cryolesion; this avoids the division of the frequently seen branch of the right coronary artery that supplies the sinoatrial node and reduces the risk of postoperative sinus node dysfunction (Fig. 65.2A and 65.2B). The second modification involves the left atrium where we prefer to extend the incision that encircles the pulmonary veins to the orifice of the left atrial appendage, and then, after excising the appendage, close the orifice transversely as part of the encircling incision. Alternatively, cryolesions can be utilized as part of the lesion encircling the pulmonary veins when the exposure of this area is poor, and incisions may be difficult to close.

Many other surgical procedures have been proposed for the treatment of AF, and these operations utilize a variety of lesion sets and energy sources. Each of the modified procedures has potential advantages regarding ease of application and, in some cases, minimally invasive approaches. However, there is no conclusive evidence that any of the modified procedures yields better or even similar results to the original operation described by Cox.

**Alternate Surgical Approaches for Atrial Fibrillation Ablation**

**Bilateral Pulmonary Vein Isolation**

Pulmonary vein isolation (PVI) can be performed epicardially or endocardially...
Fig. 65.1. Modified "cut-and-sew" Cox-maze III procedure. The first incision includes amputation of the right atrial appendage and extension on the right atrial free wall for approximately 5 cm. (With the permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

Fig. 65.3. Modified "cut-and-sew" Cox-maze III procedure. The vertical atrial incision is extended toward the tricuspid valve annulus, but it is stopped short of the right coronary artery. A cryolesion is then created at the remaining portion of the atrial muscle to the tricuspid valve annulus. Alternatively, this incision on the inside of the right atrium can be replaced with a cryolesion. (With the permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

Fig. 65.5. This figure illustrates the left atrial portion of the Cox-maze III procedure, which includes an incision that encircles the pulmonary veins and extends to the amputated left atrial appendage. The left atrial appendage is closed vertically with the line of closure joining the pulmonary vein encircling incision. There is an additional cryolesion (white line) that joins the pulmonary vein encircling incision to the mitral valve annulus. (With the permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

Fig. 65.2. (A) Modified "cut-and-sew" Cox-maze III procedure. A second incision extends from the superior to the inferior vena cava at the level of the crista terminalis. Another vertical extension of that incision is made toward the atroventricular groove. (B) In a modification to the original Cox-maze III procedure, we replaced the incision on the medial aspect of the right atrium from the cut edge of the right atrial appendage to the tricuspid valve annulus with a cryolesion. (With the permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

Fig. 65.4. Modified "cut-and-sew" Cox-maze III procedure. The interatrial septum is incised just cephalad to the fossa ovalis. (With the permission of Mayo Foundation for Medical Education and Research. All rights reserved.)

with or without left atrial appendage exclusion or excision. We view left atrial appendage ligation as an important step in surgical treatment of AF and never omit this. Epicardial PVI may be useful as an adjunctive procedure to operations that do not include left atriotomy (Fig. 65.7). When the left atrium is opened, as is the case with mitral valve repair or replacement, a bipolar radiofrequency (RF) clamp can be used to isolate the pulmonary veins by connecting the left atriotomy to the stump of the amputated left atrial appendage ("box lesion").

If the patient can be converted to sinus rhythm, it is important to check for exit block to confirm interruption of conduction from the pulmonary veins. However, demonstration of exit block or conduction delay acutely does not guarantee that lesions are transmural and that conduction will not reappear late after operation. Also, it is important to recognize that epicardial application of RF or cryoclamps to the atrial cuffs around the pulmonary vein orifices results in a double layer of atrial tissue to be ablated; with this method, transmurality may be difficult to achieve, especially in a beating perfused heart.

Minimaze Procedure

The term "minimaze" commonly refers to minimally invasive epicardial procedures without the use of cardiopulmonary bypass (Figs. 65.8 and 65.9). Lesion sets include a combination of pulmonary vein encircling lesion, left atrial isthmus lesion to the orifice of the left atrial appendage, and lateral left atrial incision without cryolesions. Wolf describes a minimally invasive procedure for AF performed through bilateral thoracoscopic ports. The operation includes bilateral antrum isolation and partial cardiac denervation. More recently, Sirak and associates describe the "five-box" thoracoscopic maze. In this procedure, bilateral thoracoscopy is performed with extensive dissection of the dome of the left atrium and transverse sinus. The procedure aims at compartmentalization of the posterior left atrium with ablation lines and connecting these lines to the mitral valve annulus, thus interrupting all the possible reentry circuits for AF.
Saline-Irrigated Cooled-Tip Radiofrequency Ablation

A "triangle-like" lesion set is created using a saline-irrigated, cooled-tip RF ablation. PVI is performed within the confines of the triangle, as well as left atrial appendage exclusion. One vertex of the triangle meets at the midportion of the posterior mitral valve annulus.

Alternate Energy Sources

The use of alternate energy sources has been increasing in the recent era due to the perceived technical complexity of the classic "cut-and-sew" Cox-maze. Cryoablation can be achieved using either nitrous oxide or argon cryoprobes, and the primary difference between the cooling techniques is the speed at which cooling of tissues occurs. A purported advantage of cryoablation is the preservation of the cardiac fibrous skeleton. Cryoablation has been used extensively in clinical practice and appears quite effective in the arrested heart. However, in the beating heart with atria that are blood-filled and perfused, complete transmural lesions may be difficult or impossible to create. Additional cooling time is necessary because of warming of the tissue by the blood interface, and there is a theoretical risk of thrombus formation within the atrium.

RF energy employs alternate current to transfer energy to atrial tissue, and a variety of instruments have been developed including rigid unipolar probes with cooled tips, flexible unipolar probes, and bipolar clamps with and without irrigation. RF ablation can be applied to the epicardial or endocardial surfaces of the atrium in a unipolar configuration. Bipolar RF probes configured as clamps have the advantage of focused discrete lesions, thus, minimizing the potential risk of injury of adjacent structures. Saline irrigation of the tissue...
during RF ablation has a cooling effect that prevents char accumulation and increases energy transfer to the tissues. Animal studies suggest a higher success rate of creating transmural lesions with irrigated delivery of RF compared with ablation without irrigation.

Less commonly used alternate energy sources include microwave energy where transmission of electromagnetic waves ablate tissues through the heat produced; with this method, there has been concern about damage to adjacent structures including reported cases of coronary artery stenosis. With laser energy, the tissue is heated directly producing photo-coagulation. The transmurality of the lesion as well as the concern for collateral damage are the limiting factors. High-intensity focused ultrasound is promising because of its ability to ablate at specific depth.

**Left Atrial Ganglion Ablation**

Ectopic impulses originating from the autonomic ganglia adjacent to the pulmonary veins have been implicated in initiating AF. These ganglia are found in the fatty epicardial tissue and have been recently mapped and ablated, which reduces the recurrence of medically refractory AF. The standard locations of these active ganglia have been previously described. The procedure is typically performed through median sternotomy and with the use of cardiopulmonary bypass. Intraoperative mapping is required with 12 V of high-frequency stimulation at a cycle length of 50 milliseconds and a pulse width of 1.5 milliseconds. An active ganglion is identified if stimulation results in a doubling of the R-R interval. All active sites were immediately ablated with an RF pen (Fig. 65.10).

**Cox-Maze IV (Ablation-Assisted Cox-Maze)**

Introduced in 2002, the Cox-maze IV procedure is another modification to the standard “cut-and-sew” maze that serves to further simplify the technique. This is done by replacing most of the incisions with bipolar RF energy and using cryoenergy in addition to achieve the complete biatrial lesion sets. This has the potential advantage of shorter ablation times, can be performed in a less invasive manner and by localization of the ablation lines between clamps, there is minimal collateral damage. However, its durability has been questioned in comparison with the maze III procedure in terms of transmurality (Fig. 65.11).

**Minimally Invasive Approaches**

Many surgeons have used modified lesion sets and alternate energy sources through minimally invasive incisions, including thoracoscopic and robotic-assisted techniques both on- and off-pump. These methods may make the procedure more acceptable to patients and cardiologists, but there is a compromise in regard to effectiveness of ablation (transfer out the lesion sets) and inability to ligate the left atrial appendage when the operation is performed exclusively through the right thorax.

**LONE ATRIAL FIBRILLATION**

This term was introduced by Evans and Swann in 1954 to describe AF not associated with systemic arterial hypertension or structural heart disease. Other designations used include isolated and "idiopathic" AF,
but it is now known that there are many triggers for lone AF. A surgical procedure for lone AF is appropriate for young patients who have limiting symptoms, especially those who have failed pharmacological treatment or become intolerant of medications. In current practice, most such patients will also have had one or more attempts at catheter ablation for control of AF. Many young patients prefer a curative procedure rather than lifetime treatment with drugs that have bothersome side effects. Surgical treatment of lone AF may also be indicated for patients who have contraindications to systemic anticoagulation, or personal preference to avoid chronic anticoagulation. Other indications for surgical treatment of lone AF include patients who have suffered a thromboembolic stroke while on anticoagulation and those with tachycardia-induced cardiomyopathy that does not respond to medical treatment or catheter ablation.

**ATRIAL FIBRILLATION IN PATIENTS HAVING OTHER CARDIAC OPERATIONS**

**Mitral Valve Surgery**

Chronic AF is present in approximately 40% of patients who undergo mitral valve surgery, and interventions on the mitral valve alone fail to restore sinus rhythm in the majority of these patients. Medical therapy, with or without catheter-based ablation, rarely restores and maintains sinus rhythm in these patients because of the chronic enlargement of the left atrium, which acts as a substrate for AF. The pulmonary veins provide a trigger for AF in approximately 90% of patients with paroxysmal arrhythmia; PVI alone would be expected to cure a majority of patients with this type of AF. However, PVI will fail as an ablative procedure in those 10% of patients in whom the pulmonary veins do not contribute to the substrate for AF.

More chronic AF leads to atrial remodeling and the development of macro reentrant pathways that sustain electrical reentry. In patients with chronic AF, the goal of treatment shifts from isolating the trigger of the arrhythmia (pulmonary veins in paroxysmal AF) to ablating the macro reentrant pathways responsible for its maintenance. In this setting, the arrhythmia is not dependent on stimuli from the pulmonary veins, and as such, PVI may be an inadequate treatment. This remodeling is present in a significant portion of patients with mitral valve regurgitation, and especially those that have evidence of left atrial enlargement. Thus, PVI as an adjunct to mitral valve repair in patients with severe mitral valve regurgitation may fail because of macro reentry pathways, the size of the left atrium, and the fact that alternate energy sources, as discussed below, may not create transmural lesions.

Handa et al. reported that the Cox-maze operation is a safe adjunct to mitral valve repair for patients with preoperative AF. In this study, the addition of the Cox-maze procedure was particularly useful in patients with continuous AF of more than 3 months duration preoperatively. Freedom from AF was 82% in patients who underwent combined maze and mitral valve repair compared with 53% in patients who underwent mitral valve repair alone. Morbidity and mortality were not increased by the addition of the maze procedure, and 75% of patients regained sinus rhythm by last follow-up. In this series, only the omission of the maze procedure and the presence of chronic AF were predictors of arrhythmia recurrence. Similar results have been reported by Ad and Cox.

Modifications of the standard maze procedure are commonly used in patients having mitral valve surgery. The use of modified lesion sets and alternate energy sources simplify ablation and, theoretically, minimize the risk of surgery. Some groups advocate only left-sided maze lesions to ablate AF. Although the pulmonary veins may not be the initiating focus for AF in all patients with mitral valve disease, isolating the pulmonary veins still remains a crucial maneuver in any attempt to ablate AF. After the heart has been arrested and a standard left atriotomy is performed, we often isolate the pulmonary veins with two “half-oval” lesions created with a flexible cryoprobe or with an RF clamp. The superior limb of this oval is created from the superior end of the left atriotomy and is carried around the two superior pulmonary veins. Similarly, the inferior limb is then created from the inferior cut edge of the left atriotomy and is carried around the two inferior pulmonary veins. A connecting lesion is then carried down from this pulmonary vein encircling lesion to the mitral valve annulus. The left atrial appendage cannot be excluded by oversewing the orifice from within the left atrium, by amputating it and oversewing it externally, or by simply ligating it externally.

Another useful method involves amputation of the left atrial appendage after creating the left atriotomy to expose the mitral valve. The open left atrial appendage stump can then serve as the area of joining the cryolesions from above and below the pulmonary veins. Bipolar RF clamps can similarly be used to create each limb of the pulmonary vein encircling lesion. In this instance, for the superior limb of the encircling lesion, one jaw of the clamp is passed epicardially through the transverse sinus, and the other through the left atriotomy and placed endocardially into the stump of the left atrial appendage. The inferior limb of the encircling lesion is created in a similar manner with one jaw placed epicardially and one endocardially with the tip meeting through the stump of the amputated left atrial appendage.

**Coronary Artery Bypass and Aortic Valve Procedures**

Studies have demonstrated that the addition of the maze procedure to aortic valve procedures or coronary artery bypass grafting (CABG) do not increase the morbidity or the periprocedure risks. Patients undergoing aortic valve procedures or CABG deserve special attention as they represent a group of patients who are less likely to experience preoperative AF and less likely to receive additional treatment for AF. There is compelling evidence that treating AF in these situations is associated with improvement in outcomes. The use of alternate energy sources as cryoenergy or RF ablation may be appropriate under these circumstances due to the concern related to long cardiopulmonary bypass time. Important questions are which category of these patients requires an additional AF ablation and is the lesion set different than in other cardiac pathology?

Evidence-based guidelines for performing adjunctive procedures for AF during cardiac surgery have been published recently by the International Society of Minimally Invasive Cardiac Surgery (ISIMICS). These experts recommended addition of surgical AF ablation to increase the chance of return to sinus rhythm, to improve ejection fraction, and also to decrease the risk of thromboembolic complications. The selection of the surgical technique differs according to patient’s risk category. With regard to the lesion set, PVI and left atrial appendage exclusion may be appropriate in patients undergoing CABG or aortic valve procedures; however, these lesion sets may not be appropriate for those with an enlarged left atrium or more complex long-standing AF.
Septal Myectomy for Hypertrophic Cardiomyopathy

In patients with hypertrophic cardiomyopathy, AF can result in profound clinical deterioration due to the loss of the atrial component of left ventricular filling. Patients who undergo septal myectomy usually enjoy dramatic relief of symptoms and improved exercise capacity; however, a number of patients will be left with underlying diastolic dysfunction with resultant increased left atrial pressure and dilatation.

The question of whether addition of concomitant surgical ablation of AF at the time of septal myectomy remains a clinical dilemma. It is unclear if surgical intervention for AF would indeed yield superior freedom from AF and improve outcomes to an appreciable extent, mostly because of the underlying substrate (extent of myocardial fibrosis) and pre-existing cardiomyopathic process. In our experience, approximately two-thirds of patients who have AF preoperatively are free from AF after septal myectomy (without surgical AF ablation). Adequate myectomy relieves left ventricular outflow tract obstruction and allows some left ventricular mass regression that may then decrease the risk of recurrent AF.

However, concomitant maze procedure at the time of septal myectomy may be useful for patients with obstructive hypertrophic cardiomyopathy who are extremely symptomatic from their arrhythmia preoperatively, are intolerant to antiarrhythmic medications, or have undergone prior catheter ablations that were unsuccessful. Published reports demonstrate that concomitant AF ablation at the time of septal myectomy is safe, is effective, and does not appear to increase operative mortality or postoperative morbidity. In our experience, concomitant procedures for AF at the time of myectomy improves late freedom from AF among patients with preoperative intermittent and continuous AF, but in patients with continuous AF, late recurrence following myectomy is much greater than this observed after AF ablation during mitral valve procedures. Among patients having septal myectomy and the maze operation, there was, in addition to reduced risk of late arrhythmia, a significant reduction in need for warfarin anticoagulation (maze: 0% vs no maze: 37%; \(P = 0.004\)). Importantly, the addition of the Cox-maze procedure in these patients undergoing septal myectomy for obstructive hypertrophic cardiomyopathy does not appear to increase operative morbidity beyond what is expected after an isolated maze procedure.

Congenital Heart Diseases

The most common atrial tachyarrhythmias among adults with congenital heart diseases are AF and flutter, and right-sided cut-and-sew lesions of the Cox-maze III procedure is effective in these patients. With the availability of newer devices such as RF and cryoablation, the procedure time for maze procedure is shortened significantly. Consequently, our current preference is to perform a biatrial maze procedure, particularly when there is chronic AF, left atrial dilation, or concomitant mitral regurgitation. In the presence of atrial flutter, we prefer to add a “right atrial isthmus” lesion, which is the posterolateral tricuspid valve annulus to the coronary sinus to the inferior vena cava. We also make an effort to close the left atrial appendage (Fig. 65.12)

In patients with atroventricular nodal reentrant tachycardia who underwent unsuccessful ablation in the electrophysiology laboratory preoperatively, we perform perinodal cryoablation on cardiopulmonary bypass after opening the right atrium and closure of any intracardiac shunt. This involves multiple applications of the cryo-probe around and in the ostium of the coronary sinus, which is then carried anteriorly toward the proximal atrioventricular node until temporary complete heart block is noted, at which time the rewarming is begun; normal atrioventricular conduction returns shortly thereafter.

In our experience, 80% of patients undergoing right-sided maze at the time of congenital heart disease repair had paroxysmal AF, and the most common diagnoses were Ebstein anomaly, isolated atrial septal defect, and tetralogy of Fallot. Approximately 90% of patients were free of AF at the time of hospital dismissal, and approximately 70% manifested sinus rhythm. Permanent pacemakers were required in 15% of these patients; the overwhelming majority of these were for sick sinus syndrome postoperatively. At last follow-up, approximately 75% of patients with preoperative chronic AF and 95% of patients with preoperative paroxysmal AF were free from subsequent atrial arrhythmias.

Atrial Fibrillation and Tricuspid Valve Disease

Tricuspid valve disease is present in up to 10% to 50% of those with significant mitral valve pathology. In most patients, concomitant tricuspid regurgitation is associated with elevated pulmonary artery pressure and tends to be functional in etiology. Tricuspid regurgitation may improve after correction of the left-sided pathology; however, it may persist or even worsen. In general, the course is difficult to predict, and reoperation to correct tricuspid regurgitation is associated with high perioperative morbidity and mortality. AF has been identified as a significant predictor for late development of tricuspid regurgitation after mitral valve surgery. In a previous study from our institution, restoration of sinus rhythm after addition of the maze procedure during mitral valve surgery was associated with significant decrease in the progression of late tricuspid regurgitation in comparison to those who continued to have AF postoperatively. Several mechanisms explain the progression of tricuspid regurgitation with the persistence of AF. First, patients in AF are more likely to have right ventricular dilatation with resulting dilatation of the tricuspid valve annulus. Second, AF is associated with higher pulmonary artery pressure late after operation in comparison to patients who are in sinus rhythm.

SPECIAL SITUATIONS

Low Ejection Fraction

AF can lead to cardiomyopathy, and multiple reports have documented that left ventricular dysfunction caused by supraventricular tachycardia can be cured or improved by conversion to sinus rhythm. AF impairs hemodynamic function by several mechanisms. First, AF results in loss
of atrioventricular synchrony and atrial contraction. This may reduce ventricular filling and thereby reduce cardiac output. The consequence of loss of atrial contraction may be especially pronounced in patients with impaired diastolic function as is seen with hypertrophied ventricles, restrictive cardiomyopathy, and mitral valve stenosis. Also, fluctuation in the R–R interval changes the diastolic filling interval, producing a variable stroke volume.

Cardiomyopathy caused by tachycardia is commonly thought to be associated with chronic arrhythmias having rates greater than 120 beats per minute. In our experience, ventricular dysfunction may be associated with resting heart rates considerably lower than this, and further, paroxysmal AF can lead to ventricular dysfunction. Our patients with tachycardia-induced cardiomyopathy having maze operations had a median resting heart rate of 88 beats per minute (range: 58 to 144 beats per minute). Furthermore, among patients with preoperative paroxysmal AF, the median preoperative resting heart rate was 62 beats per minute (range: 47 to 94 beats per minute), and during paroxysmal episodes of arrhythmia, the median heart rate measured was 84 beats per minute (range: 66 to 163 beats per minute). It is important to recognize that resting heart rate is not truly reflective of overall heart rate in patients with AF, because the heart rate response to exercise may vary, and patients with well-controlled resting heart rates may have a rapid ventricular response with minimal activity, and develop tachycardia-induced cardiomyopathy.

The identification of patients with tachycardia-induced cardiomyopathy may be challenging, and careful search for structural heart disease is necessary. The absence of structural anomalies and the documentation of AF before left ventricular dysfunction make the diagnosis of tachycardia-induced cardiomyopathy more likely. Other patients may present with AF and left ventricular impairment, and it is unclear whether the arrhythmia is causative or a consequence of ventricular dysfunction. In such patients, medical management is initiated, and cardioversion should be considered. If the ejection fraction improves when the rate is more adequately controlled, the diagnosis again is more likely.

**Prophylactic Cox-Maze**

New-onset late AF has been observed after mitral valve repair for degenerative mitral valve disease, and this can occur even without a prior AF history; this risk is greater in patients with advanced age. Those with severe mitral regurgitation and significant functional tricuspid regurgitation have altered right ventricular strain and function. Intervention on coexistent functional tricuspid regurgitation does not reduce the late risk of AF; in fact, the predisposition to late AF may already be set at the time of mitral valve repair. From our prior analysis, the following factors were identified as independent predictors for late AF: (1) advanced age, (2) increased left atrial size (more than 50 mm), (3) moderate preoperative tricuspid regurgitation, and (4) diabetes. Therefore, those with severe mitral regurgitation, left atrial enlargement, and coexistent moderate functional tricuspid regurgitation may be reasonable candidates for consideration of prophylactic maze procedure. This strategy awaits prospective, controlled studies.

**POSTOPERATIVE MANAGEMENT**

Different protocols including different antiarrhythmic regimens for the postoperative management of patients who have undergone a Cox-maze operation are used. Our drug of first choice is amiodarone; however, it is used selectively in patients who experience atrial or ventricular arrhythmias during hospitalization and is usually continued for 3 months postoperatively. Electrolytes are monitored on a daily basis, especially potassium and magnesium, and both are kept in the high-normal range. Electrical cardioversion is used as needed.

Diuretics are used liberally early after operation with the goal of achieving preoperative weight. Excision of the atrial appendages during the Cox-maze procedure removes an important source of atrial natriuretic peptide, and this may predispose the patient to fluid retention early postoperatively.

Coumadin is used for 3 months postoperatively, but there is no consensus on the need for anticoagulation beyond this interval. Some clinicians prefer to continue Coumadin believing that the risk of thromboembolism is not reduced sufficiently to avoid systemic anticoagulation. Others argue that if AF is eliminated and ventricular function is normal, the risk of thromboembolism from a postoperative patient without a left atrial appendage is very low.

**OUTCOMES**

The Cox-maze procedure has proved to be the most effective surgical procedure for treating AF and its adverse consequences of irregular rhythm, altered hemodynamics, and increased thromboembolic risk. The indications for its application continue to evolve as new techniques and instruments have been developed. These modifications have simplified surgical ablation of AF and have expanded surgical ablation to additional subgroups of patients as mentioned previously. However, evaluation of outcome for patients who have undergone the maze procedure, as well as new devices and lesion sets, is difficult because of variable methods of reporting success in eliminating AF.

Outcomes of procedures for ablation of AF are influenced by thoroughness of follow-up as well as method of assessment of cardiac rhythm. The electrocardiogram is a “snap-shot” in time and has limited ability to detect those patients that may have transient atrial arrhythmias in the follow-up period. A better method is the Holter monitor, but widespread use for routine follow-up is not feasible. After clinical evaluation and follow-up of rhythm status are obtained, the second difficulty is in how the results of the analysis are reported. “Rhythm at last follow-up” may underestimate the recurrence rate of atrial arrhythmias in the follow-up period and thus overestimate the success of the procedure. Conversely, actuarial methods used to delineate time-related events, “freedom from AF,” define any recurrent arrhythmia as a failure of the procedure and thus may underestimate the actual clinical success. Other factors that contribute to confusion in assessing results of surgical treatment of AF are viable terminology (intermittent vs. paroxysmal, etc.) and differing patient populations (lone paroxysmal AF, AF with mitral valve disease, etc.).

The HRS/EHRA/ECAS, in collaboration with the American College of Cardiology, Society of Thoracic Surgeons, and American Heart Association, published an Expert Consensus Statement on catheter and surgical ablation of AF outlining recommendations for personnel, policy, procedures, and follow-up. These guidelines were intended to standardize the design of studies, procedures performed, intensity of follow-up, and reporting success as it pertains to the surgical- or catheter-based treatment of AF. In terms of reporting success, the HRS consensus document recommends that success from AF intervention should be reported as freedom from AF without antiarrhythmic medications.
Cox-Maze III vs. Catheter-Based Ablation

There is debate as to the most effective lesion set during catheter ablation, but an equally important issue is achieving and ensuring transmural lesions. Achieving transmurality can be complicated by several factors such as tissue characteristics (e.g., thickness and fibrosis) and the unpredictability of conditions at the time of ablation. Although conduction block provides a clear endpoint for electrical isolation of the pulmonary veins, reconnection of conduction has been demonstrated in up to 64% of patients during follow-up. The cut-and-sew Cox-maze procedure by its nature ensures a transmural lesion, which we believe is the most important factor in successful electrical isolation of the pulmonary veins.

The data comparing late results of Cox-maze III to catheter-based ablation techniques are scarce. We analyzed the outcome of 97 patients aged 25 to 80 years who underwent an isolated cut-and-sew Cox-maze procedure between 1993 and 2007; this group was matched 1:2 according to age, sex, and AF type with 194 patients who underwent catheter-based ablation for lone AF. The freedom from AF at last follow-up was 82% in those patients who underwent the Cox-maze procedure with discontinuation of the antiarrhythmics, compared with 55% in those who underwent ablation, and 24% of the ablation group required a repeat ablation procedure.

Cox-Maze III vs. Cox-Maze IV

Although the Cox-maze III is considered the gold standard for surgical treatment of AF, many surgeons consider this procedure to be demanding and excessively time-consuming, especially when used in conjunction with other operations. The simplified Cox-maze IV developed at Washington University addresses these issues. The procedure appears to be effective, and in one report comparing 100 patients undergoing the Cox-maze IV with 112 having the Cox-maze III, freedom from AF was 90% following the newer procedure compared with 96% after the Cox-maze III. Also, freedom from AF off antiarrhythmics was slightly higher in Cox-maze III (83%) versus 82% in the Cox-maze IV group, as was freedom from anticoagulation, 86%, and 74% in the Cox-maze III and IV groups, respectively. There was no significant difference between the two groups in the need for a pacemaker.

Mayo Clinic Experience

Success with the standard Cox-maze procedure has varied in published reports. In general, approximately 90% of patients who undergo the Cox-maze operation are free from AF at last follow-up, with new pacemakers required in 10% to 15% of patients. Our experience is similar to others in that operative risk is low, 1.5% overall, which includes patients having concomitant intracardiac repair; risk of operation for isolated AF is <1%, which is comparable to the risk of closure of an atrial septal defect. New permanent pacemakers were required in <10% of patients, and the indication in almost all was sick sinus syndrome. This incidence of pacing postoperatively is lower than expected based on the original reports of the Cox-maze operation. In the earlier experience, clinicians were hesitant to allow patients to remain in junctional rhythm early postoperatively, but in many such patients, a stable sinus mechanism will return. Thus, some patients may have had pacemakers implanted prematurely. Additionally, technical modifications to the original Cox-maze operation may reduce injury to the sinoatrial node.

Preoperatively, patients are counseled that this operation reliably eliminates AF in most individuals but does not necessarily restore sinus rhythm. In older patients especially, there is an underlying incidence of sick sinus syndrome, and when AF is eliminated, permanent pacemakers may be necessary to manage sinus node dysfunction. Also important is the fact that conduction disturbances may also develop in those patients who require concomitant intracardiac procedures at the time of surgery for AF. Eighty percent of patients undergoing the standard biatrial maze procedure at Mayo Clinic have combined procedures.

In our experience, approximately 90% of patients are free from AF upon dismissal from the hospital. This includes patients with sinus rhythm, paced rhythm, or junctional rhythm with an adequate rate. It is important to recognize that the Cox-maze procedure, like other cardiac operations, predisposes patients to transient AF in the early postoperative period.

Surgical cure of AF appears to be durable, and at last follow-up (median: 34 months), the overall freedom from AF was approximately 85%. When outcome is analyzed in a product limit estimate (Kaplan–Meier), freedom from AF was 76% at 5 years and 51% at 10 years. In our series, late outcome and cure of AF depends on preoperative characteristics. At last follow-up (median: 41 months), 93% of patients with preoperative lone paroxysmal AF were free from their arrhythmia with an actuarial freedom from AF of 90% at 5 years and 64% at 10 years. Patients with preoperative lone chronic AF had 83% freedom from AF at their last follow-up (median: 28 months) with an actuarial freedom from AF of 80% at 5 years and 62% at 10 years. The Cox-maze operation is less durable for patients undergoing combined Cox-maze and mitral valve surgery with 70% of patients free from AF at last follow-up (median: 33 months) and an actuarial freedom from AF of 68% at 5 years and 41% at 10 years (Fig. 65.3).

Although a number of patients in our series had evidence of a junctional rhythm postoperatively, with some subsequently dismissed in this rhythm, we do not routinely utilize antiarrhythmic medications or stimulants, such as theophylline, as have been suggested. A significant number of such patients will regain a stable sinus rhythm, and it has been reported that up to 50 weeks are required until this occurs. Persistent junctional rhythm may reflect sinus node dysfunction, and this will predispose the patient to recurrent arrhythmias and stroke. In these patients, a permanent pacemaker should be considered.

FUTURE DIRECTIONS

New instruments developed to facilitate surgical ablation of AF and new lesion sets may achieve rates of AF control similar to the traditional "cut-and-sew" methods. However, equivalency has not yet been demonstrated, and future comparative studies are necessary. Also, there are many unanswered questions regarding the clinical application of the maze operation in conjunction with other cardiac procedures. Is PVI equally effective as a full Cox-maze procedure for patients with paroxysmal AF and mitral valve disease? Perhaps, the pathogenesis of AF in patients with mitral valve disease and paroxysmal arrhythmia is different from that of patients with chronic AF in the setting of mitral valve disease and a dilated left atrium. Another unresolved issue is whether concomitant left reduction atroplasty should be performed at the time of valve repair and maze procedure for patients with AF and a dilated left atrium from mitral valve disease. Finally, should a "prophylactic" maze procedure be performed in a patient with preoperative sinus rhythm and a dilated left atrium undergoing surgery for mitral valve disease? The altered atrial tissue in these patients represents an arrhythmogenic substrate, which renders them at high risk (approximately 40%) for the development of postoperative
SUGGESTED READINGS

Beyer E, Lee R, Lam BK. Point: minimally invasive repair. Clearly, the risks and benefits should be weighed before an additional procedure is performed, which carries with it the added risk of permanent transvenous pacemaker implantation.

Stulak JM, Suri RM, Dearani JA, et al. When should prophylactic maze procedure be considered in
Dr. Schaff and colleagues have given a complete overview of surgical treatment of atrial fibrillation. I would like to focus mostly on the cut-and-sew maze, which they have continued to espouse and do extremely well. Given the mortality for this procedure is <2%, it has been efficacious. The atrial fibrillation is in the cure rate 85% to 90% range as compared with 50% for catheter-based procedures. The real question is which patient will tolerate these procedures. Alternative energy responses are good but not quite as good as the cut-and-sew maze. The difficulty is the more extensive procedures take quite a bit more time and therefore there needs to be appropriate decision making as to which patients will benefit.

There is also a school of thought that solving the mitral valve issue in patients who have mitral regurgitation and atrial fibrillation may have similar results to mitral valve surgery plus maze procedure. This is presently a study being performed by the NHLBI-sponsored Cardiothoracic Surgical Network. This study is nearly closed in terms of patient entry. I believe the results will help us determine which patient will do best with mitral valve surgery alone versus mitral valve surgery plus maze procedure.

ILK
Minimally Invasive Treatment of Atrial Fibrillation

Gorav Ailawadi

INTRODUCTION

Atrial fibrillation (AF) develops in nearly 5% of patients in their lifetime and is the most common arrhythmia. An estimated 5 million Americans suffer from AF, and this number is expected to triple by 2050. AF is associated with an increased risk of stroke, thromboembolism, and death. Moreover, AF is an underdiagnosed cause for tachycardia-induced cardiomyopathy. AF is responsible for nearly 26 billion dollars annually. For these clinical and economic reasons, there is great interest in developing effective treatments for AF.

Medical therapy is the first-line therapy for patients with AF but has been shown to have poor success at rhythm restoration. The advent of surgical and ultimately catheter-based ablation technologies has revolutionized approach for this devastating disease.

AF is now classified by the terms paroxysmal, persistent, and long-standing persistent according to the ACC/AHA guidelines. Paroxysmal is characterized by recurrent episodes that last <7 days or convert to sinus without cardioversion. Persistent AF refers to AF that lasts more than 7 days, while long-standing persistent AF is AF lasting more than 1 year. The terms intermittent, chronic, and permanent AF are no longer in use.

The Cox-Maze III procedure (so-called “Cut and Sew Maze”) became the gold standard for the cure of AF. Although this procedure has excellent long-term results, it was limited in its adoption due to patient morbidity and complexity for the surgeon. Within the last several years, a number of alternate energy sources were developed to create lesion sets to treat AF, which is a variant of the Cox-Maze III, often termed Cox-Maze IV.

PATHOPHYSIOLOGY OF ATRIAL FIBRILLATION

AF is characterized by macro reentrant electrical circuits in both atria. Each patient’s electrical circuitry is unique; thus, mapping AF in any given patient can be laborious and challenging. Endocardial mapping has demonstrated that the pulmonary veins and posterior left atrium are the critical anatomic targets for ablation in patients with isolated AF as well as those with concomitant valvular heart disease. Specifically, in patients with paroxysmal AF, the source for reentrant circuit appears to be from the pulmonary veins while in patients with persistent AF, regular and repetitive activation can be identified in the posterior left atrium, the pulmonary veins, and/or the left atrial appendage (LAA). Although routine intraoperative mapping is currently not feasible for guiding intraoperative AF ablation, an anatomic approach based on our understanding of pathophysiology and on empiric results is reasonable. In fact, such an anatomic (rather than map-guided) approach is rapidly becoming the standard for catheter-based ablation of AF. The Cox-Maze III and IV use predetermined lesions/incisions in anatomic locations to interrupt these circuits. Surgical intervention typically includes excision/ligation of the LAA, which may reduce the risk of recurrent AF, thromboembolism, and stroke.

THE COX-MAZE PROCEDURES

Cox-Maze IV

With recent advances in surgical tools for ablation, there are a number of less invasive approaches to recreate variations of the Cox-Maze III lesion set. The number of cases referred for surgical ablation pales in comparison to those treated via catheter. However, there are several potential advantages to surgical ablation including creation of transmural lesions, direct or endoscopic visualization eliminating the possibility of pulmonary vein stenosis as well as collateral damage to adjacent structures like the esophagus, and the ability to excise or exclude the LAA. Limitations include the inability to replicate the complete Cox-Maze lesion set without opening the heart or performing a concomitant catheter ablation for ablation along the coronary sinus (CS) and cavotricuspid isthmus, as well as poor ability to map for gaps or atrial flutter.

We perform bilateral completely thorascoscopic epicardial ablation followed by endocardial catheter ablation. The patient is placed in supine position with double-lumen endotracheal tube intubation. Three ports are placed in the right chest. Under single-lung ventilation, the right pericardium is opened parallel to the phrenic nerve. The oblique and transverse sinuses are opened bluntly and the right pulmonary veins are encircled using a special dissector. The right veins are ablated using a bipolar radiofrequency (RF) clamp with 3 to 5 successful ablations high on the left atrium. Electrical isolation is confirmed by sensing and pacing the pulmonary veins. The atrial roof and floor lines/connecting lesions are created using a unipolar RF lesions sources from the right side to the left side using thorascopic guidance. Unipolar RF can also create a lesion from the superior vena cava (SVC) to the inferior vena cava (IVC) laterally along the right atrium. An SVC encircling lesion is made above the sinus node using bipolar RF. On the left side, the ligament of Marshall is divided after opening the pericardium posterior to the phrenic nerve. The left veins are encircled and ablated using the bipolar RF clamp. The connecting lesions are completed and the LAA is excised with an endoscopic stapler or excluded using commercially available devices (Fig. 66.1). The surgical procedure takes roughly 3 to 4 hours. Patients then undergo catheter procedure at the same setting or at a later date with mitral isthmus/CS ablation and cavotricuspid ablation. The surgical lesions are tested for gaps as well. Our results are fairly consistent with over 85% freedom from AF at 18-month follow-up of antiarrhythmics as tested with 7-day Holter monitor.
There are a number of other less invasive methods to recreate some version of the Cox-Maze III lesion set in patients with lone AF. Another common approach is through a port access approach (right mini thoracotomy) using cardiopulmonary bypass via the femoral vessels. The heart is arrested similar to a minimally invasive approach to the mitral valve. Using cryoablation and RF, the lesion set can be replicated after opening the left atrium. If right atrial lesion sets are planned, femoral venous cannula must be in as far as the SVC and the perfusion must be prepared to get air in the venous line. The LAA is oversewn from the inside. With this approach, centers are reported over 80% success in patients with failed catheter ablation.

**Cox-Maze III**

The traditional Cox-Maze III procedure infrequently performed today is through a median sternotomy. Cardiopulmonary bypass is established using bivacal and ascending aortic cannulation. Coronary artery bypass grafting distal anastomoses are completed prior to the Cox-Maze III procedure, whereas mitral valve surgery is performed after reconstruction of the left atrium. The heart is arrested using antegrade cardioplegia with or without retrograde cardioplegia.

The interatrial groove is opened anterior to the right pulmonary veins and extended around the left atrium above the pulmonary veins similar to a donor heart explant (Fig. 66.2A). Care is taken to stay away from the posterior mitral annulus where the circumflex and CS lie. A stay suture is placed at the left inferior pulmonary vein to mark the anatomy and facilitate atrial reconstruction. The LAA is excised and can either be closed separately or incorporated with closure of the left atrial cuff (Fig. 66.2B, C). As reconstruction is carried around the right side close to the CS, partial thickness bites can help avoid injury to the CS. Along the CS, a 2-minute cryolesion is created from the mitral annulus around P3 toward the CS.

The right-sided incisions begin by opening the mid-right atrium toward the 2 o’clock position on the tricuspid valve (Fig. 66.2D). The interatrial septum is then incised. An additional 2-minute cryolesion is created at the 2 o’clock position of the tricuspid annulus. The right atrial appendage is amputated and bipolar RF clamp is introduced into this stab incision and directed toward the patient’s back, creating a lesion in the right atrial appendage that ends 1 cm from the previously placed right atriotomy. The direction of the bipolar RF clamp is then reversed, and a lesion is created toward the tricuspid annulus. The bipolar RF clamp is then used to create a lesion from the right atriotomy to the SVC and to the IVC. Finally, a cryolesion is created on the right atrial isthmus, extending from the tricuspid annulus to the orifice of the IVC. The right atrial incisions are closed and the cross-clamp is removed.
Section II: Adult Cardiac Surgery

Fig. 66.2. The Cox-Maze III procedure with bipolar radiofrequency application in right atrium. (A) The left atrium is opened anterior to the left pulmonary veins, and the pulmonary vein encircling incision is carried to the level of the left inferior pulmonary vein. A stay suture is placed at this point. The left atrial appendage is excised sharply. (B) The pulmonary vein encircling incision is completed and then partially closed. (C) An incision is created to the mitral annulus, exposing the anterior surface of the coronary sinus. Cryolesions are created at the mitral annulus and coronary sinus. (D) There is a single long incision in the right atrium heading from the tricuspid annulus to the fossa ovalis; a cryolesion is created at the tricuspid annulus at the 2 o'clock position. Through this incision, bipolar radiofrequency lesions are created to the superior vena cava and to the inferior vena cava (dashed lines). A stab incision is created in the right atrial appendage, and a bipolar radiofrequency lesion is created in the appendage (dashed line).

Before weaning the patient from cardiopulmonary bypass, it is prudent to examine the region of left atrial suture lines for bleeding and repair them while on bypass. It is common for patients to require atrial pacing immediately after Cox-Maze III.

Freedom from AF ranges from 75% to 98% at 5 to 10 years following surgery. The most significant risk factors for AF recurrence after a Cox-Maze procedure include (1) duration of preoperative AF longer than 5 years, (2) persistent and long-standing persistent AF, and (3) left atrial enlargement especially >6 cm. The Cox-Maze procedure also has shown to nearly eliminate the risk of late stroke.

PULMONARY VEIN ISOLATION

In patients with paroxysmal AF, the source for AF emanates from the pulmonary veins in over 90% of patients. Thus, pulmonary vein isolation (PVI) is often adequate to treat paroxysmal AF. A variety of energy sources have been employed to perform PVI. The pulmonary veins can be isolated with a single, large, boxlike lesion (Fig. 66.3) or, alternatively, as two separate oval-shaped lesions (Fig. 66.4). Either approach is acceptable. For patients with persistent or long standing persistent AF, the mitral isthmus lesion and lesion to the LAA should be added (Fig. 66.3).

Fig. 66.3. Left atrial lesion set of the Cox-Maze III procedure. Dashed lines indicate surgical incisions. The pulmonary veins are encircled by a surgical incision, and there is a connecting incision to the mitral valve annulus. The left atrial appendage is excised, and this incision is connected to the pulmonary vein encircling incision.
Fig. 66.4. Bilateral pulmonary vein isolation with excision of the left atrial appendage. The pulmonary veins are isolated as two separate ovals that include wide areas of left atrial tissue. The left atrial appendage is excised sharply. This can also be done with RF clamps and excision of the appendage as in figure 66.1.

Fig. 66.5. Isolation of the right pulmonary veins with a bipolar radiofrequency clamp (Atricure, Inc., West Chester, OH). Under direct vision, the clamp is placed on the left atrial cuff adjacent to the pulmonary veins. With 3-5 parallel 5- to 15-second applications, the pulmonary veins and a wide left atrial cuff are isolated.

When performed for isolated AF, bilateral thoracoscopic ablation can be performed as described above. PVI is performed with bipolar RF and the veins can be tested for entrance and exit block. During concomitant cardiac surgery, PVI can be performed following sternotomy. It can be done on or offpump. The right superior pulmonary vein is dissected off the right pulmonary artery and the right veins can be encircled with a silastic catheter after opening the oblique sinus. The bipolar clamp is fed around the pulmonary veins. Three to five successful ablations are performed high on the left atrium away from the vein bifurcation (Fig. 66.5). Ablation works best if the interatrial fat pad is opened. The left-sided PVI can also be done off pump but can be challenging. At times, it is easier to perform this on pump or even with the heart arrested. The ligament of Marshall is divided and the left veins are encircled. The bipolar RF clamp is then placed around the left pulmonary veins and ablation performed as high on the left atrium as possible. The LAA can be oversewn, ligated, excised using a stapler, or excluded using commercially available devices. Results with this approach are excellent with 1 year success of 90% freedom from AF.

Other approaches include epicardial box lesion using RF or high-frequency ultrasound. In opening the left atrium, a box lesion can be created using 2-minute cryoablation lesions in a Cox- Maze IV pattern (Fig. 66.6). Similar success rates should be expected.

POSTOPERATIVE MEDICATIONS

Postoperative AF is common and occurs in about 20% to 30%. The first 3 months after ablation is considered a blanking period. If patients develop AF during this time, it does not indicate a failure of the ablation. However, in patients who do not develop AF during this time, they typically remain in sinus rhythm even beyond 3 months. We typically maintain patients after ablation on anticoagulation and antiarrhythmics for 3 to 6 months and gradually wean them off. Typically, patients are monitored with a 7- or 14-day Holter monitor at 6 months and yearly thereafter.

CURRENT CLINICAL ALGORITHM

In patients having concomitant surgery, the plan for ablation depends on the type of AF and the risk of the patient. For patients with paroxysmal AF, there is little risk in performing PVI in most patients. For extremely high-risk patients, or those with severe mitral annular calcification, PVI can add risk, especially ablating the left pulmonary veins as the heart needs to be lifted. The LAA should be excised or oversewn in all these patients. For persistent or longstanding persistent AF patients, a complete lesion set needs to be performed and there is little benefit for PVI alone. Thus, in cases where the left atrium is accessed, a complete lesion set can be performed using cryoablation or RF. In cases where the left atrium is not opened, epicardial RF ablation can be performed. In this case, we base decision to ablate on the longevity of AF, size of the left atrium, and risk to the patient. If patients are unlikely to benefit in this scenario or the risk is additive, then the LAA is excised as the only therapy.

For patients with lone AF, whether paroxysmal or persistent, most patients we see have failed catheter ablation. In these patients, we perform a total thoracoscopic RF ablation with full lesion set as described above. These patients then undergo endocardial testing and ablation of the mitral isthmus and right atrial flutter line (cavotricuspid line).
FUTURE DIRECTIONS

There is great potential in the epicardial treatment of AF for surgeons. Contrary to other areas of cardiology/cardiac surgery, surgical ablation is on the rise. Surgeons must understand the terminology and lesion sets to convince their cardiologists and electrophysiologists to refer patients. Minimally invasive and hybrid approaches are likely going to provide the most durable results at the least invasive approach. Newer technologies for ablation, testing, LAA management, and monitoring will likely lead to improved results. Surgeons must, however, not shy from treating patients with concomitant or lone AF to continue to prove our role in the management of AF.

SUGGESTED READINGS

My partner Gorav Ailawadi has developed a program with our electrophysiologists to perform minimally invasive atrial fibrillation. This will be in contrast to the full cut and sew maze that Dr. Schaff will discuss in another chapter. The bottom line is that this approach does not require a full sternotomy and without a doubt is more appealing to patients as well as to electrophysiologists. The procedure is safe but it certainly takes a while as the technology continues to evolve. The results have been outstanding. It makes sense that this treatment is available for stand-alone atrial fibrillation and I am sure we will continue to be adopted. The results of this procedure are as good if not better as catheter-based ablation.

Ilk
INTRODUCTION

Hypertrophic cardiomyopathy (HCM) is a relatively common cardiac disease that may be defined as left ventricular (LV) hypertrophy in the absence of an underlying cause such as systemic hypertension or valvular aortic stenosis. Previously, the disorder was referred to as idiopathic hypertrophic subaortic stenosis (IHSS) or asymmetric septal hypertrophy (ASH), but the preferred term is HCM with or without obstruction. Approximately 1 in 500 individuals in the general population will be affected, and this translates into approximately 600,000 people in the United States.

As discussed below, the phenotypes and the clinical presentations of patients with HCM vary widely, and this has led to some confusion in the past about the importance of LV outflow tract (LVOT) obstruction and the indications for surgical treatment. On a molecular level, HCM is an autosomal dominant disease caused by genetic mutations coding for sarcomeric proteins and myofibrils. Over 400 mutations in more than 15 genes have been identified, and double and compound heterozygosity and homozygosity have been reported. In an individual patient, the occurrence of HCM may be sporadic (20% to 40%) if it represents a new mutation or if there is incomplete penetrance in other family members. Among patients with positive family history, approximately 60% to 70% will have an identifiable HCM mutation by genetic testing. All HCM patients should have a thorough family history and pedigree analysis, preferably by a specialist in medical genetics, to identify and counsel relatives at risk. Genetic testing may be useful to identify specific mutations in the patient and relatives, but there is no clear role for genetic testing in risk stratification for patients known to have HCM.

PATHOLOGY AND PATHOPHYSIOLOGY

The diagnosis of HCM should be considered in any patient who has ventricular hypertrophy without an underlying cause, and most patients with HCM will have a maximal wall thickness ≥ 15 mm. The most common pattern of hypertrophy is diffuse involvement of the ventricular septum, and average maximal LV wall thickness is 20 to 22 mm. In 5% to 10% of patients, LV wall thickness is dramatically increased measuring 30 to 50 mm. Morphology of the septum varies according to age, and older patients with HCM often demonstrate a sigmoid configuration. Among children, increased LV wall thickness is defined as the thickness more than 2 standard deviations above the mean for age, sex, or body size (z score >2). These morphometric distinctions are not rigid, however, as patients have now been identified who are "genotype positive/phenotype negative" and may be considered to have subclinical HCM.

Other patterns of hypertrophy are recognized including mid-ventricular and apical HCM. It has been suggested that as many as one-third of patients with HCM will have segmental wall thickening involving only a portion of the ventricle and overall LV mass may be near normal. Importantly, the phenotype of the disease, the appearance, and severity of hypertrophy does not correlate with genotype, and multiple ventricular morphologies may be found in the same family.

Myocardial fiber disarray is the histologic feature of HCM, and myocytes show large, bizarre nuclei with degenerating muscle fibers and fibrosis. The disorganized whirling of muscle fibers is characteristic of HCM, but myocardial disarray is not pathognomonic for HCM and may be present in myocardium in any conditions in which there is pressure overload.

In the classic form of HCM with obstruction, the mitral valve, especially the anterior leaflet of the valve, moves anteriorly during systole, and the posterior leaflet closes against the mid- and free-edge third of the anterior leaflet instead of at the free edge as occurs normally. The free edge of the anterior leaflet is then displaced upward and narrows the LVOT. Anterior displacement of the valve leaflets produces mitral valve regurgitation (MR) of variable degree, and the jet is oriented in a posterolateral direction. Apposition of the anterior leaflet to the bulging septum produces a contact lesion, a whitish endocardial scar, which is useful in guiding septal myectomy. It is important to note that the occurrence of systolic anterior motion (SAM) of the mitral valve is often dynamic, and provocative maneuvers such as Valsalva, squatting, exercise, and in some cases, adrenergic stimulation may be necessary to elicit SAM, MR, and LVOT obstruction.

Recently, Maron and colleagues reported that mitral valve leaflet length is increased in patients with HCM, an average of 7 mm for the anterior leaflet and 4 mm for the posterior leaflet. Although absolute leaflet length did not correlate with the presence or absence of LVOT obstruction, the authors did find that a ratio of anterior leaflet length to LVOT diameter of >2.0 was associated...
with subaortic obstruction. The surgical implications of this finding are unclear, but it was suggested that the elongation of the mitral valve leaflets might constitute a primary phenotypic expression of HCM.

Anomalies of papillary muscles are present in 15% to 20% of patients with HCM who undergo myectomy. These abnormalities include anomalous papillary muscles, direct insertion of papillary muscles into the anterior mitral valve leaflet, fusion of the papillary muscle to the ventricular septum or LV free wall, and accessory muscles and accessory anomalous chordae (false chords). In most cases, these abnormalities do not complicate myectomy or contribute to outflow tract obstruction, but in some patients, anomalous papillary muscles, especially those that insert directly into the body of the anterior leaflet, can contribute to outflow tract obstruction.

Coronary arteries are larger than normal in patients with HCM, and basal coronary flow is increased at rest. In symptomatic patients with HCM, however, coronary flow reserve (CFR) is decreased compared with controls, and phasic flow is abnormal with a greater amount of flow during diastole. Decreased CFR is associated with a reduction in coronary resistance, suggesting that the mechanism is not due to narrowing of intramyocardial small arteries or compression of the microcirculation; indeed, the reduction in CFR in patients with HCM may be the result of near maximal vasodilatation of the microcirculation in the basal state.

Atherosclerotic coronary artery disease (CAD) is present in approximately 5% to 15% of patients with HCM depending on the population studied, and at our clinic, significant CAD was detected in half of the patients who were selected for coronary angiography, and disease was severe in 26%. Survival of HCM patients with obstructive CAD is reduced compared with HCM patients without CAD, and survival is also poorer than patients without HCM who have comparable CAD and normal ventricular function.

Muscular bridging of the left anterior descending (LAD) coronary artery is relatively common and has been identified in 15% of patients with HCM undergoing coronary angiography at our clinic. It is unclear whether bridging of the LAD plays a role in the pathophysiology of the disease and associated symptoms of angina, but for adult patients, risk of death and, in particular, sudden cardiac death are not increased among patients with HCM with myocardial bridging. In contrast, Yetman and coworkers reported that among children with HCM, systolic compression of LAD was present in 285 cases and was associated with a greater incidence of chest pain (60% vs. 19%; P = 0.04), cardiac arrest with subsequent resuscitation (50% vs. 4%; P = 0.004), and ventricular tachycardia (80% vs. 8%; P < 0.001). Myocardial ischemia was postulated to be the cause of this poor outcome.

The most important pathophysiologic feature of HCM is diastolic dysfunction with elevation of the LV end-diastolic pressure, which, in turn, increases left atrial and pulmonary venous pressures. These hemodynamic abnormalities account for the common symptoms of effort dyspnea and limited aerobic capacity. It is understandable, therefore, that atrial arrhythmias, particularly atrial fibrillation (AF), may dramatically worsen diastolic filling when the ventricle is noncompliant and is dependent on atrial contraction.

Elevation of LV end-diastolic pressure is further aggravated by LVOT obstruction and by associated MR. Thus, while surgical myectomy has a minimal immediate effect on the overall LV mass, symptoms related to diastolic dysfunction are immediately improved when outflow gradients and MR are relieved. A secondary effect of septal myectomy on diastolic function is regression of hypertrophy.

A less common mechanism whereby LV hypertrophy led to diastolic dysfunction is the situation where concentric ventricular hypertrophy is so severe that muscle mass encroaches upon the ventricular cavity and reduces the normal cavity size. This is particularly striking in patients with the apical form of HCM where the distal one-third to distal one-half of the left ventricle may be obliterated (during diastole and systole) by muscle. Surgical remodeling by apical myectomy may increase end-diastolic volume and, thus, improve diastolic function.

In the past, there was debate on the importance of outflow tract obstruction as a mechanism for symptoms in patients with HCM. In many instances, outflow tract obstruction is labile, and previously, clinicians questioned whether catheter entrapment accounted for LVOT gradients measured during invasive catheterization. It is now recognized that outflow obstruction is much more common than previously thought. For example, Maron found resting outflow tract gradients of ≥50 mmHg in 37% of 320 patients with HCM and, more importantly, found exercise-induced gradients (mean 80 ± 43 mmHg) in an additional 106 patients. It appears, therefore, that as many as 70% of patients with HCM who come to clinical evaluation will have significant outflow tract obstruction. An important finding in this study was the relative unreliability of the Valsalva maneuver (sensitivity 40%) compared with exercise Doppler echocardiography in detecting these dynamic gradients. Latent obstruction can also be documented during hemodynamic catheterization by isoproterenol challenge, a technique that may be useful in patients who are unable to exercise or in patients in whom reliable Doppler echocardiography cannot be measured.

In patients with obstructive HCM, symptoms of dyspnea and fatigability may also relate to the severity of MR. As is true with LVOT obstruction, associated MR may be dynamic and difficult to appreciate in the resting state. Symptomatic patients with moderate or severe degrees of MR associated with HCM with obstruction are excellent candidates for septal myectomy because the MR and associated symptoms (dyspnea and fatigability) are almost always abolished or significantly improved with relief of LVOT obstruction.

MR that results from SAM is eccentric and directed posterolaterally during late systole. A centrally directed jet should raise suspicion of a primary leaflet abnormality contributing to valve leakage. Rupture of chordae with resultant leaflet prolapse can precipitate congestive heart failure, and hemodynamics may worsen if HCM is not recognized and patients are managed medically with afterload reduction. Preoperative tranesophageal echocardiography (TEE) is unnecessary in most patients, but TEE is critically important intraoperatively in assessing the results of myectomy.

**CLINICAL PRESENTATION AND NATURAL HISTORY**

Many patients with HCM are asymptomatic, but most who come to surgical attention will have limiting symptoms. Typical symptoms caused by obstructive HCM are exertional dyspnea, chest pain (angina), and/or lightheadedness, especially lightheadedness is associated with rapid change in posture. Although some patients present in childhood and adolescence, the most common clinical scenario for patients referred for septal myectomy is the development of symptoms in the fourth, fifth, or sixth decade of life. In most patients, it is the development of symptoms that leads to the diagnosis of HCM, and, thus, it is unknown whether LV outflow gradients existed previously. It seems likely, however, that in most patients, the development of symptoms corresponds to the development of subaortic obstruction. Occurrence of AF can also precipitate symptoms and predispose to systemic embolism, which occurs in 6% of patients. AF is found in 30% of older patients with HCM.
It is interesting to note that approximately one-third of patients with HCM who are symptomatic will have exacerbation of symptoms, predominantly dyspnea or presyncope, after meals. Postprandial symptom exacerbation is associated with higher resting LVOT gradients and advanced clinical symptoms.

In the general population, survival of patients with HCM is similar to survival of individuals without disease, and high mortality in HCM in earlier reports is likely due to excess numbers of high-risk patients included in studies from tertiary referral centers. More recent natural history studies indicate that the annual mortality rate of patients with HCM is approximately 1%, but there are several important subgroups that have higher risk of cardiac death. For example, HCM is the most common cause of sudden death among young athletes.

The importance of LVOT obstruction with regard to late outcome of patients with HCM has been controversial, but there is now substantial evidence that survival of HCM patients with outflow obstruction is reduced in comparison to patients without obstruction. Studies by Maron et al., Autore and associates, and Elliot and coworkers have demonstrated convincingly a strong correlation between resting outflow gradients and late risk of death. In a longitudinal follow-up of 1,101 patients with HCM, Maron et al. reported that patients with outflow tract obstruction (a basal gradient of at least 30 mmHg) had a risk of death from HCM or symptom progression that was more than four times that observed among patients without obstruction (Fig. 67.1). The association of outflow tract obstruction on limiting symptoms and death was independent of other clinical variables. Of note, patients with obstruction and mild symptoms (NYHA class II) were more likely to have progression to severe symptoms or to die from heart failure than asymptomatic patients with cardiomyopathy (Fig. 67.2).

Elliot et al. reported that risk of sudden death is relatively low (<0.4% per year) in asymptomatic patients with LVOT obstruction and none of the recognized risk factors for SCD, but their study did demonstrate reduced survival among patients with LVOT obstruction and nonsustained ventricular tachycardia, abnormal exercise blood pressure response, a family history of premature sudden death, unexplained syncope, or severe LV hypertrophy.

The prognosis of patients with latent obstruction is less clear, but a study by Vaglio et al. suggests that the clinical course is similar to patients with resting obstruction. In their series, one-quarter of patients required invasive therapy for relief of symptoms, and annual mortality was 2% per year, a rate higher than that reported for patients with HCM and no LVOT obstruction.

**Indications for Operation**

Septal myectomy is, in general, reserved for patients who continue to have limiting symptoms despite medical treatment. Pharmacologic therapy usually begins with beta-adrenergic blocking agents, which have a negative inotropic effect and may mitigate latent outflow gradients provoked with exercise. Beta-blockers are less effective in reducing high resting gradients. The calcium antagonist, verapamil, has been used for patients with nonobstructive and obstructive HCM with the aim of improving ventricular relaxation and decreasing LV contractility, but hemodynamic and electrophysiologic side effects limit long-term use. Disopyramide has negative inotropic effects and is a type I-A antiarrhythmic agent that can improve symptoms by reducing resting gradients. However, this drug also has side effects including dry mouth and eyes, constipation, and difficulty in micturition. Also, it increases atrioventricular nodal conduction and thus may increase ventricular rate in patients.
with AF. It is important to realize that while medications may ameliorate symptoms, drug therapy does not appear to decrease the probability of sudden death. In a recent study of 173 patients who were taking amiodarone, beta-blockers, verapamil, and/or sotalol for the treatment of symptoms, there was no difference in sudden death mortality compared with patients who were on no pharmacologic therapy.

Although guidelines emphasize the importance of preliminary medical treatment before consideration of surgery, there are other important considerations regarding indications for septal myectomy in patients with obstructive HCM. Some patients (Fig. 67.3) have very favorable anatomy with localized hypertrophy in the subaortic septum and relatively normal wall thickness throughout the rest of the ventricle. In these patients, septal myectomy may be the preferred treatment rather than prolonged medical therapy because the results of surgery are so predictably good and relief of outflow tract gradient would be expected to relieve symptoms completely as there is little remaining substrate for diastolic dysfunction. Not infrequently, patients will prefer surgical treatment because of intolerance to side effects of medical treatment, especially side effects of high-dose beta-blockers. A final group of patients who might be considered earlier for surgical myectomy are patients who have high resting gradients (≥50 mmHg) and have a history of prior cardiac arrest or a strong family history of sudden cardiac death.

### SURGICAL TECHNIQUES

A standard median sternotomy is preferred to provide adequate access both to the aorta and to the left ventricle. We favor normothermic cardiopulmonary bypass using a single, two-staged venous cannula and cold blood cardioplegia (initial dose of 1,000 to 1,200 ml) for myocardial protection. Adequate exposure of the subaortic septum is critically important, and several maneuvers facilitate the operation. Pericardial sutures are used only on the right side to elevate pericardium toward the surgeon and allow the left ventricle to fall posteriorly in the thorax. Next, an oblique aortotomy is made slightly closer to the sinotubular ridge than is usual for aortic valve replacement, and the incision is carried through the midpoint of the noncoronary aortic sinus of Valsalva to a level approximately 1 cm above the valve annulus. As illustrated in Figure 67.4, the edge of the proximal aorta is held out of the way with stay sutures of 4-0 polypropylene, and a cardiotomy sucker is placed through the aortic valve and used to depress the anterior leaflet of the mitral valve and protect it from injury. The right aortic valve cusp is collapsed against the sinus wall where it will usually stay. A sponge stick is used to depress the right ventricle and rotate the septum posteriorly, orienting the LV outflow anteriorly.

A standard No.10 scalpel blade is used for incision in the septum that begins just to the right of the nadir of the right aortic sinus (Fig. 67.5). The initial incision in the septum is made upward and then leftward over to the anterior leaflet of the mitral valve. Scissors are used to complete excision of this initial portion of myocardium. The area of septal excision is then deepened and lengthened toward the apex of the heart being certain to excise hypertrophied septum beyond endocardial scar. Trabeculations are excised, and the myectomy site is further enlarged with the use of pituitary rongeurs. Adequate septal myectomy usually yields 3 to 12 g of muscle. The use of the sponge stick to depress the heart posteriorly will improve exposure of the distal extent of the myectomy. The aortotomy is closed in two layers with 4-0 polypropylene suture, and the operation proceeds as usual.

This technique described above for more extended myectomy differs from the standard Morrow operation in which parallel incisions create a trough in the septum that extends up to 3 cm from the aortic valve. With the extended myectomy, the wider excision of muscle in the immediate subaortic area improves exposure of the distal extent of the hypertrophied septum, and excision extends up to 7 cm from the aortic valve. Inadequate myectomy results more often from failure to excise sufficient length of the septum (toward the apex) than from inadequate depth of excision. Importantly, the methods described above have proved adequate for all patients with subaortic obstruction, and maneuvers such as anterior leaflet plication are unnecessary and, we believe, potentially harmful. Mitral valve replacement is reserved for patients with intrinsic leaflet abnormalities that cannot be repaired.

To confirm complete relief of the LVOT obstruction, we routinely measure

---

**Fig. 67.3.** Some anatomic subtypes of hypertrophic cardiomyopathy compared with a normal heart (panel A). Patients who predominantly have septal hypertrophy shown in (panel B) are good candidates for operation because of the relative lack of thickening in the remaining ventricle and the low likelihood of residual diastolic heart failure.
Fig. 67.4. An oblique aortotomy extended into the noncoronary sinus gives the best exposure of aortic valve and subaortic septum.

Fig. 67.5. Septal excision begins just to the right of the nadir of the right aortic sinus and extends leftward to the attachment of the anterior leaflet of the mitral valve. The depth of muscle excised is approximately 1.5 to 2.0 cm, but more important than depth is extent of excision toward the apex. This is guided visually by endocardial scar, and as illustrated in the inset, the initial excision is almost always supplemented by excision of another large portion of the more distal septum.

Simultaneous aortic and LV pressure by direct needle puncture before and after myectomy. If the resting LVOT gradient is diminished by the effects of anesthesia, premature ventricular beats are induced by stimulating the ventricle to elicit the dynamic gradient produced by the Brock-enbrough phenomenon; the postextrasystolic systolic contraction is more forceful due to increased contractility and decreased afterload (Fig. 67.6); the same maneuver is then repeated after myectomy. In some patients, it is necessary to provoke LVOT gradient during surgery with isoproterenol (Fig. 67.7). Intraoperative TEE can identify residual MR, SAM, and any septal defects created by excision of septal muscle.

Severe MR in patients with obstructive HCM is not an indication for mitral valve replacement. Indeed, MR due to SAM is always relieved when outflow tract obstruction is corrected. In patients who have suspected intrinsic mitral valve disease in addition to obstructive HCM, direct mitral valve repair may be necessary, but we prefer first to perform extended septal myectomy and then discontinue cardiopulmonary bypass and reassess mitral valve function by echocardiography. When, in addition to obstructive HCM, there is marked degenerative mitral valve disease producing prolapse with or without ruptured chordae, valve repair is possible in over 85% of patients.

Unroofing of coronary artery bridging is performed in selected cases, particularly in young patients and those who have angina preoperatively. After the identification of the coronary artery distal to the intramyocardial segment, the anterior surface of the vessel is exposed by sharp dissection that is continued proximally until the LAD reemerges onto the epicardium. The divided myocardium over the artery is usually 3 to 5 mm thick. If the course of the artery is so deep that trabeculations of the right ventricular cavity are entered, pledgeted sutures placed deep into the coronary artery repair the opening into the ventricle.

OUTCOMES OF MYECTOMY

In experienced centers, risk of hospital death after isolated septal myectomy for obstructive HCM is very low, <1% (Fig. 67.8), and similar to risk of operation for elective mitral valve repair. As is true with other procedures, perioperative risk of septal myectomy may be higher among very elderly patients (particularly those with severe disabling symptoms associated with pulmonary hypertension), patients with prior myectomy, or those requiring concomitant procedures.
Complications such as complete heart block requiring permanent pacemaker and iatrogenic ventricular septal perforation have become uncommon (≤1% to 2%). Partial or complete left bundle branch block is a frequent finding after surgical myectomy but is not associated with adverse sequelae. However, if the patient has complete right bundle branch block preoperatively, interruption of the left bundle after myectomy increases the risk of complete heart block. This is particularly important in patients who have had alcohol septal ablation prior to operation. Alcohol septal ablation causes right bundle branch block in up to 60% of patients, and in patients who have had previous alcohol septal ablation, the risk of pacemaker insertion following surgical myectomy was 36% compared with 3% for those without prior intervention.

Adequate relief of LVOT obstruction with septal myectomy dramatically improves symptoms in exercise capacity in symptomatic patients with obstructive HCM. In our experience, approximately 90% of severely symptomatic patients have improvement of greater than or equal to two function classes, and relief of outflow gradients by myectomy is equally effective in improving limitation due to dyspnea, angina, or syncope. Importantly, symptomatic benefit of myectomy is directly related to reducing the basal outflow gradient and MR and improving LV systolic and end-diastolic pressures (in more than 90% of patients), which, in turn, may also favorably influence LV diastolic filling and myocardial ischemia. Relief of the gradient may decrease left atrial size and the subsequent risk of developing AF.

Late recurrence of significant resting LV outflow gradients is very uncommon after successful myectomy in either adults or children with obstructive HCM, and this is in contrast to patients who have surgery for the relief of congenital membranous subaortic stenosis. Common causes of recurrent LVOT obstruction and symptoms include limited myectomy at the first operation, mid-ventricular obstruction, and anomalies of papillary muscles. Most often, inadequate myectomy at initial operation is due to failure to extend the myectomy far enough toward the apex of the heart.

As mentioned previously, most patients are referred for septal myectomy because of persistent symptoms despite medical treatment. There is, however, evidence that operation may improve survival of patients with obstructive HCM. In a study from our clinic, Ommen and associates reported that late survival of 289 patients with obstructive
HCM undergoing septal myectomy was 98%, 96%, and 83%, 1, 5, and 10 years postoperatively, and this survival was similar to that of an age- and sex-matched U.S. population and similar to survival of HCM patients without obstruction. In the same study, myectomy patients had superior survival free from all-cause mortality \((P < 0.001)\), HCM-related mortality \((P < 0.001)\), and SCD \((P = 0.003)\) compared with unoperated HCM patients with obstruction (Fig. 67.9), and on multivariable analysis, performance of myectomy had a strong, independent association with survival \((\text{hazard ratio} 0.43; P < 0.001)\).

Recent studies also suggest mechanisms whereby relief of LVOT gradients might improve survival. The extent of LV hypertrophy is an important determinant of survival in patients with HCM, and successful myectomy results in some regression of LV hypertrophy. Thus, patients with the obstructive form of HCM may have an additive burden of ventricular hypertrophy caused by pressure overload that is relieved by successful myectomy. Although the severity of LV hypertrophy is a determinant of survival in unoperated patients, LV mass and wall thickness are not predictors of late survival in HCM patients following myectomy.

Relief of LVOT obstruction may also reduce the risk of serious arrhythmias. McLeod and associates reviewed patients with HCM who had received ICDs, and during a median follow-up of 4.5 years, 12 patients \((17\%)\) in the nonmyectomy group and only one patient \((2\%)\) in the myectomy group had appropriate ICD discharges (Fig. 67.10). The average annualized event rate was 4.3% per year in the nonmyectomy group, compared with 0.24% per year following myectomy \((P = 0.004)\). Thus, surgical myectomy and relief of outflow gradient are associated with a marked reduction in the incidence of appropriate ICD discharges and risk of SCD.

Latent obstruction is the term used to describe low resting LVOT gradients \((0 \text{ to } 30 \text{ mmHg})\) that increases to over 50 mmHg with provocation by Valsalva maneuver, exercise, inhalation of amyl nitrite, or infusion of catecholamines. Indeed, as many as one-third of patients with HCM and exertional symptoms will have low resting LVOT gradients. Septal myectomy should be considered in patients with latent obstruction because studies have shown that the degree of functional improvement and late survival in this subgroup of patients are similar to the clinical improvement experienced by patients who have successful operation for relief of high resting gradients (Fig. 67.11).

Selective infarction of the septum by infusing alcohol into the septal branches of the LAD can relieve LVOT obstruction, and there are obvious advantages to the patient of avoiding surgical incision and hospitalization. In a review of alcohol septal ablation from 42 published studies \((2,959 \text{ patients})\), resting LVOT gradient decreased from 65 to 16 mmHg \((P < 0.001)\), basal septal diameter reduced from 21 to 14 mm \((P < 0.001)\), and hospital mortality was 1.5%. However, the incidence of complete heart block requiring permanent pacemaker was 11%, and other important complications included coronary dissection \((1.8\%)\), pericardial effusion \((0.6\%)\), ventricular fibrillation \((2.2\%)\), stroke \((1.1\%)\), new right bundle branch block \((46\%)\), and new left bundle branch block \((65\%)\). Also, symptoms persisted in 11% of patients, redo alcohol ablation was required in 6.6%, and surgical myectomy was necessary in 2.0%. Thus, while this procedure is less invasive, it has significant morbidity, and residual gradients and incidence of conduction abnormalities are higher than that observed following septal myectomy.

Some patients with obstructive HCM may not be candidates for alcohol septal...
ablation because of unfavorable coronary anatomy. Also, concern has been raised about the potential long-term risk of sudden death related to arrhythmogenic substrate from the resulting septal scar. Cardiac magnetic resonance imaging demonstrates that in most patients, alcohol septal ablation causes transmural tissue necrosis, located more inferiorly in the basal septum than myectomy; the infarct usually extends into the right ventricular side of the septum and sometimes spares the basal septum leading to residual gradients at follow-up. A recent report from a registry of 874 patients (average age 55 years) who underwent alcohol septal ablation describes postprocedure survival of 86% and 74% at 5 and 9 years, considerably lower than the 96% and 83% of 5- and 10-year survival of surgical patients. In our practice, alcohol septal ablation is considered an option for patients who because of advanced age, infirmity, and/or comorbid conditions have increased risk for operation. For most patients, however, septal myectomy remains the gold standard for patients with HCM and severe LV outflow obstruction who are refractory to maximal medical therapy.

**SPECIAL CONSIDERATIONS**

There are few guidelines for the management of asymptomatic patients with HCM. Patients without symptoms may be discovered to have HCM during the course of evaluation of other cardiopulmonary disease, as a result of pedigree analysis of affected family members, or through genetic testing precipitated by identification of HCM in a relative. Negative inotropic drugs and beta-blockers may be useful for associated comorbid conditions such as systemic hypertension, but there is no evidence that these medications alter the course of HCM. Asymptomatic patients should be cautioned to avoid extreme exercise and should have thorough evaluation for risk factors for SCD. For patients who have no obstruction and no symptoms, surgery is not a consideration. For asymptomatic patients with HCM and very severe LVOT obstruction, however, decision-making is more difficult. Formal exercise testing with measurement of peak oxygen consumption may be helpful in uncovering significant cardiopulmonary limitation in patients who minimize symptoms. Established guidelines caution against septal reduction therapy in asymptomatic patients, but septal myectomy may be appropriate in selected young patients who have appropriate anatomy, very high resting and exercise gradients, and strong family history of premature cardiac death.

Sudden cardiac death is a special concern in HCM, and there is debate on the appropriate use of ICDs for primary and secondary prevention of SCD. Variables that appear to identify patients at increased risk of arrhythmic events include prior cardiac arrest or sustained ventricular tachycardia, a family history of premature sudden death due to HCM, repetitive nonsustained ventricular tachycardia on ambulatory Holter monitoring, massive ventricular hypertrophy (wall thickness >30 mm), and hypotensive response to exercise. Other findings such as myocardial bridging in young patients or myocardial fibrosis detected by cardiac MRI may also increase the risk of sudden death.

Apical HCM is a relatively rare morphologic subtype of HCM that is more common in Asia than in the West. It has a benign course in most patients, but diastolic dysfunction leading to heart failure may occur. In many of these patients, diastolic heart failure appears to be due to very small LV end-diastolic volume related to encroachment on the LV cavity by the hypertrophied apical muscle. The diastolic heart failure in selected symptomatic patients with small LV cavities may have improved LV remodeling achieved by myectomy through an apical incision (Figs. 67.12 and 67.13).
Other patients with HCM who may be surgical candidates are patients with mid-ventricular obstruction. In its pure form, mid-ventricular obstruction occurs because of hypertrophy of the papillary muscles and mid-septum, which come into contact during systole. The resulting high intracavitary gradients can cause exertional-related dyspnea and angina, as is seen with subaortic obstruction. Also, ventricular arrhythmias may occur in approximately 20% of patients with mid-ventricular obstruction who develop apical aneurysms. A key differentiating feature separating these patients from patients with typical subaortic obstruction is the lack of SAM of the mitral valve apparatus with mid-ventricular obstruction. Relief of mid-ventricular obstruction improves symptoms, and in our experience, the best surgical approach is a transapical ventriculotomy. Through this incision, the hypertrophied ventricular septum is easily exposed, and endocardial scar guides the extent of myectomy. Also, it is relatively simple to shave the anterolateral and/or posteromedial papillary muscles, which contribute to the mid-ventricular obstruction.

Children with HCM are usually asymptomatic, and the overall annual mortality for pediatric HCM beyond the first year of life is relatively low, approximately 1% per year. However, symptomatic HCM and HCM-related SCD can occur in childhood. As is true with adults, symptomatic children with obstructive HCM can be dramatically improved with extended transaortic myectomy, but there are special considerations in operating on infants and young children. Exposure of the subaortic septum may be difficult when the aortic diameter is small, and extreme care should be taken to avoid injury to the aortic valve cusps and to the mitral valve leaflets. In our experience with myectomy in 127 children, there has been no operative mortality, but injury to the aortic valve producing valvular regurgitation occurred in 6% of patients; fortunately, valve repair was possible, and no patient required replacement at the time of myectomy.

There is general consensus that an ICD is strongly warranted for secondary prevention of SCD in patients with prior cardiac arrest or sustained and spontaneously occurring ventricular tachycardia, and should be considered for primary prevention in patients with multiple clinical risk factors and in selected patients with a single major risk factor such as a history of SCD in a close relative. In patients who receive a device for secondary prevention, the yearly rate of appropriate ICD discharge is 10%; for HCM patients with ICDs implanted for primary prevention, the rate is 4% per year. For patients who need an ICD and are referred for septal myectomy, we prefer to delay device implantation until the third or fourth day postoperatively and avoid the potential for lead dislocation if the ICD is placed immediately preoperatively.

**SUGGESTED READINGS**

Wan CK, Dearani JA, Sunt DJ III, et al. What is the best surgical treatment for obstructive hypertrophic cardiomyopathy and degenerative

**EDITOR’S COMMENTS**

I doubt many people have near the experience that Dr. Schaff has in the surgical treatment of hypertrophic cardiomyopathy. Dr. Schaff has given us a thorough review and his analysis of results as well as surgical therapy is outstanding. I think there are two important points to take from this discussion. The most important is the length of the myectomy, may be more important than the depth of myectomy. As Dr. Schaff has noted first that the failure to do a long enough myectomy can lead to recurrences. Second, he has noted that mitral regurgitation can be helped with both the myectomy and occasionally concomitant mitral repair. He reserves mitral valve replacement to those patients who have intrinsic mitral valve disease. I think these are critical points and his approach should essentially lead to good results.

ILK
Cardiac Tumors
Bo Yang, Himanshu J. Patel, Francis D. Pagani, and Richard L. Prager

HISTORICAL BACKGROUND
Realdon Columbus first described a cardiac tumor as an anatomic finding in Padua, Italy, in 1559. Centuries later, in 1931, the first classification system similar to what is in current use was reported by Yater. In his monograph, he reported nine cases of primary cardiac tumors from pathologic examination. However, it was not until 1934 that the first antemortem diagnosis of a cardiac tumor (sarcoma) was made by Barnes, who used electrocardiography and a biopsy of a lymph node. Twelve years later, Mahaim’s classic paper described over 400 cardiac tumors.

The era of operative treatment of cardiac neoplasms was ushered in by Beck in 1936, when he successfully removed a teratoma located on the right ventricular (RV) surface. Bahnson is credited with the removal of the first right atrial myxoma with inflow occlusion, but the patient died postoperatively on day 24. Following the advent of cardiopulmonary bypass in 1953, left-sided intracardiac neoplasms were successfully removed first by Crafoord in Sweden in 1954. By 1964, the removal of 60 intracardiac neoplasms had been reported. The addition of cardiac echocardiography allowed easier antemortem diagnosis, and thus resulted in an increase in the number of tumor resections.

EPIDEMIOLOGY AND CLASSIFICATION
Cardiac neoplasms can be divided into primary and secondary types. Primary tumors are typically more common, but the overall incidence is still quite low, at 0.15% to 0.2% in autopsy series. Most primary cardiac tumors are benign (70%; Table 68.1). More than half of the primary cardiac neoplasms in adults are myxomas.

Malignant primary cardiac tumors (Table 68.2) are more frequently seen in adults than in children. Of malignant cardiac tumors, metastatic malignancies (Table 68.3) comprise the majority of those noted. Virtually every neoplasm has been shown to metastasize to the heart. The most frequent primary malignancies are leukemic neoplasms (54%), melanoma (34%), and bronchogenic carcinoma (10%), with others including sarcoma, breast, and esophageal carcinoma. Primary cardiac malignancies are uncommon, and most frequently are sarcomas.

MYXOMAS
Myxomas are the most frequently seen adult cardiac neoplasm. They usually occur sporadically but have been reported in autosomal-dominant inherited forms in 5% of cases. The typical sporadic tumor is seen in women aged 30 to 60 years and is solitary in nature. The familial form is more likely seen in younger patients, often male, and multicentric in nature. The two types can be differentiated on the basis of DNA ploidy, with the familial type having an abnormal ploidy. Carney complex is an autosomal X-linked inheritance characterized by cardiac myxoma, cutaneous pigmented lentigines, and primary pigmented adrenocortical disease with hypercortisolism.

Myxomas are typically located in the atria (most commonly on the limbus of the fossa ovalis) (Fig. 68.1A) but can arise in the ventricles. Multiple myxomas with involvement of different heart chambers have been reported but are very rare. The tumors are variable in their gross pathologic appearance (Fig. 68.1B), and can be papillary or smooth, pedunculated, or sessile, but are often quite friable. They are usually white or yellow and may be covered with thrombus. On cut sections, they frequently contain areas of hemorrhage. They are typically 5 to 6 cm in size but have been reported to reach up to 15 cm. Histopathologically, they have an acid mucopolysaccharide matrix and contain smooth muscle cells, capillaries, and reticulocytes. Calcification is reported more frequently in right atrial myxomas. These tumors typically grow outward into the cardiac chambers and rarely invade into the walls of the heart. However, those tumors that are bialtrial in location are thought to be a result of bidirectional growth of the myxoma because they are usually attached to the same point on the atrial wall. Usually, they are limited to the subendocardial region at their base. The subendocardial multipotential mesenchymal cell is considered the precursor cell for myxoma, thus accounting for the variable cell types seen in the tumor.

The natural history of myxomas is of rapid growth. Although these tumors are considered to be benign, there have been reports of extensive local extension, as well as metastatic spread. The familial type is more likely to be recurring and more aggressive.

The clinical presentation patterns of myxomas relate to their potential to cause obstruction (congestive heart failure, atrial fibrillation, fatigue, and syncope), embolization, and constitutional symptoms (myalgias, fevers, arthralgias, and weakness). Occasionally, they can present with evidence of infection, with a syndrome not unlike infective endocarditis. Physical findings can include signs of right- or left-sided congestive failure, the early diagnostic “tumor plop,” or diastolic rumbles.

The workup of a suspected myxoma includes echocardiography as the most useful test for diagnosis. Although surface echocardiograms can identify the pathology in most cases, the transesophageal echocardiogram (Fig. 68.1C) gives the best images and provides details regarding the location and attachment areas for tumors even as small as 2 mm. This aids in planning the operative approach. We also request left heart catheterizations to aid in the diagnosis of coronary disease in patients older than the age of 45 years or even younger if they have significant risk factors or symptoms. Computed tomography (CT) and magnetic resonance imaging (MRI) are rarely utilized at our center for suspected myxomas because in the setting of a myxoma, they typically do not add additional information. However, if there is suspicion that the

**Fig. 68.1.** (A) Typical operative approach using median sternotomy and cardiopulmonary bypass using a bicaval inflow technique. The exposure of the tumor is via a biatrial approach, and the tumor (white arrow) is readily delivered via the left atriotomy. (B) Gross pathologic appearance of this myxoma, which consists of large, mottled-tan hemorrhagic tissue, somewhat gelatinous and myxoid, measuring 6 cm in maximal dimension. (C) Transesophageal echocardiogram of this tumor in vivo. Note the “ball-valve” obstruction of the mitral valve caused by the tumor. The attachment is to the left atrial wall, along the fossa ovalis.

---

Tumor may not be a myxoma, cardiac-gated CT scans or cardiac-gated MRI may better delineate the extent of involvement of adjacent structures by the tumor. It is important to exclude endocarditis as a cause of cardiac mass.

The indication for operation in patients with a myxoma is the presence of one. Given the risk of embolization (8% to 10%) or obstruction, we typically perform the operation in an urgent manner following the establishment of diagnosis. These patients are usually operated on during the same hospitalization. Initial attempts are made to diurese the patients while obtaining necessary workup, but the surgery is typically not delayed. Anticoagulation with heparin is important to
institute during the time of evaluation because it is felt to decrease the risk of embolization.

Operative Approach

Median sternotomy is the incision of choice. However, in this era of minimally invasive surgery, other options include anterolateral thoracotomy (fourth intercostal space), partial sternotomy (with a “J” or “T” extension), or in female patients, a submammary incision. We utilize a “no-touch” technique to minimize the risk of embolization until the aortic cross-clamp is in place. Cannulation for cardiopulmonary bypass is performed with bicaval inflow, and if the tumor is in the typical location in the left atrium, left ventricular venting through the left superior pulmonary vein is not performed, to avoid dislodging tumor material. The patient’s temperature is allowed to drift down to 32 to 34°C, and the heart is arrested with cold blood antegrade cardioplegia. We often use a biatrial approach, having exposed the left atrium through the interatrial groove. The right atrial incision is a standard one, approximately 1 cm parallel to the atrioventricular groove. This exposure usually results in adequate immediate visualization of the tumor (Fig. 68.1A). If the tumor is small, it may be delivered through the left atriotomy with minimal manipulation. When it is larger, gentle application of pressure to the RV outflow tract area may aid in exposing the stalk of the tumor. The tumor is then removed with a 0.5- to 1-cm margin of tissue, taking care not to injure the mitral annulus, the area of conductive tissue, and the tricuspid annulus. The defect is closed primarily if the stalk is ≤1 cm and with a patch (pericardium or Gore-Tex) if the stalk is larger. It should be emphasized that adequate resection with negative margins is the key in resection of this tumor to avoid the risk of recurrence. A copious amount of saline is then used to irrigate the ventricular cavity, and the atria are closed in a routine manner. After draining the heart, the patient is weaned from cardiopulmonary bypass.

If the tumor is in the right atrium, cannulation may be done in a bicaval manner or with a superior vena cava cannula and a femoral vein cannula. A standard right atriotomy is made, and the tumor is then resected. If the tumor extends to the entrance of the inferior vena cava into the pericardium, deep hypothermic circulatory arrest may be needed to aid in complete resection.

Operative mortality is typically <5%, with the majority of deaths occurring in the older patient population (>70 years of age). Morbidity can be related to embolic phenomena (e.g., stroke). Atrial fibrillation is commonly seen both preoperatively and postoperatively in these patients and may require anticoagulation (given the raw surface of the atria in this scenario). Patients who underwent myxoma resection had survival characteristics that were not significantly different from that of an age- and gender-matched population, whereas those who underwent resection of fibromas, papillary fibroelastomas (PFE), lipomas, and other benign tumors had significantly poorer survival characteristics. Recurrence is estimated to be <5% in patients with sporadic myxomas, but up to 25% in patients with the familial form. Therefore, all patients should continue to get routine echocardiographic follow-up after myxoma resection.

PAPILLARY FIBROELASTOMAS

These benign tumors typically occur on valves or adjacent endocardium and comprise 7% to 10% of cardiac neoplasms. They are usually asymptomatic but can present with embolic phenomena (stroke) or with obstruction of coronary arteries (myocardial ischemia, infarction, or sudden death). PFE usually affects the anatomically contiguous structures of the aortic valve, the left ventricle outflow tract, and the anterior leaflet of the mitral valve. Their gross pathologic appearance consists of a frondlike mass with multiple projections, and they are typically small. Primary surgical excision is recommended for symptomatic PFEs, with left heart side location and with a specific picture suggestive for possible embolization. The indication in asymptomatic patients is not clearly defined. If the tumor is mobile, or larger than 1 cm or the patient is undergoing open heart surgery, the tumor should be resected. Asymptomatic patients with small nonmobile lesions (<1 cm) should be closely followed up with echocardiography. An interval of 4 weeks is advisable after an intracerebral hemorrhage. Surgical resection can be achieved by complete excision without any inclusive margin of normal tissue. A simple valve-sparing shave excision is adequate in majority of patients, whereas valvular repair or replacement is required when leaflet is damaged or restricted. Every effort should be made to repair rather than replace the valve.

Lipomas

Lipomas can occur at any age in any location within the pericardium. These tumors are typically slow growing and present with obstructive or compressive symptoms. Grossly, these tumors are like lipomas seen elsewhere in the body, being well-encapsulated and containing mature adipocytes. Resection is indicated in the presence of symptoms. Tumors found incidentally are resected at the time of other cardiac operations, assuming that the addition of this procedure confers minimal added risk. These tumors are not thought to recur, so a large negative margin is likely not necessary.

When these tumors exist in a nonencapsulated form in the interatrial septum, the condition is called lipomatous hypertrophy of the interatrial septum. This entity is often difficult to separate from neoplasm, but the addition of MRI allows identification of masses with fat, intense signals. Very little is known about the natural history of this entity, and typical indications for resection have not been identified but may include arrhythmias occurring with this pathology. If this lesion is found intraoperatively or preoperatively on transesophageal echocardiography, resection is not felt to be necessary.

Rhabdomyoma

The most frequently seen tumor in children is rhabdomyoma (45% to 60% of cardiac tumors in children vs. <1% of cardiac tumors in adults). It will often present in the first few days of life with symptoms of obstruction. The diagnosis is established on echocardiography. This neoplasm is usually multicentric, occurring with equal frequency in either ventricular chamber. Tuberous sclerosis is sought for because greater than one half of patients with rhabdomyoma have this hereditary disorder. Partial or complete spontaneous regression has been observed, more frequently in younger patients or those with smaller tumors. Surgery was recommended only for symptomatic patients with significant intracardiac obstruction and hemodynamical change, respiratory compromise, or significant risk of systemic embolization. For those patients in which complete resection is not achievable, relief of the obstruction and restoration/preservation of sufficient heart function is the primary goal. The prognosis is poor if they have associated tuberous sclerosis.

Fibromas

Fibromas are cardiac tumors that present often in children. They are usually located in the ventricular chambers and are solitary. Presenting symptoms are secondary to obstruction or arrhythmias. Because these tumors can calcify, they are occasionally
identified on chest X-rays. Complete surgical resection is the goal for cure, but debulking can be associated with long-term survival.

**CARDIAC PHEOCHROMOCYTOMAS**

Less than 2% of pheochromocytomas occur in the thoracic cavity. Those occurring in the intrapericardial location are often located in the dome of the left atrium. The diagnosis is suspected on clinical manifestations and laboratory confirmation of catecholamine oversecretion. Localization is obtained with the $^{131}$I-metaiodobenzylguanidine (MIBG) scan. A CT scan is the next most appropriate test for identifying the extent of involvement of adjacent structures. We also obtain transesophageal echocardiograms in all patients to evaluate the cardiac chambers and valves, as well as to obtain information about the extent of tumor. Finally, cardiac catheterization is performed in selected patients to identify significant coronary disease. Management first consists in controlling the hyperadrenergic syndrome ($\alpha$-blockade and if necessary intravenous hydration, followed by $\beta$-blockade if needed). The tumors are then removed using cardiopulmonary bypass. Complete resection is the goal.

**CARDIAC PSEUDONEOPLASMS**

There are five reactive and “pseudoneoplastic” tumors of the heart, which mimic true neoplasms either by clinical imaging or microscopically, including inflammatory myofibroblastic tumor (IMT), hamartoma of mature cardiac myocytes, mesothelial/monocytic incidental cardiac excrescences, calcified amorphous tumor (CAT), and lipomatous hypertrophy of the atrial septum. Surgical resection is recommended for IMTs and CATs. Castleman disease is a poorly understood, benign lymphoproliferative disease that may behave in a malignant manner, depending on the structures it invades, including the heart and great vessels. Surgical resection is recommended for unicentric lesion.

**PRIMARY MALIGNANT CARDIAC NEOPLASMS**

Primary cardiac malignancies are rare and almost always a type of sarcoma. In order of decreasing frequency, the types include angiosarcoma (Fig. 68.2), rhabdomyosarcoma, malignant mesothelioma, and fibrosarcoma. They can arise in any location and are often disseminated widely at the time of diagnosis. The symptoms are dependent on the location and the extent

---

**Fig. 68.2.** Selected cuts of a cardiac-gated thoracic computed tomography scan demonstrating this large angiosarcoma arising from the left atrial wall. (A) Neoplasm filling approximately 80% of the left atrial volume. (B) Tumor extension into the left superior pulmonary veins. (C and D) Sagittal and coronal views, respectively, each showing extension into the pulmonary veins. LIPV, left inferior pulmonary vein; LSPV, left superior pulmonary vein; MV, mitral valve; RSPV, right superior pulmonary vein.
of the tumor, and seem not to be related to the tumor histology. For the left heart sarcomas, most patients present with shortness of breath and dyspnea on exertion due to the obstruction of intracardiac blood flow. The right heart sarcoma tends to be bulky, grow in a more exophytic manner, be more infiltrative, and metastasize earlier, but not usually cause heart failure. The preoperative workup includes a search for extracardiac spread. CT scan and PET/CT scan are excellent modalities to assess the primary tumor and metastasis. Tissue diagnosis is very helpful in planning operation, but sometimes it is very difficult to obtain especially from those left-sided tumor. Operative therapy is reserved for those in whom metastases are absent, and some centers advocate adjuvant chemotherapy. If tumors are not resectable, chemotherapy and radiation therapy may be considered.

Overall, the prognosis of cardiac sarcomas is very poor with median survival of 6 months. The median survival was improved to 12 months with surgery and 25 months with complete surgical resection. The prognosis is dependent on the anatomical location, extent of tumor, and completeness of resection of the tumor rather than the tumor histology. The cardiac group at Methodist DeBakey Heart and Vascular Center introduced the surgical technique of cardiac explantation, ex vivo tumor resection, cardiac reconstruction, and subsequent cardiac reimplantation and cardiac autotransplantation for the left heart sarcomas. They reported that this approach improved the completeness of local resection, decreased local recurrence, and extended patient’s survival. For the right heart sarcomas, the complete resection can include the superior vena cava, a short segment of inferior vena cava, the entire right atrium, the tricuspid valve, the right coronary artery, and up to about 30% of the RV muscle mass if the RV function is normal.

There have been recent reports of orthotopic heart transplantation as a therapeutic option in patients with cardiac neoplasms (sarcoma, pheochromocytoma, lymphoma, and myxoma). In malignant tumors, reported median survival has been 12 months. However, this remains a controversial option, given the scarcity of donor organs, the need for rapid treatment in patients after presentation, and, finally, the unknown effect of immunosuppression on future malignant and metastatic potential.

**METASTATIC CARDIAC NEOPLASMS**

Metastatic tumors typically involve the pericardium, followed by epicardial, myocardial, and endocardial involvement in decreasing frequency. The mode of metastasis is dependent on primary tumor. Melanoma, sarcoma, and pulmonary malignancies spread by hematogenous routes. Direct extension is frequently seen in association with pulmonary, breast, thymic, and esophageal cancers.

Symptoms occur infrequently in metastasis, but when they do occur, they usually result from pericardial effusions. The therapy in this setting is a palliative subxiphoid pericardial drainage procedure. This procedure often results in durable symptomatic relief. Some authors advocate a formal “pericardial window” procedure to allow drainage into the left chest. We believe that this approach is not significantly different from simple subxiphoid drainage because the left lung often adheres to the “window,” thus eliminating the possibility of continuous drainage of pericardial fluid into the left chest. Moreover, this procedure may require general anesthesia (with double-lumen intubation), whereas a subxiphoid approach can be performed under local anesthesia.

Myocardial metastases from neuroendocrine tumor (NET) occur very rarely with an incidence of 4% of NET. Midgut NET is most often described to be associated with cardiac metastases. Cardiac metastases can be located in the myocardium of the left ventricle, right ventricle, biventricule, or in the ventricular septum too. Malignant arrhythmia or cardiac arrest can develop if the tumor infiltrates the conductive structures of the heart, such as the AV node and His bundle. Echocardiography and MRI are most frequent image modalities. PET/CT is more sensitive for detection of metastases in general and will more likely contribute to earlier detection of cardiac metastases. More than 50% of those patients can have carcinoid syndrome due to systemic effect of circulating vasoactive peptides, mainly serotonin and may develop carcinoid heart disease for the same reason. The cardiac involvement is characterized by progressive fibrosis and smooth muscle proliferation of right-sided valvular and endocardial structures leading to impaired function of the tricuspid and pulmonary valves due to thickening and regurgitation, which can eventually lead to RV failure. Surgical resection of the metastatic NET should be considered if the primary site is controlled and the metastatic tumor is resectable. If the carcinoid valve disease is developed, valve replacement is indicated.

**RENAL CELL CARCINOMAS**

Renal cell carcinomas (hypernephromas) are an important group of metastatic tumors to the heart. About 5% of all hypernephromas present with direct vena caval extension to the right atrium (Fig. 68.3A). In such cases, symptoms of caval obstruction, including lower body edema, gastrointestinal intolerance, and ascites predominate. If complete resection is performed and there is an absence of distant metastasis, 5-year survival can be 75%. Other tumors that extend from the abdomen into the right atrium include hepatic, adrenal, and gynecologic tumors.

Our approach to these tumors is a multidisciplinary one with urologists or surgical oncologists. Preoperative workup includes chest, abdomen, and pelvic CT scanning, transesophageal echocardiography, and left and right heart catheterization in selected patients. Tumors that are confined to Gerota fascia with extension into the vena cava or right atrium without regional lymph node or distant metastasis have the best prognosis, but only distant metastasis is an absolute contraindication to surgery.

The patients are prepared and draped from the neck to the upper thighs. The abdominal team starts with an exploratory laparotomy and mobilization of the kidney. After the kidney is mobilized and the retroperitoneum is hemostatic, a median sternotomy is performed and the patient is placed on cardiopulmonary bypass. The patient is cooled to 18°C, and neuroprotective agents (Solu-Medrol, pentobarbital, and mannitol) are administered. The ascending aorta is cross-clamped, and cardioplegia is delivered in an antegrade manner. Bypass is discontinued, and the right atrium is incised with an extension down to the inferior vena cava. We typically do not use adjunctive retrograde cerebral perfusion because resection of the tumor is accomplished usually in <20 minutes. In a combined manner, the abdominal and thoracic teams resect all tumor and thrombus. Bypass is then initiated, the cross-clamp is removed, and the patient is then rewarmed. The incisions in the vena cava and right atrium are closed. After adequate rewarming, the patient is weaned from bypass.

Another approach without profound hypothermia and circulatory arrest is used by the Stanford group. The immediate
infrahepatic cava is exposed and controlled. A short opening is made on the IVC and the tumor is extracted out from right atrium and IVC if possible. The infrahepatic cava is then clamped and the IVC is repaired. If the caval tumor does not just slip out, but requires an endarterectomy approach to dissect it from the cava, then an aortic occlusion balloon is inserted through the femoral artery and parked above the celiac. The patient is cooled to 25°C. The aorta is occluded above the celiac artery to avoid blood from hepatic veins running into the operative field, and upper body circulation is maintained with cardiopulmonary bypass. After the tumor is resected from right atrium and IVC, and the cava is repaired, the aortic occlusion balloon is deflated, and the lower body circulation is resumed

**SUMMARY**

Operative therapy of cardiac neoplasms generally comprises a small portion of all cardiothoracic surgical practice. These pathologic entities often require considerable clinical judgment for both diagnosis and treatment. However, because a significant percentage of these tumors can be treated with good results, they often provide surgeons a chance to dramatically alleviate symptoms in patients debilitated by these neoplasms.

**SUGGESTED READINGS**

It is ironic that the heart–lung machine is rarely used today in the treatment of the very condition that inspired its creation: acute pulmonary embolism (PE). Dr. Gibbon was inspired to his life’s work as a research resident at the Massachusetts General Hospital in 1931 as he sat at the bedside of a young woman dying of a massive PE. Have we wrongfully relinquished this part of our surgical heritage?

Acute PE is a remarkably common phenomenon, particularly among hospitalized individuals. The majority of acute pulmonary emboli result in little morbidity, and most are likely entirely unrecognized. Massive PE, however, may lead to hemodynamic collapse and death via a combination of mechanical obstruction of central right ventricular outflow and a peripheral vasospastic response in the remaining unobstructed vasculature. Although such massive emboli represent a relatively small proportion of acute events, they account for significant mortality and morbidity each year by virtue of the frequency with which PE occurs.

Why then is surgical embolectomy an uncommon procedure in most practices? The 2011 American Heart Association Scientific Statement on the management of massive and submassive PE discusses catheter-based embolectomy and thrombolysis more extensively than surgical embolectomy, with the surgical approach being reserved only for patients with contraindication to thrombolysis or in whom thrombolysis has failed. It should be noted that while the guidelines state that “... surgical embolectomy is reasonable for patients... who remain unstable after receiving fibrinolysis,” massive bleeding can be anticipated to complicate any invasive procedure until normal coagulation is restored. The guidelines of the British Thoracic Society published in 2003 are even more dismissive of the role of surgical intervention, with only thrombolysis and “invasive approaches (thrombus fragmentation and IVC filter insertion)” entertained as options for the management of massive PE. Surgical embolectomy, it was noted, was not an option as it was available in few centers.

Why has there been reluctance to offer surgical embolectomy? Apart from logistical issues regarding on-site cardiac surgical support, published mortality rates for acute pulmonary embolectomy traditionally have ranged from 20% to 60%, making it difficult to argue that the surgical results were any better than the natural history. A closer look, however, suggests that the hesitancy to proceed to the operating room may itself be part of the problem. Preoperative cardiac arrest roughly doubles the mortality rate, and the time interval between diagnosis and operation has similarly shown to have a profound effect on surgical risk. This becomes, of course, a self-perpetuating problem with many physicians, on the basis of the reported high risk of the procedure, reluctant to refer patients for surgery unless profound hemodynamic instability is present. It is only fair to add, however, that technically inadequate surgical embolectomy is likely a contributor to excessive mortality as well.

A critical assessment of the data suggests that there is, in fact, a small but definite place for surgical embolectomy in the management of massive PE. Furthermore, with the remarkable advances in the biocompatibility of extracorporeal membrane oxygenation (ECMO) technology in recent years, the cardiac surgeon, it may be argued, should once again be center stage as part of a multidisciplinary team evaluating all treatment options up front when a patient suffers massive PE. As surgeons we must, of course, take the responsibility for true “around-the-clock” availability and for performing the lowest risk procedure with the best possible results. We aim here to review our current approach to this condition in our hospital including a small number of technical points that are important for both minimizing the intraoperative insult to the struggling right ventricle and optimizing the relief of outflow obstruction. With such an approach, we believe that others can achieve the kind of results reported by Leacche and colleagues in 2006 with a 6% 30-day mortality rate among 47 patients undergoing embolectomy and 1- and 3-year survival rates of 86% and 83%, respectively, or those of Kadner and colleagues with an 8% overall mortality rate including a 28% mortality among patients experiencing a preoperative cardiac arrest.

In most instances, the diagnosis of acute PE will have already been made by the time the surgeon is called. Still, it is important to be familiar with current diagnostic modalities, as frequently the patient is being concurrently evaluated for aortic dissection or acute coronary syndrome. Of course, a clinical history consistent with deep vein thrombosis, such as the postoperative orthopedic patient in a long-leg cast, a history of malignancy or pelvic surgical patient after prostatectomy or hysterectomy, or trans-oceanic air travel can be quite helpful. Physical examination is seldom enlightening; however, biomarkers may be revealing; serum D-dimer enzyme-linked immunosorbent assay is almost universally elevated in the presence of acute pulmonary embolus and is frequently used in emergency rooms as a screening test, while elevation in cardiac biomarkers including troponin I and T, and natriuretic peptides have been shown to have negative prognostic impact with the concurrent diagnosis of PE. Nuclear scintigraphy has been almost entirely replaced by helical computerized tomographic (CT) scanning (Fig. 69.1). An adequate scan requires an appropriately timed bolus of contrast material, and a scan performed for other reasons may not image the pulmonary arteries adequately to rule out the diagnosis. Conversely, while CT scanning has the added advantage of providing information about other intrathoracic pathology, a contrast bolus timed appropriately for PE may be inadequate to rule out aortic dissection. The place of nuclear scintigraphy lies principally with...
the evaluation of pregnant women and patients allergic to contrast agents or with a marginal renal function.

An increasingly important recent diagnostic tool from a surgical standpoint is echocardiography (Fig. 69.2). Right ventricular function can be rapidly assessed in the emergency room or ICU by transthoracic echo, whereas embolic material may be identified in the pulmonary vasculature or, far more importantly, in the atria as “embolus in transit,” including those traversing a patent foramen ovale. Certainly, transesophageal echo should be performed in the operating room if at all possible.

When called to evaluate the patient at the bedside for surgical intervention, it is important to remember that, in addition to simple mechanical obstruction, the pathophysiology of pulmonary hypertension in acute PE entails the release of serotonin from platelets, histamine from tissues, and circulating thrombin. Hypoxia due to ventilation/perfusion mismatch and increased dead space will also worsen pulmonary vasoconstriction. Accordingly, oxygenation should be optimized before determining that a patient must go to the operating room.

It is widely accepted that systemic hypotension despite inotropic support is an indication for aggressive intervention—surgical, catheter-based, or lytic—as is persistent, refractory hypoxemia. The difficulty, however, is that operative risk is markedly elevated once the patient is in profound shock or suffers cardiac arrest. Accordingly, the challenge is to stratify patients early with regard to risk of poor outcome with anticoagulant therapy alone. In 2005, Sukhija and colleagues showed a reduction in in-hospital mortality among patients with right ventricular dysfunction who received timely pulmonary embolectomy, and multiple other studies have demonstrated the association of right ventricular dysfunction to both short and long-term mortality. Accordingly, the 2011 AHA scientific statement recommends swift intervention either with fibrinolysis or invasive intervention for those with right ventricular dysfunction.

Perhaps because of their wide availability and familiarity with their use in the context of treating acute coronary syndromes and more recently stroke, thrombolytics have taken center stage in the aggressive treatment of the unstable patient with massive PE. It is important to remember, however, that use of thrombolytics is not without risk. In the International Cooperative PE Registry, the incidence of cerebral events with thrombolytics was 3%. Furthermore, Thabut’s meta-analysis of thrombolytic studies reported in 2002 found no improvement in mortality rate when they were used in unselected patients as compared with heparin, but an almost twofold increased risk of hemorrhage (risk ratio 1.76, confidence interval 1.04 to 2.98). To be fair, among the four registries documenting the outcomes of patients with PE (MAPPET, ICOPER, PIETE, and EMPEROR), there is suggestion of a decrease in mortality among patients with hemodynamic compromise who are treated with thrombolytics although the numbers are small. There are also a few randomized control trials, mostly in intermediate-risk patients, which show a reduction in pulmonary artery pressures and reduction in thrombus burden albeit with no survival benefit except in high-risk patients.

Catheter embolectomy is another option, and one that is undergoing rapid evolution. Endovascular techniques include clot fragmentation, clot aspiration, and rheolytic therapy. The clinical efficacy of percutaneous therapy alone (Rotarex, Aspirex, Angiojet) has been reported to range from 81% to 92% and when combined with thrombolytic therapy to range from 91% to 100% depending on the modality. The mortality rate associated with these interventions, however, has been 16%
While this is far from the standard of care, those who have gained more widespread acceptance of ECMO (Vortex Medical Albany, NY), a modified bypass circuit with a movable suction cannula and a series of filters within the circuit that works well for proximal thrombus or embolism, and the EKOS catheter (EKOS Corp, Bothell, WA) that provides for directed thrombolysis and ultrasonic acceleration of clot lysis. Both of these devices show promise, but the data are sparse regarding clinical efficacy currently.

It has been our view that surgical intervention performed before hemodynamic collapse has an operative risk equivalent to or lower than that of thrombolytic therapy in most cases. Surgical pulmonary embolectomy is performed safely on a warm, perfused, beating heart with a minimal pump run in most cases. Surgery is clearly the option of choice when there is clot in transit present in the right atrium or, even more compelling, trapped in a patent foramen ovale or atrial septal defect. Operative intervention may be contraindicated, however, in the patient in full arrest who cannot be pharmacologically resuscitated or in whom thrombolytics have been recently administered. In these settings, we have found the institution of percutaneous ECMO remarkably effective with gratifying cases of successful weaning from support and discharge from the hospital with intact cardiovascular and neurologic function. While this is far from the standard of care, results have been so encouraging as to stimulate us to question whether our own surgical paradigm should be inverted with placement of the patient with massive PE and right ventricular dysfunction on ECMO prior to any sort of surgical or catheter-based intervention rather than viewing ECMO as a support for those who fail to come off bypass after surgical embolectomy.

Given the aforementioned data concerning increased morbidity and mortality in patients with right ventricular dysfunction, there is argument for rapid decompression of the heart to allow recovery of myocardial function.

For patients not requiring surgical intervention, heparin is the cornerstone of therapy. Individuals with heparin-induced thrombocytopenia may require the use of a direct thrombin inhibitor like argatroban or hirudin analogs. In either case, oral warfarin will be indicated for 3 to 6 months.

**ANATOMIC CONSIDERATIONS**

The anatomy of the pulmonary vasculature should be familiar to all cardiothoracic surgeons. What may be less well appreciated, however, is the remarkable access to lobar vessels via median sternotomy. All lobar and segmental vessels can be accessed via separate incisions in the right and left pulmonary arteries from within the pericardial space as one would during pulmonary thromboendarterectomy. This is an important point as a true saddle embolus lodged at the pulmonary bifurcation without distal fragments is relatively uncommon. More often, a large amount of embolic material is impacted in the orifices of the lobar vessels and will be inaccessible, particularly on the right side, via an incision limited to the main pulmonary artery.

**OPERATIVE PROCEDURE**

Pulmonary embolectomy is accomplished on normothermic cardiopulmonary bypass without cardioplegic arrest to minimize further insult to the right ventricle. Bicaval cannulation with tapes permits complete removal of thrombus bilaterally under direct vision. There are some older reports of pulmonary embolectomy under simple inflow occlusion, and this remains an option if cardiopulmonary bypass is unavailable; however, a much more complete job can be performed with the aid of the pump without risking hypoperfusion of end organs during the procedure.

Once the decision has been made to proceed with surgical intervention, the patient should be expeditiously transported to the operating room. Routine anesthetic monitoring including an arterial blood pressure line and an internal jugular introducer should be placed, but insertion of a pulmonary artery catheter at the beginning of the case should be avoided. Intraoperative tranesophageal echocardiography is a routine in our institution and greatly facilitates intraoperative decision-making particularly with regard to exploration of the right atrium and evaluation for clot in transit.

The groin vessels should be prepped into the field in case postoperative ECMO is necessary. A full sternotomy permits complete inspection of the right atrium. Of note, on more than one occasion, we have observed poor venous return from the inferior vena cava line only to find clot in transit impacted in the cannula oriﬁce. For this reason, the superior vena cava cannula is placed first so that partial bypass may be initiated if clot is dislodged from the inferior vena cava. Jakob has even advocated routine massage of the lower extremities and abdomen with open aspiration of the inferior vena cava using cardiotomy suckers to extract additional material in transit.

Normothermic cardiopulmonary bypass is instituted, and tapes are passed around the superior vena cava and inferior vena cava. If a patent foramen ovale or paradoxic embolus in transit has been identified by tranesophageal echo, a brief episode of cardioplegic arrest will be necessary and should be performed first to permit maximal reperfusion. In such instances, opening the right and left atria via a Dubost incision through both atrial-free walls and the septum will assure control of the distal clot (Fig. 69.3). After the patent foramen ovale and left atrium have been closed, the cross-clamp should be removed to permit maximum reperfusion.

If no patent foramen ovale is identified, it is preferable to perform the entire procedure without cardioplegic arrest. Clot in transit in the right atrium can easily be removed with the heart beating (Figs. 69.4 to 69.6). If right atrial exploration is not required, a bullet-tip sucker can be dropped into the right atrium via a stab wound with a purse-string suture to scrape coronary sinus return and reduce the formation of a paradoxical embolus in transit.

---

**Fig. 69.3.** Paradoxical embolus in transit can be identified by transesophageal echo. When it is identified, the left atrium must be opened before making any attempt to remove the thrombus. This may be accomplished via simultaneous standard right and left atriotomies or, as shown here, a Dubost incision extending vertically across the right atrial free wall and Waterston’s groove into the left atrium. This permits the surgeon to open the septum into the patent foramen while controlling the thrombus. This should be performed with a brief episode of cardioplegic arrest at the beginning of the procedure, providing the remainder of the bypass run for the struggling right heart to reperfuse and recover.
amount of blood passing through the right ventricle and into the pulmonary artery.

Clot in the pulmonary arteries should be removed via the same incisions used for the relief of chronic pulmonary thromboembolic disease during pulmonary thromboendarterectomy. Embolic material lodged in the left lung should be removed under direct vision via a pulmonary arteriotomy beginning in the main pulmonary artery and extending out onto the left pulmonary artery to the level of the pericardial reflection or just beyond (Fig. 69.7). Via this arteriotomy, the clot can be removed with stone forceps. Note that care must be taken not to grasp the bifurcation itself, as the pulmonary artery can be easily torn. We also pass soft endotracheal suction catheters down the artery orifices while massaging the lungs to remove any small clot that has migrated distally (Fig. 69.8). This is frequently productive. Balloon-tipped embolectomy catheters should not be passed as the pulmonary vessels are extraordinarily fragile and rapidly taper in diameter, making rupture of the vessels a very real possibility.

The incision in the right pulmonary artery is made between the aorta and superior vena cava again as one would when doing a pulmonary thromboendarterectomy for chronic disease. With a blunt-bladed retractor separating the aorta and superior vena cava, the transverse portion of the right pulmonary artery can be readily accessed (Fig. 69.9). A linear incision first in the posterior pericardium overlying the vessel and then in the vessel itself provides ready access to all of the lobar and

Fig. 69.4. If embolus in transit is identified in the right atrium, this can be extracted via a standard right atrial incision without cardioplegic arrest. This approach provides optimal protection of the right ventricle during the procedure.

Fig. 69.5. Common duct stone forceps are ideally suited for extraction of the thrombus.

Fig. 69.6. Any fragments of clot are easily extracted using a wide-mouthed sucker.

Fig. 69.7. Thrombus in the left pulmonary artery is accessed via an incision beginning in the main pulmonary artery. Adequate access permitting direct visualization of the segmental vessels requires extension of the incision onto the left pulmonary artery itself. This may require division of the pericardial reflection over the ventral surface of the pulmonary artery. Some caution in the application of electrocautery is appropriate superiorly to prevent injury to the recurrent nerve. Again, common duct stone forceps are ideal for extraction of thrombus under direct vision.

Fig. 69.8. More distal fragments of thrombus can be cleared with a wide-mouthed suction catheter or flexible endotracheal suction catheter. Massage of the lungs can be performed to milk thrombus proximally for removal. Balloon-tipped embolectomy catheters should not be introduced. The pulmonary vasculature is fragile, and the risk of rupture with such devices is real.
segmental vessels. If one has not previously performed an arteriotomy such as this, one will be surprised how central the takeoff to the right upper lobe is. The right upper lobe branch, right middle lobe branch, and the segmental vessels to the right lower lobe can be directly inspected. Again, clot is removed under direct vision using stone forceps (Fig. 69.10). This is followed with a flexible suction catheter and massage of the lungs (Fig. 69.11). These arteriotomies are easily closed with running 4-0 Prolene (Fig. 69.12). Pericardial patch augmentation is seldom necessary. The patient is then weaned from cardiopulmonary bypass, with inotropic support for the right ventricle routine. A pulmonary artery thermodilution catheter can now be passed.

The final step in the procedure is insertion of an inferior vena cava filter via a purse-string suture on the right atrial appendage (Fig. 69.13). There is general agreement that an inferior vena cava filter is indicated in patients with contraindications to anticoagulation, if PE has recurred while on anticoagulant therapy, or if PE is sufficiently severe that recurrent PE would be life-threatening. Although such filters do not prevent thrombosis and some argue that they are themselves a nidus of thrombosis, it is our practice to insert a filter in all patients with chronic disease as well as anyone having an embolus severe enough to require emergent surgery.

**POSTOPERATIVE CONSIDERATIONS**

Postoperatively, these patients frequently require significant inotropic support while the right ventricle recovers from surgery or, in some instances, venoarterial ECMO support to unload the right ventricle allowing for faster recovery while supporting systemic circulation. With biocompatible circuits, our threshold for such support has diminished. This mode may also allow for more rapid lung recovery, as well. These patients should be aggressively anticoagulated postoperatively with heparin followed by warfarin for 6 months.

A search should certainly be made for factors predisposing these patients to PE, and efforts should be made toward secondary prevention. Surgeons should take part in encouraging patients in secondary
prevention of modifiable factors such as obesity, tobacco abuse, use of oral contraceptives, or postmenopausal hormone replacement. If no causes are identified, consideration should be given to a search for occult malignancy. Consultation with a hematologist and systematic search for a prothrombotic state is routine. If no treatable cause is identifiable or patients have evidence of a hypercoagulable state, warfarin therapy is indicated for life.

**SUGGESTED READINGS**

Goldhaber SZ. Integration of catheter thrombectomy into our armamentarium to treat acute pulmonary embolism. Chest 1998;114:1237.

---

**EDITOR’S COMMENTS**

Sundt and colleagues have discussed surgical treatment of acute pulmonary embolus. As the authors have mentioned that cardiac surgery was born around the concept, but for whatever reason we tend to only be called when the patient is terminal. Certainly, acute pulmonary embolectomy in the patients who have already arrested is futile due to anoxic cerebral injury. The question, therefore, is the sweet spot where the surgical approach is preferred. Certainly in those patients who have not arrested the mortality for this procedure is surprisingly low.

My belief is that this procedure is best used when there is a need for mechanical support while performing an embolec­tomy. There are patients who are hemodynamically challenged and echo shows right ventricular strain. These patients cannot wait for the outcome of thrombolytic therapy or anticoagulation. In these situations, urgent/semielective pulmonary embolectomy will work beautifully. Unfortunately, we are called when things are too late. I think institutions that do best with this procedure are those where all the clinicians are aware of the multiple modalities of treating pulmonary embolus.

ILK
Pulmonary thromboendarterectomy (PTE) for the treatment of chronic thromboembolic pulmonary hypertension (CTEPH) is an uncommon surgical procedure; however, it is the only curative option that provides immediate and permanent cure for this devastating disease. The condition is remarkably underdiagnosed, and as a result, the procedure is uncommonly applied. Patients with chronic pulmonary hypertension secondary to thromboembolic disease may present with a variety of debilitating cardiopulmonary symptoms. However, once it is diagnosed, there is no curative role for medical management, and surgical removal of the thromboembolic material is the only therapeutic option.

The exact incidence of pulmonary embolism (PE) is unknown, but there are some valid estimates. Acute PE is the third most common cause of death (after heart disease and cancer). Approximately, 75% of autopsy-proven PEs are not detected clinically. It is estimated that PE results in approximately 700,000 symptomatic episodes in the United States yearly. The disease is particularly common in hospitalized elderly patients. Of the hospitalized patients who develop PE, 12% to 21% will die in the hospital, and another 24% to 39% die within 12 months. Thus, approximately 36% to 60% of the patients who survive the initial episode live beyond 12 months, and they may present later in life with a wide variety of symptoms.

The mainstay of treatment of patients with deep vein thrombosis (DVT) and acute PE is medical management. In general, cardiac surgeons rarely intervene in hospitalized patients who suffer a massive embolus that causes life-threatening acute right heart failure and severe hemodynamic compromise. In contrast, the only treatment for patients with chronic pulmonary thromboembolic disease is the surgical removal of the disease by means of PTE. Medical management in these patients is only palliative, and surgery by means of transplantation is an inappropriate use of resources with less than satisfactory results.

The prognosis for patients with pulmonary hypertension is poor, and it is worse for those who do not have intracardiac shunts, since the shunt will reduce right-sided pressures. Thus, patients with primary pulmonary hypertension and those with pulmonary hypertension secondary to pulmonary emboli fall into a higher risk category than those with Eisenmenger syndrome and have a higher mortality rate. In fact, once the mean pulmonary pressure in patients with thromboembolic disease reaches \( \geq 50 \text{ mmHg} \), the 3-year mortality approaches 90%.

Surgical preferences are dependent on both the principal disease process and the reversibility of the pulmonary hypertension. With the exception of thromboembolic pulmonary hypertension, lung transplantation is the only effective therapy for patients with end-stage pulmonary hypertension. Although it has been performed less frequently in the last few years, pulmonary transplantation is still used in some centers as the treatment of choice for patients with thromboembolic disease. However, a true assessment of the effectiveness of any therapy should take into account the total mortality after the patient has been accepted and put on the waiting list. Thus, the mortality for transplantation (and especially double-lung or heart–lung transplantation) as a therapeutic strategy is much higher than is generally appreciated because of the significant loss of patients awaiting donors. Bearing in mind, in addition, the long-term use of immunosuppressants with their associated side effects, the higher operative morbidity and mortality, the inferior prognosis even after successful transplantation, and the long waiting period, one can see that transplantation is clearly an inferior alternative to PTE and should be considered an inappropriate and outdated form of therapy.

**INCIDENCE**

Determining an accurate incidence of CTEPH is almost impracticable. Most patients with this condition do not have a clear history of DVT or PE. Furthermore, the majority (about 75%) of autopsy-proven PEs are not clinically diagnosed. This makes the exact incidence of this disease even more difficult to determine than that of acute PE. A conservative estimate only considers patients who do have an acute PE and survive the episode. There are approximately 600,000 such patients every year in the United States. The incidence of chronic thrombotic occlusion in the population depends on what proportion of patients fails to resolve acute embolic material. Recent studies have shown that of these patients, up to 3.1% will have symptomatic CTEPH at 1 year and 3.8% will have it at 2 years. If these figures are correct, and if one counts only patients with symptomatic acute pulmonary emboli, approximately 18,000 to 22,000 individuals would progress to CTEPH in the United States each year. However, because many (if not most) patients diagnosed with chronic thromboembolic disease have no antecedent history of acute embolism, the true incidence of this disorder must be much higher.

Regardless of the exact incidence or the circumstances, it is clear that both acute embolism and its chronic relation, fixed chronic thromboembolic occlusive disease, are much more common than generally appreciated and are seriously underdiagnosed. Calculations extrapolated from mortality rates and the random incidence of major thrombotic occlusion found at autopsy support a postulate that more than 100,000 people in the United States currently have pulmonary hypertension that could be relieved by operation.
PATHOLOGY AND PATHOPHYSIOLOGY

Most cases of chronic pulmonary emboli arise from previous acute embolic episodes, even though the majority of individuals with chronic pulmonary thromboembolic disease are unaware of a past thromboembolic event and give no history of deep venous thrombosis. Why some patients have unresolved emboli is not certain, but a variety of factors must play a role, alone or in combination.

For instance, the volume of acute embolic material may simply overwhelm the lytic mechanisms, and the total occlusion of a major arterial branch may prevent lytic material from reaching, and therefore dissolving, the embolus completely. Furthermore, repetitive emboli may not be able to be resolved. Other causes may relate to the fact that the emboli may be made of substances that cannot be resolved by normal mechanisms (already well-organized fibrous thrombus, fat, or tumor), and the lytic mechanisms themselves may be abnormal. In some groups, patients may actually have a propensity for thrombus or a hypercoagulable state.

In general, after the clot becomes wedged in the pulmonary artery, one of two processes occurs: (1) the clot may proceed to canalization, producing multiple small endothelialized channels separated by fibrous septa (i.e., bands and webs) or (2) it may continue to form a solid mass of dense, fibrous connective tissue, without canalization, totally obstructing the arterial lumen.

In addition, chronic indwelling central venous catheters and pacemaker leads are sometimes associated with pulmonary emboli. Less frequent causes include tumor emboli; tumor fragments from stomach, breast, and kidney malignancies have been demonstrated to cause chronic pulmonary arterial occlusion. Right atrial myxomas may also fragment and embolize.

Whatever the predisposing factors to residual thrombus within the vessels, the genesis of the resultant pulmonary vascular hypertension is more complex than generally appreciated. With the passage of time, the increased pressure and flow as a result of redirected pulmonary blood flow in the previously normal pulmonary vascular bed can create a vasculopathy in the small precapillary blood vessels similar to the Eisenmenger syndrome.

Factors other than the simple hemodynamic consequences of redirected blood flow are also probably involved in this process. For example, after a pneumonectomy, 100% of the right ventricular output flows to one lung, yet little increase in pulmonary pressure occurs, even with follow-up to more than a decade. In patients with thromboembolic disease, however, we frequently detect pulmonary hypertension even when <50% of the vascular bed is occluded by thrombus, and not uncommonly as early as a few months to 1 year after the initial episode. It thus appears that an array of sympathetic neural connections and hormonal changes may be responsible for setting off pulmonary hypertension in the initially unaffected pulmonary vascular bed. This process can occur with the initial occlusion in either the same or the contralateral lung.

Regardless of the cause, the evolution of pulmonary hypertension as a result of changes in the previously unobstructed bed is serious because this process may lead to an inoperable situation. Accordingly, with our accumulating experience in patients with thrombotic pulmonary hypertension and superior surgical outcomes, we have increasingly been inclined toward early operation so as to avoid these changes.

CLINICAL PRESENTATION

There are no specific signs or symptoms associated with pulmonary hypertension as a result of chronic pulmonary thromboembolism, which explains the degree of underdiagnosis with this condition. The most common symptom associated with thromboembolic pulmonary hypertension, as with all other causes of pulmonary hypertension, is exertional dyspnea. Generally, this dyspnea is out of proportion to any abnormalities found on clinical examination. Like complaints of easy fatigability, dyspnea that initially occurs only with exertion is often attributed to anxiety or being “out of shape.” In patients with more advanced disease and higher pulmonary artery pressures, syncope or presyncope (lightheadedness during exertion) is another common symptom.

Non-specific chest pains occur in approximately 50% of patients with more severe pulmonary hypertension. Hemoptysis can occur in all forms of pulmonary hypertension and probably results from abnormally dilated vessels distended by increased intra-vascular pressures. Peripheral edema, early satiety, and epigastric or right upper quadrant fullness or discomfort may develop as the right heart fails (cor pulmonale). Some patients with chronic pulmonary thromboembolic disease present after an additional small acute pulmonary embolus that may produce acute symptoms of right heart failure. A careful history will bring out symptoms of dyspnea on minimal exertion, easy fatigability, diminishing activities, and episodes of angina-like pain or lightheadedness. Further examination reveals the signs of pulmonary hypertension.

The physical signs of pulmonary hypertension are the same no matter what the underlying pathophysiology. Initially, the jugular venous pulse is characterized by a large A wave. As the right heart fails, the V wave becomes predominant. The right ventricle is usually palpable near the lower left sternal border, and pulmonary valve closure may be audible in the second intercostal space. Occasional patients with advanced disease are hypoxic and slightly cyanotic. Clubbing is an uncommon finding.

As the right heart fails, a right atrial gallop is usually present, and tricuspid insufficiency develops. Because of the large pressure gradient across the tricuspid valve in pulmonary hypertension, the murmur is high pitched and may not exhibit respiratory variation. These findings are quite different from those usually observed in tricuspid valvular disease. A murmur of pulmonic regurgitation may also be detected.

DIAGNOSIS

To ensure the diagnosis in patients with chronic pulmonary thromboembolism, a standardized evaluation is recommended for all patients who present with unexplained pulmonary hypertension. This workup includes a chest radiograph, although a large number of patients present with a relatively normal chest radiograph, even in the setting of high degrees of pulmonary hypertension. When abnormal, the chest X-ray may show either apparent vessel cutoffs of the lobar or segmental pulmonary arteries, or regions of oligemia suggesting vascular occlusion. Central pulmonary arteries are also typically enlarged, and the right ventricle may be enlarged without enlargement of the left atrium or ventricle (Fig. 70.1).

The ventilation–perfusion lung scan is the essential test for establishing the diagnosis of unresolved pulmonary thromboembolism. An entirely normal lung scan excludes the diagnosis of both acute and chronic, unresolved thromboembolism. The usual lung scan pattern in most patients with pulmonary hypertension is either relatively normal or shows a diffuse nonuniform perfusion. When subsegmental or larger perfusion defects are noted on the scan, even when matched with ventilatory defects, pulmonary angiography is appropriate to confirm or rule out thromboembolic disease.
Pulmonary angiography is the gold standard for the diagnosis of chronic pulmonary thromboembolism. In addition to identifying the level of obstruction and providing a surgical roadmap, right heart catheterization can be performed in the same setting, measuring right heart parameters and evaluating the degree of pulmonary hypertension and pulmonary vascular resistance (PVR). Organized thromboembolic lesions do not have the appearance of the intravascular filling defects seen with acute pulmonary emboli, and experience is essential for the proper interpretation of pulmonary angiograms in patients with unresolved, chronic embolic disease. Typically, organized thrombi appear as unusual filling defects, webs, or bands or as completely thrombosed vessels that may resemble congenital absence of the vessel (Fig. 70.2). Organized material along a vascular wall of a recanalized vessel produces a scalloped or serrated luminal edge. Because of both vessel-wall thickening and dilation of proximal vessels, the contrast-filled lumen may appear relatively normal in diameter. Distal vessels demonstrate the rapid tapering and pruning characteristic of pulmonary hypertension.

In recent years, higher resolution computed tomography (CT) scans of the chest have been used more frequently in the diagnosis of PE. The presence of large clots in lobar or segmental vessels generally confirms the diagnosis. In addition, in rare situations where occlusion of main pulmonary arteries is present or there are concerns of external compression, CT scans can be helpful to differentiate thromboembolic disease from other causes of pulmonary vascular obstruction such as mediastinal fibrosis, lymph nodes, and tumors. CT scanning has the disadvantage, however, that it may miss distal disease.

Pulmonary angiography remains the gold standard for the diagnosis and for planning the operative approach. In addition to pulmonary angiography, patients older than 45 years of age undergo coronary arteriography and other cardiac investigation as necessary. If significant disease is found, additional cardiac surgery is performed at the time of PTE.

Pulmonary angioscopy may be performed in patients where the differentiation between the primary pulmonary hypertension and distal small-vessel pulmonary thromboembolic disease is difficult. The pulmonary angioscope is a fiberoptic telescope that is placed through a central line into the pulmonary artery. The tip contains a balloon that is then filled with saline and pushed against the vessel wall. A bloodless field can thus be obtained to view the pulmonary artery wall. The classic appearance of chronic pulmonary thromboembolic disease by angioscopy consists of intimal thickening, with intimal irregularity and scarring, and webs across small vessels. The presence of embolic disease, occlusion of vessels, or thrombotic material is diagnostic.
**Chapter 70: Chronic Pulmonary Thromboembolism and Pulmonary Thromboendarterectomy**

**ALTERNATIVE TREATMENTS**

Medical therapy for CTEPH is of limited value and is palliative at best. There are a wide variety of pharmacologic agents in recent use for the treatment of primary pulmonary hypertension. These include calcium-channel blockers such as diltiazem and nifedipine, prostacyclins such as epoprostenol (Flolan, Remodulin), prostacyclin analogs, endothelin-receptor antagonists (Tracleer), and nitric oxide. However, thromboembolic disease represents a mechanical obstruction that is not amenable to drug therapy.

Right ventricular failure is generally treated with diuretics and vasodilators, and although some improvement may result, the effect is generally transient because the failure will not resolve until the obstruction is removed. Similarly, the prognosis is unaffected by medical therapy, which should be regarded as only supportive. However, because of the bronchial circulation, pulmonary embolization seldom results in tissue necrosis. Surgical endarterectomy, therefore, will allow distal pulmonary tissue to be used once more in gas exchange.

Chronic anticoagulation represents the mainstay of the medical regimen. Anticoagulation is primarily not only used to prevent future embolic episodes but also serves to limit the development of thrombus in regions of low flow within the pulmonary vasculature. Inferior vena cava filters are used routinely to prevent recurrent embolization. If caval filtration and anticoagulation fail to prevent recurrent emboli, immediate thrombolysis may be beneficial, but lytic agents are incapable of altering the chronic component of the disease.

The only other surgical alternative for these patients is transplantation. However, we consider transplantation to be inappropriate for the treatment of this disease and believe it is an outdated form of surgical management for CTEPH. Considering the mortality and morbidity rates of patients on the waiting list, the higher risk of the operation, and the lower survival rate (approximately 80% at 1 year at experienced centers for transplantation vs. at least 95% for pulmonary endarterectomy), we believe that PTE is the superior choice. Furthermore, pulmonary endarterectomy appears to be permanently curative, and the issues of a continuing risk of rejection and immunosuppression are not present.

**PULMONARY THROMBOENDARTERECTOMY**

The first successful pulmonary “thrombo-endarterectomy” was performed by Allison in 1960, and took place in a patient who 12 days before had a thigh injury that had led to a pulmonary embolus. Allison used a sternotomy and surface hypothermia, but only fresh clots were removed. Since then, there have been many occasional reports of the surgical treatment of chronic pulmonary thromboembolism, but most of the surgical experience in pulmonary endarterectomy has been reported from the University of California, San Diego (UCSD), Medical Center. Braunwald commenced the UCSD experience with this operation in 1970, which now totals <2,800 cases. The operation to be described, using deep hypothermia and circulatory arrest, is now our standard procedure.

**Indications**

When the diagnosis of thromboembolic pulmonary hypertension has been firmly established, the decision for operation is made based on the severity of symptoms and the general condition of the patient. Early in our pulmonary endarterectomy experience, Moser and colleagues pointed out that there were three major reasons for considering thromboendarterectomy: hemodynamic, alveolar respiratory, and prophyllactic. The hemodynamic goal is to prevent or ameliorate right ventricular compromise caused by pulmonary hypertension. The respiratory objective is to improve respiratory function by removing a large ventilated but unperfused physiologic dead space. The prophyllactic goal is to prevent progressive right ventricular dysfunction or retrograde extension of the obstruction, which might result in further cardiorespiratory deterioration or death. Our subsequent experience has added another prophyllactic goal: the prevention of secondary arteriopathic changes in the remaining patent vessels.

The ages of the patients in our series have ranged from 7 to 86 years. An ideal patient will have a severely elevated PVR level at rest, the absence of significant comorbid disease that is unrelated to right heart failure, and the appearances of chronic thrombi on angiogram that appear to be in balance with the measured PVR level. Exceptions to this general rule, of course, occur.

Some patients (increasingly in our practice) have discordance between the angiographic appearance and a very high PVR. This indicates that there may be secondary arteriopathic changes, but provided that the basis for the elevated PVR is thromboembolic we will still accept these patients for operation, though they might not have an optimal result. Although most patients have a PVR level in the range of 800 dynes/second/cm\(^{-5}\) and pulmonary artery pressures less than systemic, the hypertrophy of the right ventricle that occurs over time makes pulmonary hypertension to suprasystemic levels possible. Therefore, many patients (perhaps 30% in our practice) have a level of PVR in excess of 1,000 dynes/second/cm\(^{-5}\) and suprasystemic pulmonary artery pressures. There is no upper limit of PVR level, pulmonary artery pressure, or degree of right ventricular dysfunction that excludes patients from operation.

We have become increasingly aware of the changes that can occur in the remaining patient (unaffected by clot) pulmonary vascular bed subjected to the higher pressures and flow that result from obstruction in other areas. Therefore, with the increasing experience and safety of the operation, we are tendng to offer surgery to symptomatic patients whenever the angiogram demonstrates thromboembolic disease. A rare patient might have a PVR level that is normal at rest and elevated with minimal exercise. This is usually a young patient with total unilateral pulmonary artery occlusion and unacceptable exertional dyspnea because of an elevation in dead-space ventilation. Operation in this circumstance is performed to reperfuse lung tissue, reestablish a more normal ventilation/perfusion relationship (thereby reducing minute ventilatory requirements during rest and exercise), and preserve the integrity of the contralateral circulation. If one has not been previously implanted, an inferior vena caval filter is routinely placed several days before the operation.

**OPERATIVE TECHNIQUES**

**Principles**

Although the essential techniques of PTE are quite similar to those of other open-heart operations, there are several guiding principles for this procedure. The disease is almost always bilateral, although the volume of chronic thromboembolic material may vary significantly between the two lungs. Furthermore, for pulmonary hypertension to be a major factor, both pulmonary arteries must be substantially involved. The surgery is therefore always bilateral. The only reasonable approach to both pulmonary arteries is through a median sternotomy incision. Historically, there were many reports of unilateral operation, and occasionally this is still performed, in inexperienced centers, through
a thoracotomy. However, the unilateral approach ignores the disease on the contralateral side, subjects the patient to hemodynamic jeopardy during the clamping of the pulmonary artery, and does not allow good visualization because of the continued presence of bronchial blood flow. In addition, collateral channels develop in chronic thrombotic hypertension not only through the bronchial arteries but also from diaphragmatic, intercostal, and pleural vessels. The dissection of the lung in the pleural space via a thoracotomy incision can, therefore, be extremely bloody. The median sternotomy incision, apart from providing bilateral access, avoids entry into the pleural cavities and allows the ready institution of cardiopulmonary bypass.

Cardiopulmonary bypass is essential not only to ensure cardiovascular stability when the operation is performed but also to allow cooling of the patient for periods of circulatory arrest. Exceptional visibility of the pulmonary vasculature is required. A bloodless field is an absolute requirement to define an adequate endarterectomy plane and then to follow the pulmonary endarterectomy specimen deep into the subsegmental vessels. Because of the copious bronchial blood flow usually present in these cases, periods of circulatory arrest are necessary to ensure perfect visibility. Again, there have been sporadic reports of the performance of this operation without circulatory arrest. However, it should be emphasized that although endarterectomy is possible without circulatory arrest, a complete and full endarterectomy is not. We always initiate the procedure without circulatory arrest, and depending on the collateral flow, a variable amount of dissection is possible before the circulation is stopped, but never complete dissection. The circulatory arrest periods are limited to 20 minutes, with restoration of flow between each arrest. With experience, the endarterectomy usually can be performed with a single period of circulatory arrest on each side.

A true endarterectomy in the plane of the media must be accomplished. It is essential to appreciate that the removal of visible thrombus is largely incidental to this operation. Indeed, in most patients, no free thrombus is present; on initial direct examination, the pulmonary vascular bed may appear normal to an inexperienced eye. The early literature on this procedure indicates that thrombectomy was often performed without a complete endarterectomy, and in these cases, the pulmonary artery pressures did not improve, often with the resultant death of the patient.

**Preparation and Anesthetic Considerations**

The operative preparation and anesthetic concerns are for the most part quite similar to those for any open-heart procedure. Routine monitoring for anesthetic induction includes a surface electrocardiogram, cutaneous oximetry, and radial artery pressure lines. After induction, a pulmonary artery catheter and a transesophageal echocardiographic probe are also inserted. We generally include a femoral arterial line for more accurate assessment during rewarming and on discontinuation of cardiopulmonary bypass. It is quite common for these patients to develop some degree of peripheral vasoconstriction after hypothermic circulatory arrest, thereby making radial pressure readings inaccurate. The femoral line is generally removed in the intensive care unit when the two readings are correlated.

Electroencephalographic recording is routinely performed to ensure the lack of cerebral activity before circulatory arrest is induced. The patient’s head is enclosed in a cooling jacket, and cerebral cooling is begun after the initiation of bypass. Temperature measurements are made of the esophagus, tympanic membrane, urinary catheter, rectum, and blood (through the Swan–Ganz catheter). If the patient’s condition is stable after the induction of anesthesia, up to 500 mL of autologous whole blood is withdrawn for later use, and the volume deficit is replaced with crystalloid solution.

**Operative Techniques**

After a median sternotomy incision is made, the pericardium is incised longitudinally and attached to the wound edges. Typically, the right heart is enlarged, with a tense right atrium and a variable degree of tricuspid regurgitation. There is usually severe right ventricular hypertrophy. These patients are generally quite sensitive to any manipulation of the heart, and with critical degrees of obstruction, the patient’s condition may become quite unstable.

Anticoagulation is achieved with the use of beef-lung heparin sodium (400 units/kg, intravenously) administered to prolong the activated clotting time beyond 400 seconds. Full cardiopulmonary bypass is instituted with high ascending aortic cannulation and two caval cannulae. These cannulae must be inserted into the superior and inferior vena cavae sufficiently to enable subsequent opening of the right atrium. The heart is emptied on bypass, and a temporary pulmonary artery vent is placed in the midline of the main pulmonary artery 1 cm distal to the pulmonary valve. This will mark the beginning of the left pulmonary arteriotomy.

When cardiopulmonary bypass is initiated, surface cooling with both the head jacket and the cooling blanket is begun. The blood is cooled with the pump-oxygenator. Cooling generally takes 45 minutes to 1 hour. When ventricular fibrillation occurs, an additional vent is placed in the left atrium through the right superior pulmonary vein. This prevents atrial and ventricular distension from the large amount of bronchial arterial blood flow that is common with these patients.

Generally, the primary surgeon starts the operation on the patient’s left side. During the cooling period, some preliminary dissection can be performed, with full mobilization of the right pulmonary artery from the ascending aorta. The superior vena cava is also fully mobilized. The approach to the right pulmonary artery is made medial, not lateral, to the superior vena cava (Fig. 70.3). All dissection of the pulmonary arteries takes place intrapericardially, and neither pleural cavity should be entered. An incision is then made in the right pulmonary artery from beneath the ascending aorta out under the superior vena cava and entering the lower lobe branch of the pulmonary artery just after the takeoff of the middle lobe artery (Fig. 70.4). It is important that the incision stays in the center of the vessel and continues into the lower rather than the middle lobe artery.

A modified cerebellar retractor is placed between the aorta and superior vena cava. Upon opening the pulmonary artery, a varying degree of loose thrombus may be present. The material is then removed to ensure good visualization of the vascular bed. It is most important to recognize, however, that first, an embolectomy without subsequent endarterectomy is quite ineffective regardless of the size of thromboembolic material, and second, in most patients with chronic thromboembolic hypertension, direct examination of the pulmonary vascular bed at operation generally shows no obvious embolic material. Therefore, to the inexperienced or cursory glance, the pulmonary vascular bed may well appear normal even in patients with severe chronic embolic pulmonary hypertension.

When the patient’s temperature reaches 20°C, the aorta is cross-clamped and a single dose of cold cardioplegic solution (1 L) is administered. Additional myocardial protection is obtained by the use of a cooling jacket. The entire procedure is now
performed with a single aortic cross-clamp period with no further administration of cardioplegic solution.

If the bronchial circulation is not excessive, the endarterectomy plane can be found during this early dissection. However, although a small amount of dissection can be performed before the initiation of circulatory arrest, it is unwise to proceed unless perfect visibility is obtained because the development of a correct plane is essential. Recognizing the plane is perhaps the most crucial and technically challenging part of the operation.

When blood obscures direct vision of the pulmonary vascular bed, thiopental is administered (500 mg to 1 g) until the electroencephalogram becomes isoelectric. In most cases, the electroencephalogram is already isoelectric when the core temperature reaches 20°C. Circulatory arrest is then initiated, and the patient undergoes exsanguination. All monitoring lines to the patient are turned off to prevent the aspiration of air. Snares are tightened around the cannulae in the superior and inferior venae cavae. It is rare that one 20-minute period for each side is exceeded. Although retrograde cerebral perfusion has been advocated for total circulatory arrest in other procedures, it is not helpful in this operation because it does not allow a completely bloodless field, and with the short arrest times that can be achieved with experience, it is not necessary.

A microtome knife is used to develop the endarterectomy plane posteriorly because any inadvertent egress in this site could be repaired readily or simply left alone. Dissection in the correct plane is critical because if the plane is too deep, the pulmonary artery may perforate, with fatal results, and if the dissection plane is not deep enough, inadequate amounts of the chronically thromboembolic material will be removed, leaving the patient with residual pulmonary hypertension.

After the plane is correctly developed, a full-thickness layer is left in the region of the incision to ease subsequent repair (Fig. 70.5). The endarterectomy is then performed with an eversion technique. Because the vessel is everted and subsegmental branches are being worked on, a perforation here will become completely inaccessible and invisible later. This is why the absolute visualization in a completely bloodless field provided by circulatory arrest is essential. It is important that each subsegmental branch is followed and freed individually until it ends in a "tail" beyond which there is no further obstruction. Residual material should never be cut free; the entire specimen should "tail off" and come free spontaneously.

After the right-sided endarterectomy is completed, circulation is restarted, and the arteriotomy is repaired with a continuous 6-0 polypropylene suture. The hemostatic nature of this closure is aided by the nature of the initial dissection, with the full thickness of the pulmonary artery being preserved immediately adjacent to the incision.

After the completion of the repair of the right arteriotomy, the surgeon moves to the patient’s right side. The pulmonary vent catheter is withdrawn, and an arteriotomy is made from the site of the pulmonary
Section II: Adult Cardiac Surgery

Fig. 70.5. The plane of dissection is first raised posteriorly and continued toward the edge of the arteriotomy but trimmed short in the region of the incision. This results in a full-thickness artery for subsequent closure.

Fig. 70.6. Surgical approach to the left pulmonary artery. The approach begins in the mid-portion of the main artery and carried past the takeoff of the left upper lobe. The incision stays in the midline of the vessel as far as the pericardial reflection. A more distal incision provides limited view.

vent hole laterally to the pericardial reflection, avoiding entry into the left pleural space. Additional lateral dissection does not enhance intraluminal visibility, may endanger the left phrenic nerve, and makes subsequent repair of the left pulmonary artery more difficult (Fig. 70.6).

The left-sided dissection is virtually analogous in all respects to that accomplished on the right. The duration of circulatory arrest intervals during the performance of the left-sided dissection is subject to the same restriction as the right.

After the completion of the endarterectomy, cardiopulmonary bypass is re instituted and warming is commenced. If the systemic vascular resistance level is high, nitroprusside is administered to promote vasodilation and warming. The rewarming period generally takes approximately 90 minutes, but it varies according to the body mass of the patient.

The pulmonary artery is then closed, and the pulmonary vent is replaced. The right atrium is then opened and examined. Any intra-atrial communication is closed. Although tricuspid valve regurgitation is invariable in these patients and is often severe, tricuspid valve repair is not performed unless there is a structural defect. Right ventricular remodeling occurs within a few days, with the return of tricuspid competence. If other cardiac procedures are required, such as coronary artery or mitral or aortic valve surgery, these are conveniently performed during the systemic rewarming period. Myocardial cooling is discontinued after all cardiac procedures have been concluded. The left atrial vent is removed, and the vent site is repaired. All air is removed from the heart, and the aortic cross-clamp is removed.

When the patient has rewarmed, cardiopulmonary bypass is discontinued. Dopamine hydrochloride is routinely administered at renal doses, and other inotropic agents and vasodilators are titrated as necessary to sustain acceptable hemodynamics. The cardiac output is generally high, with a low systemic vascular resistance. Temporary atrial and ventricular epicardial pacing wires are placed.

Despite the duration of extracorporeal circulation, hemostasis is readily achieved, and the administration of platelets or coagulation factors is generally unnecessary. Wound closure is routine. A vigorous diuresis is usual for the next few hours, also a result of the previous systemic hypothermia.

There are four broad types of pulmonary occlusive disease related to thrombus that can be appreciated, and we use the following classification: type I disease (approximately 20% of cases of thromboembolic pulmonary hypertension; Fig. 70.7) refers to the situation in which major vessel clot is present and readily visible on the opening of the pulmonary arteries. As mentioned earlier, all central thrombotic material has to be completely removed before the endarterectomy. In type II disease (approximately 60% of cases; Fig. 70.8), no major vessel thrombus can be appreciated. In these cases only thickened intima can be seen, occasionally with webs, and the endarterectomy plane is raised in the main, lobar, or segmental vessels. Type III disease (approximately 20% of cases in our series; Fig. 70.9) presents the most challenging surgical situation. The disease is very distal and confined to the segmental and subsegmental branches. No occlusion of vessels can be seen initially. The endarterectomy plane must be carefully and painstakingly raised in each segmental
and subsegmental branch. Type III disease is most often associated with presumed repetitive thrombi from indwelling catheters (such as pacemaker wires) or ventriculoatrial shunts. Type IV disease (Fig. 70.10) does not represent primary thromboembolic pulmonary hypertension and is inoperable. In this entity, there is intrinsic small-vessel disease, although secondary thrombus may occur as a result of stasis. Small-vessel disease may be unrelated to thromboembolic events (“primary” pulmonary hypertension) or occur in relation to thromboembolic hypertension as a result of a high-flow or high-pressure state in previously unaffected vessels similar to the generation of Eisenmenger syndrome. We believe that there may also be sympathetic “cross-talk” from an affected contralateral side or stenotic areas in the same lung.

**POSTOPERATIVE CARE**

Although much of the postoperative care is common to that of the more ordinary open-heart surgery patients, there are some important differences. Meticulous postoperative management is essential to the success of this operation. All patients are mechanically ventilated for at least 24 hours, and all patients are subjected to a maintained diuresis with the goal of reaching the patient’s preoperative dry weight within 24 hours.

The electrocardiogram, systemic and pulmonary arterial and central venous pressures, temperature, urine output, arterial oxygen saturation, chest tube drainage, and fluid balance are monitored. A pulse oximeter is used to continuously monitor peripheral oxygen saturation. Management of cardiac arrhythmias and output and treatment of wound bleeding are identical to those for other open-heart operations. In addition, higher minute ventilation is often required early after the operation to compensate for the temporary metabolic acidosis that develops after the long period of circulatory arrest, hypothermia, and cardiopulmonary bypass. Extubation should be performed on the first postoperative day, if possible.

**Complications**

Patients are not only subject to all complications associated with open-heart and major lung surgery (arrhythmias, atelectasis, wound infection, pneumonia, mediastinal bleeding, etc.) but also may develop complications specific to this operation. One such complication is the development of a “reperfusion response.” This is a specific complication that occurs in most patients to some degree and is related to localized pulmonary edema. Reperfusion injury is defined as a radiologic opacity seen in the lungs within 72 hours of pulmonary endarterectomy. This unfortunately loose definition may, therefore, encompass many causes, such as fluid overload and infection.

True reperfusion injury that directly adversely impacts the clinical course of the patient now occurs in approximately 8% to 10% of patients. In its most dramatic form, it occurs soon after operation (within a few hours) and is associated with profound desaturation. Edema-like fluid, sometimes with a bloody tinge, is suctioned from the endotracheal tube. Frank blood from the endotracheal tube, however, signifies a
mechanical violation of the blood–airway barrier that has occurred at operation and stems from a technical error. This complication should be managed, if possible, by identification of the affected area by bronchoscopy and balloon occlusion of the affected lobe until coagulation can be normalized.

One common cause of the reperfusion pulmonary edema is persistent high pulmonary artery pressures after operation when a thorough endarterectomy has been performed in certain areas, but there remains a large part of the pulmonary vascular bed affected by type IV change. However, the reperfusion phenomenon can also be encountered in patients after a seemingly technically perfect operation with complete resolution of high pulmonary artery pressures. In these cases, the response may be one of reactive hyperemia after the revascularization of segments of the pulmonary arterial bed that have long experienced no flow. Other contributing factors may include perioperative pulmonary ischemia and conditions associated with high-permeability lung injury in the area of the now denuded endothelium. Fortunately, the incidence of this complication is very much less common now in our series, probably as a result of the more complete and expeditious removal of the endarterectomy specimen that has come with the large experience over the last decade and the recognition that an aggressive diuresis is required postoperatively.

Management of the “Reperfusion Response”

Early measures should be taken to minimize the development of pulmonary edema with diuresis, maintenance of the hematocrit levels, and the early use of ventilatory peak end-expiratory pressure. Once the capillary leak has been established, treatment is supportive because reperfusion pulmonary edema will eventually resolve if satisfactory hemodynamics and oxygenation can be maintained. Careful management of ventilation and fluid balance is required. The hematocrit is kept high (32% to 36%), and the patient undergoes aggressive diuresis, even if this requires ultrafiltration. The patient’s ventilatory status may be dramatically position sensitive. The inspired oxygen fraction (FiO₂) level is kept as low as is compatible with an oxygen saturation of 90%. A careful titration of positive end-expiratory pressure is carried out, with a progressive transition from volume-limited to pressure-limited inverse ratio ventilation and the acceptance of moderate hypercapnia. The use of steroids is discouraged because they are generally ineffective and may lead to infection. Infrequently, inhaled nitric oxide at 20 to 40 parts per million can improve the gas exchange. On occasion, we have used extracorporeal perfusion support (extracorporeal membrane oxygenator or extracorporeal carbon dioxide removal) until ventilation can be resumed satisfactorily, usually after 7 to 10 days.

CONCLUSION

It is increasingly apparent that pulmonary hypertension caused by chronic PE is a relative common condition that is
under-recognized and carries a poor prognosis. Medical therapy is ineffective in prolonging life and only transiently improves the symptoms. The only therapeutic alternative to PTE is lung transplantation. The advantages of thromboendarterectomy include a lower operative morbidity and mortality and excellent long-term results without the risks associated with chronic immunosuppression and chronic allograft rejection. The mortality for thromboendarterectomy at our institution is now in the range of 3%, with sustained benefit. These results are clearly superior to those for transplantation in both the short and long terms.

Although PTE is technically demanding for the surgeon, requiring careful dissection of the pulmonary artery planes and the use of circulatory arrest, excellent short- and long-term results can be achieved. Successive improvements in operative technique developed over the last two decades now allow pulmonary endarterectomy to be offered to patients with an acceptable mortality rate and excellent anticipation of clinical improvement. With this growing experience, it has also become clear that unilateral operation is obsolete and that circulatory arrest is essential.

We have performed >2,800 pulmonary endarterectomies at the University of California, San Diego, Medical Center, with almost all of these carried out since 1990. With our growing experience, we are now able to offer this procedure to some very high-risk patients with a total overall mortality rate of about 3%. The vast majority of patients enjoy a dramatic hemodynamic improvement postoperatively. A reduction in pulmonary pressures and PVR to normal levels and a corresponding improvement in pulmonary blood flow and cardiac output are generally immediate and sustained. In general, these changes can be assumed to be permanent. Whereas before the operation, >95% of the patients are in New York Heart Association (NYHA) functional class III or IV, at 1 year after the operation, 95% of patients are in NYHA functional class I or II.

In addition, echocardiographic studies have demonstrated that with the elimination of chronic pressure overload, right ventricular geometry rapidly reverts toward normal. Right atrial and right ventricular enlargement regresses. Tricuspid valve function returns to normal within a few days as a result of restoration of tricuspid annular geometry after the remodeling of the right ventricle, and therefore tricuspid repair is not part of the operation.

Even with increased awareness of this disease, coupled with our continuous effort in spreading our understanding and knowledge, the principal difficulty remains that this is an under-recognized condition. Increased understanding of both the prevalence of this condition and the possibility of a surgical cure should avail more patients of the opportunity for relief from this debilitating and ultimately fatal disease.

Congenital Cardiac Surgery
INTRODUCTION

The hallmark of congenital heart disease is the variability in spatial relationships as well as interconnections among the various cardiac and vascular structures. To appreciate these types of abnormalities, it is first necessary to define certain terms that may have different meanings from those used to describe normal anatomy. When cardiac chambers are described, the terms right and left refer only to morphological characteristics which will be further elaborated upon below. They do not refer to the right–left frame of reference in the body. For example, right ventricle refers to a particular cardiac structure with specific morphological features, regardless of its location in the body. When the right–left frame of reference is intended, the terms right-sided or left-sided are used.

It is also important to recognize which structures are, by definition, part of a chamber and which are frequently associated with that chamber. For example, the normal right ventricle includes the infundibulum or outflow tract portion of the heart, whereas there are some hearts in which the infundibulum is partially or entirely related to the left ventricle (anatomically corrected malposition or double outlet left ventricle). Therefore, the presence of infundibulum does not define the right ventricle, but rather is usually associated with it.

Another concept that is central to a morphological approach to congenital heart disease is the recognition of the difference between anatomical, physiological, and surgical diagnoses. This chapter will concern itself entirely with anatomical descriptions and diagnoses. Some of the terms can also be used in a physiological sense; it is vital that one cannot make the mistake of using them interchangeably. For example, anatomically, transposition of the great arteries means that the aorta arises above the morphological right ventricle and the pulmonary artery above the left ventricle. This is true regardless of whether the right ventricle receives desaturated blood from the body or fully saturated blood from the lungs. Transposition physiology, however, refers to any anatomical situation in which the pulmonary artery receives blood of a higher saturation than the aorta. If a term is used without further clarification, it should always refer to anatomical diagnoses, whereas physiologic terms should always be stated as such, for example, “transposition physiology” or “physiological mitral stenosis.”

CLASSIFICATION OF CONGENITAL HEART DISEASE

Aims and Basic Principles

The purpose of a classification system is to permit the identification of all examples of anatomy, physiology, and surgery of congenital heart disease in a way that permits storage and retrieval from computerized databases. The aim of a classification system is really to classify entities, not names. As Shakespeare said, “What’s in a name? That which we call a rose by any other name would smell as sweet.” (Romeo and Juliet II, ii, 43). There seems to be a broad consensus on what the entities are. Rather than trying to win over everyone to the best nomenclature, classification systems should focus on the following five principles: (a) organization, (b) economy, (c) accuracy, (d) precision, and (e) quantification.

Organization is essential with any comprehensive classification system. Simple alphabetical listing of diagnoses is unhelpful because of the absence of a standardized nomenclature. Instead diagnoses should be grouped by the organization of the heart itself according to a systematic method. In this way, all possible diagnoses related to a given portion of the heart can be viewed at one time and the appropriate one selected. Because of the fact that there are different schools of thought as to organization, it is unlikely that a single standardized nomenclature will be developed in the near future. One approach to this problem is the one adopted by the International Society for Nomenclature of Paediatric and Congenital Heart Disease. This multidisciplinary group including pediatric cardiologists, cardiac surgeons, and morphologists has created the International Paediatric and Congenital Cardiac Code, which essentially maps terms from one nomenclature system to those of another so that entities will have a single numerical code or group of codes irrespective of the original terms. Inherent in this approach is acceptance of the notion that different groups may use different organizational approaches to categorize entities and may thus “arrive” at the same diagnostic entity by way of different paths. For example, our group would categorize tricuspid atresia as a form of abnormal atrioventricular alignment—specifically an abnormal atrial-to-atrioventricular valve (AVV) connection, whereas another group might think of the same entity as a form of single ventricle or univentricular heart. The path is not as important as assuring that a given entity is always coded in the same way, regardless of the approach. Because of this, definitions of entities are essential. Economy refers to saving time of the physician who determines which diagnoses to use and saving computer space with the avoidance of redundant information. This is accomplished through mutual exclusivity. Diagnoses are grouped within organizational categories into subgroups where diagnoses are mutually exclusive—only one diagnosis within that subgroup is possible. For example, only one atrial situs, one ventricular situs, one great artery situs, one atrial-to-atrioventricular, one AVV-to-ventricle connection, and one ventriculo arterial alignment abnormality are possible. Additional diagnoses that are thought to relate a group of similar abnormalities are superfluous, and if ultimately shown to be incorrect (i.e., abnormalities not similar), can actually be counterproductive. Provision of redundant information during data
entry is wasteful of time as well as computer storage space.

Accuracy means that a given diagnosis has the same meaning every time it is used. The meaning does not change with context. In other words, a particular anatomical ventricular septal defect (VSD) has the same designation regardless of ventricular-arterial alignment and great artery position. The atrial situs designation is the same whether there is dextrocardia or levocardia. Dependence on context complicates data retrieval, since a given diagnosis could have different meanings depending on what other diagnoses are present in each case.

Precision is the ability to classify fine anatomical detail if the information is available. Nonspecific diagnoses should only be used if more precise information is lacking. For example, a plain chest roentgenogram may indicate a right aortic arch (not further specified), but magnetic resonance imaging (MRI) or angiography may show a right aortic arch with retroesophageal diverticulum. A dilution of information would occur if only “right aortic arch” were used as the diagnosis. Whereas if one were searching for all right aortic arches, general as well as specific entities could be included.

Quantification is the option to assign an indication of severity to certain diagnoses. Sometimes the severity of a lesion is as important as the anatomical detail. While an epidemiologist may consider all VSDs of a particular type equally significant, the clinician may wish to distinguish small VSDs from large. In many cases, the designation is arbitrary but may still be useful.

Implementation—The Segmental Approach

The segmental approach to diagnosis in congenital heart disease was developed by Van Praagh to provide a systematic method for describing congenital heart defects. It fits the basic principles outlined above. Important features that distinguish Van Praagh’s segmental approach from many other systems include the following: (1) diagnoses are based on morphological analysis. While physiological correction of defects is the primary goal of cardiac surgery, it is also clear that attention to the underlying morphology is important as it influences surgical approach as well as long-term function. (2) The system is not situs-dependent; each segment is diagnosed independently. Situs-dependent systems suffer from two shortcomings. If the situs is found to be different than initially thought, all of the dependent diagnoses change as well. If the situs is ambiguous or if the downstream connections are not one-to-one, as in double inlet ventricles, the concept of a situs-dependent system breaks down. (3) There is a hierarchy of diagnoses (Fig. 71.1). Those entities at the top do not change the diagnoses or nomenclature of those below, but they have greater significance: internal organization is more important than a stenotic valve in terms of classification. (4) There is a logical sequence to the analysis and description of the heart.

The cardiovascular system is thought of as having three major segments—viscero atrial situs, ventricular loop, and great artery situs. The situs or spatial organization of each of the segments can be described independently using morphological features of the chambers and vessels. Adjacent segments are related to each other by intersegmental alignments. The three major segments can be thought of as the blueprints of each of the floors of a three-story house. Each can be understood individually without reference to the other two, hence independence. The intersegmental alignments are analogous to stairways that connect adjacent floors.

Once segments and intersegmental alignments have been determined, individual chamber, valve, and vessel diagnoses are made. Continuing the architectural analogy, chamber, valve, and vessel abnormalities are like the furnishings of individual rooms.

Cardiac Segments

Viscero atrial situs describes the arrangement of the asymmetrical abdominal viscera and vessels, the lungs, and the atria. There are three forms of viscero atrial situs: solitus, inversus, and ambiguus. Situs solitus is characterized by a right-sided liver, left-sided stomach, and right-sided inferior vena cava (IVC). The atria display characteristic right atrial morphology of the right-sided appendage (described specifically in the “Chambers, Valves, and Vessels” section), left atrial morphology of the left-sided appendage, IVC entering the right-sided atrium, and septum primum attached to the left side of septum secundum. Situs inversus means the mirror image of solitus, viz., left-sided liver and IVC, right-sided stomach, right atrial appendage on the left, left atrial appendage on the right, IVC entering left-sided atrium, and septum primum attached to the right side of septum secundum. Situs ambiguus has characteristics of both situs solitus and situs inversus in the same person. For example, a liver that spans the abdomen from right to left (sometimes referred to as a “midline” liver) being both right-sided and left-sided has characteristics of both solitus and inversus. Similarly, bilateral morphologic right or bilateral morphologic left atrial appendages mean one solitus and one inversus. In the same way, a left-sided abdominal IVC that crosses to the right in the liver and enters a right-sided atrium with right atrial appendage morphology has features of both situs inversus (abdominal) and situs solitus (atrial). All these examples of combinations of situs solitus and situs inversus are termed situs ambiguus. This is the viscero atrial situs seen in the abdominal heterotaxy syndrome. Most, but not all, of these patients have splenic abnormalities: asplenia or polysplenia. The terms bilateral right sidedness and bilateral left sidedness are conveniences for remembering the constellation of abnormalities frequently seen with asplenia (bilateral right sidedness, since the normal right side has no spleen) or polysplenia (bilateral left sidedness, since the normal left side has a spleen, so multiple spleens is like multiple left sides), but do not carry the force of viscero atrial situs since there are numerous exceptions to the symmetry implied by those terms.

Ventricular loop is the designation for the situs of the ventricles. There are two types: D loop and L loop. Unlike the atria that are virtually always side-by-side, the ventricles, while frequently so, may be oriented anteroposteriorly or supero inferiorty, still displaying one of two internal spatial organizations. Therefore, a designation independent of a simple right–left frame of
reference is necessary. Just as it is possible to distinguish a right hand from a left hand without seeing the attachment to the rest of the body, that is, without a right–left frame of reference, so too it is possible to distinguish the two stereoisomers of ventricular organization. By focusing on ventricular inflow, outflow, and septum, it is possible to attribute chirality or handedness to the ventricular organization (Fig. 71.2). If one holds his hand with the thumb, index finger, and middle finger mutually orthogonally, with the thumb representing ventricular inflow, the index finger, outflow, and the middle finger pointing to the septum, a right hand in the morphologic right ventricle indicates a D loop arrangement of ventricles. If the left hand fits the right ventricle, there is an L loop. Just as a right hand can always be distinguished from a left, so too D loop ventricles should not be mistaken for L loop ventricles regardless of the position of the heart or ventricles in three-dimensional space. What if the right ventricle does not have all three components: inflow, outflow, and septum, for example, tricuspid atresia has no right ventricular inflow? The ventricles are always concordant with each other having adjacent inflows, adjacent outflows, and a septum common to both. Because of this a right-handed right ventricle is matched with a left-handed left ventricle. Similarly, a left-handed right ventricle would go with a right-handed left ventricle. Therefore, in the case of tricuspid atresia one would simply determine the handedness of the left ventricle and interpret the ventricular loop as just described.

**Great artery situs** refers to the spatial arrangement of the semilunar valves and great arteries. A special spatial arrangement exists when the great arteries are normally aligned with the ventricles (see intersegmental connections below). Thus, a special segmental description is given in those cases where the pulmonary artery arises above the right ventricle and the aorta normally above the left ventricle. If the two great arteries spiral about each other in a clockwise manner (viewed from the ventricles) so that the ascending aorta crosses the right pulmonary artery, this is designated solitus normal great arteries. If they spiral counterclockwise with the ascending aorta crossing the left pulmonary artery, they are termed inversus normal great arteries. For all other cases—transpositions and malpositions described under intersegmental connections—the great artery segment is called D if the aortic valve is to the right of the pulmonary valve, L if the aortic valve is to the left of the pulmonary, and A if aortic valve is directly anterior (i.e., same sagittal plane) to the pulmonary.

**Segmental notation:** The purpose of the segmental approach to diagnosis is not only to have designations for the various spatial arrangements of the cardiac structures but also to have a concise way of communicating the basic organization of the heart when also listing the various intersegmental connections and chamber, valve, and vessel abnormalities mentioned below. This shorthand description of the cardiac organization is the segmental notation. Van Praagh conceived of each heart as representing a subset of all the possible spatial arrangements that could occur in nature. He borrowed mathematical set notation—braces { }—to accomplish this. Each heart can be described as a three-member subset of the whole with the first member of the set representing viscero-atrial situs, the second, ventricular loop, and the third, great artery situs. Furthermore, the possibilities for each member of the set are designated by their first letter in capital form with the individual members separated by commas (Fig. 71.3). Therefore, the viscero-atrial segment can be described by S, I, or A for situs solitus, inversus, or ambiguous. Similarly, the second member, ventricular loop, is represented by D or L for D loop or L loop organization of the ventricles. The great artery notation is S or I for solitus normal or inversus normal if the pulmonary artery arises above the right ventricle and aorta normally above the left ventricle, or D, L, or A for aortic valve to the right, left, or directly anterior relative to the pulmonary valve. In cases where the information is insufficient to determine the particular segment, that member of the subset may be represented by the letter X.

In the cases of normal arrangement of cardiac chambers and vessels, the segmental notation is {S,D,S} for viscero-atrial situs solitus, ventricular D loop, and solitus normal great arteries. These would also be the segments in classical tetralogy of Fallot, and the same segmental notation would apply to classical tricuspid atresia with normally aligned great arteries. Thus, it can be seen that the segmental description does not describe abnormalities of chambers, valves, or vessels nor does it describe...
Anatomy and Classification of Congenital Heart Disease

Chapter 71: Segmental notation consists of a three-member set in braces { }. The first member is the visceral atrial situs—solitus, inversus, or ambiguous; the second is the ventricular loop—D or L; and the third is the great artery situs—solitus normal, inversus normal, D, L, or A transposition or malposition. The meaning of those terms is discussed in the text and is represented diagrammatically in the figure. Great artery situs diagrams with malposition or transposition of the great arteries in the lower right represent the two semilunar valves viewed from above; the aorta is shown with coronary arteries. LA, left atrium; RA, right atrium; ?, ambiguous morphology, a combination of solitus and inversus.

Intersegmental connections (except for normally aligned great arteries). Classical complete transposition of the great arteries has segments {S,D,D}, since the atria and ventricles are normally arranged, but in the absence of normally aligned great arteries the segmental notation indicates that the aorta is to the right of the pulmonary artery at the level of the semilunar valves. The same segmental description could apply to a case of double outlet right ventricle with the aorta to the right of the pulmonary artery. Classical physiologically corrected transposition of the great arteries has segments {S,L,L} indicating normal (solitus) arrangement of the atria but a ventricular L loop plus aorta to the left of pulmonary artery. Transposition of the great arteries {S,D,L} has situs solitus of viscera and atria, ventricular D loop but the transposed aorta is to the left of the pulmonary artery, rather than to the right as in the {S,D,D} form. This difference in segments does not imply different connections but rather an altered spatial arrangement, which has implications for associated abnormalities (e.g., hypoplasia of the right ventricle, strad-
duling tricuspid valve) as well as for surgical approaches. Figure 71.4 shows examples of spatial arrangements of atria, ventricles, and great arteries with their corresponding segmental notation. The segmental designation is a fundamental part of the overall cardiac diagnosis and is not meant to be a parenthetical, that is, extraneous or explanatory, supplement. Thus, it is incorrect to substitute parentheses ( ) or square brackets [ ] for the curly braces { } used in mathematical set notation.

INTERSEGMENTAL ALIGNMENTS

Each pair of adjacent segments has a discrete set of intersegmental alignments. Under the principle of economy described above, intersegmental alignment diagnoses are mutually exclusive entities.

Atrioventricular alignments are really a combination of atrial-to-AVV connection and AVV-to-ventricle connection. There are four basic types of atrial-to-AVV connection: two AVVs, one from each atrium; one common AVV from both atria; right AVV atresia, that is, no AVV from the right-sided atrium but one AVV from the left-sided atrium; and left AVV atresia. Each atrial-to-AVV connection has several possible AVV-to-ventricle connections: with two AVVs, each may enter one ventricle (normal), one or both may enter two ventricles (straddling AVV[s]), or both may enter one ventricle (double inlet ventricle) (Fig. 71.5); with a common AVV, it may connect to both ventricles equally (balanced), unequally (unbalanced), or only one ventricle (common inlet) (Fig. 71.6); with AVV atresia, the other valve may enter the ipsilateral ventricle, the contralateral ventricle, or both ventricles (straddling AVV) (Fig. 71.7).

Ventriculo arterial alignment names do not necessarily reflect anatomical reality! The ventricles are connected to the great arteries via the infundibulum or AV canal. (The normal right ventricle is connected to the pulmonary artery via the infundibulum, while the left ventricle is connected to the aorta via the AV canal, hence mitral-aortic fibrous continuity.) However, unlike the atrioventricular alignments, most classification systems have not used this relationship in developing their nomenclatures. Instead, ventriculo arterial alignments tend to be based on a system in which each great artery is “assigned” to one, and only one, ventricle. When the ventricular septum is intact, the assignment is straightforward. In the presence of the commonly seen relatively large VSD near the great arteries, the assignment can be problematic. All such classification schemes have, therefore, adopted certain rules governing assignment of great arteries to ventricles. We use the rules shown pictographically in Figure 71.8 that can be stated as follows: (1) The pulmonary artery is assigned to a ventricle if the pulmonary valve lies more than 50% above it. (2) Since the aorta normally may lie predominantly above the ventricular septum rather than above the left ventricular cavity, mitral valve-to-aortic valve fibrous continuity, if present, determines assignment of the aorta to the left ventricle, regardless of how far the aorta extends above the right ventricle in the setting of a large VSD. Mitral valve is defined as that valve on the side of the left ventricle or its remnant (compared with the right ventricle or its remnant). For the purposes of assigning aorta to a ventricle, obviously, if there is only one ventricle and no remnant of the other, the point is moot. (3) If mitral–aortic fibrous continuity is not present, the 50% rule, as described for the pulmonary artery above, applies. (4) With conotruncal anomalies and pulmonary atresia, it may not be feasible to assign the pulmonary artery to either ventricle; in those cases only the aorta is assigned: right ventricular aorta with pulmonary atresia or left ventricular aorta with pulmonary atresia. Using these rules, the ventriculo-arterial alignments are named according to Figure 71.8.

As with any system of more or less arbitrary rules, there are potential problems or “exceptions.” Here are a few. If there is tenuous mitral–aortic fibrous continuity through a tiny VSD so that the aorta arises virtually exclusively above the right ventricle, it is assigned to the right ventricle. If there is no mitral valve but a common AVV instead, the above rules apply to the portion of the common AVV attached to the left ventricle, as if it were a mitral valve. Finally, if there is no mitral valve due to AVV atresia, the 50% rule applies but the aorta, if assigned to the left ventricle is considered normally aligned unless there is clearly subaortic infundibular muscle. Thus, typical hypoplastic left heart with mitral atresia is considered to have normally aligned great arteries. In the case of left ventricular aorta with pulmonary atresia, as long as there is mitral to aortic fibrous continuity solitus normal—S—or inversus normal—I—great arteries are considered appropriate designations.

Chamber, Valve, and Vessel Abnormalities

An exhaustive description of all chamber, valve, and vessel abnormalities is not within the scope of this chapter. The following sections indicate the characteristics that define the various structures and list some of the surgically important anatomical abnormalities.
Venae cavae and coronary sinus: The superior vena cava (SVC) connects veins from the upper portion of the body to the heart. Normally, there is a single, right-sided SVC that enters the right atrium, but single SVCs can connect to a coronary sinus (CoS) or to the left atrium. Bilateral SVCs may be present, most commonly with a right SVC connecting to the right atrium and a left SVC connecting to a CoS and ultimately draining to the right atrium. However, each may connect to its ipsilateral atrium as in heterotaxy, or rarely, both may connect to the same atrium. A venous structure that is in a similar position to the SVC but connects a pulmonary vein confluence to the innominate vein is not considered to be an SVC because it does not connect to the heart. Rather, the term vertical vein or connecting vein is appropriate.

The IVC enters the right atrium guarded medially by the right venous valve, which blends with the septum primum portion of the atrial septum, and laterally by the right venous (Eustachian) valve. The anterior commissure of these two venous valves forms the tendon of Todaro, which points to the AV node. The IVC is almost always single at the level of the heart. (Double IVC refers only to duplication of the infra-renal portion.) While two IVC-like vessels may enter the heart either in the same atrium or one in each atrium, one vessel almost invariably enters only hepatic veins. Because the IVC is nearly always single at atrial level, it is used as a strong indicator of the right atrium (see below). However, there are two potentially ambiguous situations that render this unacceptable for all cases: the so-called absent IVC and an IVC which enters both atria via a so-called sinus venosus-type atrial septal defect (ASD) of the inferior caval variety. In absent IVC, the renal-to-hepatic portion of the IVC is absent so that the veins of the lower portion of the body (except the hepatic veins) are drained by the azygos vein to a SVC. Only the hepatic veins connect directly to the right atrium. In the IVC type of sinus venosus ASD, the right atrium cannot be defined by IVC entrance since it straddles the atrial septum.

The CoS usually enters the right atrium near the entrance of the IVC (Fig. 71.9). Its entrance is partially covered by the Thebesian valve that may be an extension of the Eustachian valve or a separate structure. The AV node may extend into the mouth of the CoS. If there is SVC connection to the CoS, its orifice will be quite large and could be mistaken for an ASD or occasionally for a common atrium. A large CoS ostium may also occur with anomalous connection of pulmonary veins or, rarely, hepatic veins to the CoS. Uncommonly, the CoS ostium may enter the left atrium and rarely there may be no patent CoS ostium, in which case the CoS drains into an SVC remnant (vein of Marshall), which drains blood superiorly to the innominate vein. Surgical or catheter device occlusion of the vein of Marshall in this situation results in coronary venous obstruction.

The morphological right atrium is characterized by a broad-based appendage which, on the exterior, blends almost imperceptibly with the venous portion of the atrium. Anderson has pointed out that this is more definitively seen from the interior...
Fig. 71.8. Ventriculo arterial alignments. The rules for assigning great arteries to ventricles discussed in the text are shown diagrammatically. For the pulmonary artery across the top row, the pulmonary artery is said to arise from the right ventricle if its valve is more than 50% above the right ventricle. It is assigned to the left ventricle if more than 50% above that. If there is pulmonary atresia (PAtr) without clear evidence of association with either ventricle, no assignment is made (far right column). For the aorta (Ao), the rules are depicted in the far left column. The Ao is assigned to the LV in a normal fashion (Ao (nl)) if there is mitral valve-to-aortic valve fibrous continuity, regardless of the degree to which the aorta may be situated above the right ventricle. If there is no mitral-aortic fibrous continuity such as occurs with subaortic conus, the aorta is assigned to the left ventricle but as an abnormal alignment (Ao [abnl]) if it arises more than 50% above left ventricle, or is assigned to right ventricle if more than 50% above that. Note that mitral aortic discontinuity does not necessarily imply the presence of subaortic conus, since there could be tricuspid valve–aortic valve fibrous continuity. The ventriculo-arterial alignments for each of the combinations of aortic and pulmonary assignment are given in the corresponding boxes.

aspect as pectinate muscles extending all the way to the crux of the heart. The fact that pectinate muscles comprise a large portion of the effective right atrial cavity makes that chamber more compliant than the left atrium whose appendage is more isolated from the main cavity. Septum secundum or the superior limbic band of the atrial septum is seen in front of septum primum or the flap valve of the foramen ovale from the right atrial aspect. Typically, the IVC enters the right atrium with the exception of those situations noted above under Venae cavae. The SVC and CoS, being much more variable, cannot be used to define the right atrium. When the SVC does enter the right atrium, the crista terminalis forms the lateral aspect of the entrance internally. The external aspect of this structure is the sulcus terminalis in which lies the sinus node.

The atrial septum has three portions (Fig. 71.9), most easily appreciated in the newborn but still identifiable in the adult heart: septum primum, septum secundum, and canal septum. The septum primum or flap valve of the foramen ovale is the thin central portion of the septum. In the fetus and preterm infant, it is so thin as to be transparent. At term, it is typically translucent and becomes somewhat thicker with advancing age but is always thinner than the other two components of the septum. It is this structure that is torn by balloon septostomy. Defects in or deficiency of septum primum are called ostium secundum ASDs. Septum secundum, or the superior limbic band, is a thick muscular ridge at the superior aspect of the atrial septum immediately medial to the SVC (if one enters the atrium directly). The septum primum usually has two points of attachment onto the left atrial side of septum secundum with the space between the two being the foramen ovale. The superior aspect of septum primum (between the two points of attachment) forms a half-moon shape. The third portion of the atrial septum is the atrioventricular canal septum, a thick muscular tissue anterior to septum primum extending to the level of the AVVs and actually continuing on to become the canal or the so-called inlet portion of the ventricular septum. It is the canal septum that is deficient or absent in cases of common atrioventricular canal including the ostium primum ASD. Other apparent ASD are actually vessel ostia. Sinus venosus atrial septal defects are examples of either right pulmonary vein straddling atrial septum and/or a venae cava straddling the septum. CoS ostium-type ASD occurs when the CoS is unroofed into the left atrium. ASD types are shown in Figure 71.10.

By definition, the tricuspid valve is the right-sided AVV in a D loop or the left-sided AVV in an L loop. Because of the marked variability in morphology of the AVVs and the propensity for AVV morphology to be influenced by the ventricle into which they enter, the above definition is used to avoid ambiguity in such circumstances as double inlet ventricles in which both AVVs may appear morphologically similar. Having thus defined tricuspid valve, it is nonetheless worth describing the commonly seen morphology. The classical three leaflets are anterior, posterior, and septal. While the name implies three leaflets, this is not always the case. Frequently, the newborn has only two distinct leaflets with no commissure between the anterior and posterior leaflets. The most characteristic feature of the tricuspid valve is the similarity of depth (annulus-to-free edge) of all leaflets.

The morphological right ventricle has broad or coarse and relatively parallel trabeculations. If an AVV is present, there are chordal attachments onto the face (not simply the crest) of the ventricular septum as well as onto the free wall. There is typically a single large papillary muscle attached to the septal band by the moderator band.

Ventricular septum: The right ventricular septal surface, like the rest of the right ventricle, shows coarse, parallel trabeculations. A large trabeculation called the septal band appears like an appliqué on top of the septum. At its inferior aspect, the septal band
becomes the moderator band and that, in turn, the main papillary muscle of the right ventricle. The superior portion of the septal band has the shape of the letter “Y.” The papillary muscle of the conus or muscle of Lancisi is usually at or slightly posterior to the forking of the “Y.” The infundibular septum normally fills the “Y” of the septal band. However, in cases of infundibular (conal) septal malalignment or hypoplasia the “Y” is empty, that is, there is a VSD in its place, and the infundibular septum is not part of the ventricular septum. The right bundle branch runs along the septal band between the upper two-thirds and the lower one-third, and extends onto the moderator band to the base of the main papillary muscle. The septal–moderator band complex marks the boundary between the sinus portion of the right ventricle below and the outflow tract above. Pathological extension of the septal–moderator band complex can divide the two, resulting in subpulmonary stenosis—anomalous muscle bundle or the so-called double-chambered right ventricle.

The left ventricular septal surface is smooth over the one-half to two-thirds basilar portion and has fine interdigitating trabeculations over the apical one-third to one-half. The left bundle branch penetrates the septum from the right ventricular side and divides into an anterior and a posterior fascicle, which run along the smooth portion of the left ventricular septal surface before traveling around the ventricular free wall or across the left ventricular cavity to the bases of the two left ventricular papillary muscles.

One interesting aspect of the ventricular septum is that despite what the name implies, it is not necessarily located entirely between the ventricular cavities. In cases where one ventricular sinus is hypoplastic (e.g., aortic atresia or pulmonary atresia with intact ventricular septum) or absent (e.g., tricuspid atresia, double-inlet left ventricle), a structure with the morphology of the ventricular septum lies between one ventricle and either an outlet chamber or the exterior of the heart. Hence, ventricular septum does not always imply two well-developed ventricular sinuses. Thus, a defect in that structure is a VSD even if the two chambers joined are not full fledged ventricles, as in double-inlet (single) left ventricle with right ventricular outlet chamber.

VSDs occur in five morphological types based on location relative to landmarks in the ventricular septum, most easily recognized from the right ventricular septal surface (Fig. 71.11). This can be thought of as the “Geographical” classification. The key landmarks are the septal band, the muscular or trabecular septum, the infundibular septum, and the annulus of the tricuspid valve. Conoventricular VSDs are located between the conal (infundibular) septum and the muscular or trabecular septum but with the conal septum still situated in the “Y” of septal band. This is in the general location of the membranous ventricular septum but is often larger than the 1 to 3 mm diameter of the normal membranous septum. It can be separated from the membranous septum by a small amount of muscle. This type of VSD is frequently partially covered by a portion of the septal leaflet of the tricuspid valve. Conal septal malalignment VSDs, or malalignment for short, are located in the “Y” of the septal band because the infundibular septum is displaced out of the “Y.” The AV canal-type VSD, also called inlet VSD is located beneath the entire length of the AV (either tricuspid or common AVV) that opposes or intersects the ventricular septum. The defect comes up to the valve, that is, there is no muscle between the defect and the valve. (VSDs with interposed muscle between defect and AV are considered posterior muscular; see below.) Conal septal hypoplasia VSDs are, like malalignment defects, located in the “Y” of septal band, but without malalignment. Any remnant of the infundibular septum is normally aligned with the septal band, but there is actual deficiency of the infundibular septum. All other VSDs are termed muscular. Muscular VSDs are located in the muscular or trabecular septum in any of the following general areas: posteroinferior to main portion of septal band, midmuscular; inferior aspect of muscular septum, “inferior muscular”; beneath septal leaflet of tricuspid valve but with muscle bar separating defect from valve annulus, posterior muscular; distal to the moderator band, apical muscular; anterior to main portion of septal band, anterior muscular. Muscular VSDs often have...
the appearance of multiple defects when viewed from the right ventricle, or when viewing angiography or color Doppler, due to the lattice-like trabeculations of the right ventricular septal surface. However, such defects are usually single on the left ventricular side. Thus, the term multiple VSDs could mean multiple streams from a single muscular VSD or multiple VSD types. This should be specified whenever the term “multiple VSDs” is used. The five main types of VSDs are shown in (Fig. 71.12).

In addition to these five main types, there are combinations of some of the above: malalignment–conal septal hypoplasia, malalignment–canal type, malalignment–canal-type–conal septal hypoplasia, conoventricular–muscular.

In keeping with the principle of accuracy—independence from context—the definitions of the various VSDs are uninfluenced by associated conotruncal or other malformations. This is why the terms subpulmonary, subaortic, beneath both (doubly committed), or beneath neither (uncommitted) are not acceptable by themselves, because a subaortic defect with normally aligned great arteries is in the same anatomical location as a subpulmonary defect with transposition of the great arteries. (These terms may be used in a supplementary manner with an anatomical term to specify great artery location in double outlet right or left ventricles.)

There are other classifications of VSDs beside the geographical approach. One is the “Borders” approach popularized by Anderson. This approach emphasizes the constitution of the borders over the location within the septum. Thus, most VSDs are described as perimembranous, subarterial, or muscular if a border of the VSD is made up by the area of tricuspid valve–aortic valve fibrous continuity, one or both semilunar valves, or only muscle, respectively. It is important to understand that these two approaches are not simply different but equivalent names. Rather, they represent different frames of reference, so that perimembranous VSDs include all canal type or inlet VSDs, some, but not all conoventricular VSDs (some are muscular), some but not all malalignment VSDs, and some but not all conal septal hypoplasia VSDs. In the geographical approach, the borders are mentioned as descriptions but are not the primary elements of classification. Similarly, in the Borders approach, secondary terms such as perimembranous inlet, perimembranous outlet are used, although we believe this is contrary to the goal of economy.

The pulmonary valve is normally a trileaflet valve with the infundibular septal commissure facing the aortic valve and all three commissures equally spaced around the valve's circumference. Pulmonary valvar stenosis, not part of a conotruncal anomaly, is typically a domed valve with all three commissures rudimentary and a central orifice, whereas pulmonary stenosis with a conotruncal anomaly is usually bicuspid or unicuspid with at least a rudimentary septal commissure.

The pulmonary arteries refer to the main and proximal right and left branch pulmonary arteries. These, in turn, supply the peripheral pulmonary arteries. The morphological right pulmonary artery courses anterior to the right mainstem, eparterial, bronchus. The morphological left pulmonary artery crosses over the left mainstem (hyparterial) bronchus. Absent right or left pulmonary artery means absence of the proximal pulmonary artery, not the entire pulmonary arterial tree. In such cases, the peripheral pulmonary artery may be supplied by a ductus arteriosus.
bronchial artery, other systemic collateral vessel, or, rarely, a coronary artery. True pulmonary arteries always arise anterior to the tracheobronchial tree. Therefore, a confluence behind the trachea is always some form of systemic collateral vessel.

Pulmonary veins, numbering anywhere from three to five, drain blood from the lungs and normally connect to the morphological left atrium. Any other connection is considered “anomalous pulmonary venous connection,” regardless of the ultimate destination of the pulmonary venous blood. Hence, partial or total anomalous pulmonary venous connections are anatomical terms, whereas partial or total anomalous pulmonary venous return are physiological diagnoses, describing the destination of the blood, which may or may not be concordant with their anatomical counterparts.

The morphological left atrium is best characterized by a discreet, narrow-based appendage, distinct from the venous portion. Pectinate muscles, being confined to the appendage portion, do not come near the crux of the heart as do the pectinate muscles in the morphological right atrium. As mentioned previously, the absence of the accordion-like pectinate muscles from the main cavity of the left atrium renders it less compliant than the morphological right atrium. This has implications for pressure changes engendered by AVV regurgitation, especially that which occurs acutely.

The mitral valve is defined as the left AVV in a D-loop heart and the right AVV in an L-loop. The rationale for this approach is described above under tricuspid valve. The usual mitral valve morphology is a bileaflet valve with the anterior leaflet deeper (from annulus to leaflet edge) than the posterior or mural leaflet. The anterior leaflet is shorter in circumferential length than the posterior leaflet.

The morphological left ventricle is characterized by fine, interdigitating trabeculations, and absence of AVV chordal attachments to the ventricular septal surface. The left ventricle usually has two papillary muscles—anterolateral and posteromedial—arising from the ventricular-free wall. The left ventricle does not usually have an infundibulum; however, this is not by the way of definition. That is, the left ventricle, as defined, can give rise to the infundibulum. It must be emphasized that a left ventricular infundibulum, if present, is on the same side of the ventricular septum as the left ventricular sinus. When the infundibulum is on the opposite side of the ventricular septum as described above under “ventricular septum,” it must be presumed to be a right ventricular infundibulum.

The aortic valve, like the pulmonary valve described above, is normally a trileaflet valve with evenly spaced commissures. Valvar stenosis is almost always due to a bicuspid or unicuspid valve with one or two rudimentary commissures, respectively. Unicuspid valves have a funnel shape with an eccentric orifice. The commissure between the left coronary and noncoronary cusps is nearly always well developed. Rarely, aortic stenosis can be from a dysplastic tricuspid aortic valve.

The aorta arises above the aortic valve and supplies at least one of the brachiocephalic vessels. Unlike the pulmonary artery that may be atretic or even absent, the ascending aorta is virtually always patent down to the level of the valve even if the valve is atretic, because it carries at least coronary blood flow. The aortic arch is said to be left or right according to which bronchus it crosses over, regardless of the side of its origin from the heart. However, arch sidedness can be inferred very reliably from the fact that the first arch vessel usually contains the carotid artery opposite the side of the arch. However, rare exceptions necessitate more complete evaluation such as MRI or CT scan if arch sidedness is crucial to be known prior to surgery.

There are three main coronary arteries—right (ventricular), anterior descending, and (left ventricular) circumflex—and one minor coronary—infundibular or conal branch. The coronaries follow the ventricles. Thus, the right ventricular coronary can be right- or left-sided just as the right ventricle can be. Normally, the anterior descending and circumflex coronaries arise from a single vessel named left (ventricular) main coronary artery. Similarly, the right and conal branch arise from a single vessel, the right coronary. A common variant is for the right and conal branch to arise from separate orifices from the same sinus of valsalva. However, other combinations are possible, particularly with conotruncal anomalies in which the spatial relationship between the aorta and the ventricles differs from normal. Hence, the anterior descending can arise from the conal branch of the right coronary as in some cases of tetralogy of Fallot, or the right and the (left ventricular) circumflex can arise from one vessel and the anterior descending from the other, as occurs in about one-quarter of D-transposition of the great arteries cases.

Conotruncal anomalies are defects involving the outflow tract (infundibular) portion of the heart, including the infundibular septum, the proximal great arteries, and the semilunar valves (Fig. 71.13). These anomalies are determined by the relative amounts of infundibular (conal) muscle beneath each
Cardiac Malpositions

The heart is normally located within the thorax, in the mediastinum, extending predominantly into the left chest, although it crosses the midline slightly into the right chest. Locations outside this usual one are called cardiac malpositions. They fall into two broad categories: intrathoracic and extrathoracic. Intrathoracic malpositions include dextrocardia, heart predominantly in the right chest; mesocardia, predominantly midline; extreme levocardia, entirely in the left chest, that is, more leftward than normal; absent pericardium, in which part or all of the heart lies in an abnormal position within one of the chest cavities; and pericardial diaphragmatic defect, in which the heart is raised up above herniated liver, as if the heart were perched on a “pitcher’s mound.” Extra-cardiac malpositions include ectopia cordis and thoracopagus conjoined twins.

Syntax for Cardiac Diagnoses

The convention for listing diagnoses is to use the following order:

Cardiac syndromes (e.g., hypoplastic left heart syndrome, heterotaxy syndrome with asplenia).
Cardiac malpositions (dextrocardia).
Atrioventricular alignment abnormalities.
Ventriculo arterial alignment abnormalities.
Ventricular arterial alignment abnormalities.
Segmental notation.
Chamber, valve, and vessel abnormalities beginning at the arterial end of the heart and proceeding to the venous end.
Arrhythmias and physiological diagnoses.
Surgical diagnoses and residua in chronological order.

For example, one case showing all of the above headings could be “heterotaxy syndrome with asplenia, dextrocardia, common atrioventricular canal, double-outlet right ventricle (A,D,D) with mirror image right aortic arch, pulmonary stenosis, total anomalous pulmonary venous connection to the ductus venosus, persistent left SVC to left-sided atrium, ectopic atrial rhythm, status post-modified (polytetrafluoroethylene tube graft) left Blalock-Taussig shunt, status post-Fontan operation with residual left pulmonary artery stenosis.” In cases where some of the above headings are normal, those are simply omitted. For example, one could have “ventricular septal defect and persistent left superior vena cava to coronary sinus,” or “tricuspid atresia with ventricular septal defect and pulmonary stenosis.” One must always include the segmental notation if there is a ventriculo arterial alignment abnormality. It is also useful to include the segmental notation when there is a cardiac malposition even if the segments are normal, because the segmental description clarifies the type of malposition instead of using additional, and frequently ambiguous, descriptions such as dextroposition and dextroversion.

SUGGESTED READINGS

Complex forms of congenital heart disease are being seen with increasing frequency in most centers for congenital cardiac surgery in part because the relative success with surgical palliative interventions for congenital heart disease has improved and surgical therapy is being more widely applied to malformations that in the past were associated with very high mortality. Thus, it becomes increasingly important for cardiac surgeons and cardiologists to be able to communicate effectively the anatomic features of these complex defects. The anatomic classification scheme devised by Van Praagh and described in this chapter has advantages for creating a consistent description of certain features of the heart. Thus, the use of the Van Praagh classification system can accurately convey information about the situs of the heart, the situs or isomerism of the ventricles, and the position of the aortic origin. It must be emphasized, however, that these classification systems are primarily anatomic. Physiologic and surgical definitions and definitions of common complex malformations that have come into the terminology of congenital heart disease but are anatomically ambiguous must also be taken into account in any classification scheme or description of cardiac malformations. Thus, cardiac syndromes such as hypoplastic left heart syndrome, heterotaxy syndromes, and cardiac malpositions should also be used in descriptive terminology of cardiac malformations. These syndromes have surgical implications and can make communication simpler. The segmental notation scheme of Van Praagh then is complementary information. A hierarchical scheme of description is important because certain features are ambiguous. For example, double-outlet right ventricle with transposition of the great arteries is a relative misnomer because either double-outlet right ventricle or transposition should be the primary diagnosis and the location of the great arteries can be described separately. Transposition of the great arteries has certain anatomic and certain physiologic abnormalities separate from double-outlet right ventricle.

Certain phrases have become commonly used that may be anatomically somewhat inaccurate but remain part of the nomenclature. For example, corrected transposition of the great arteries, isolated ventricular inversion, the Taussig-Bing heart, complete transposition of the great arteries, and AV canal are diagnoses that may be embryologically inaccurate, not anatomically descriptive, or may have physiologic connotations. Additional descriptors such as the concordancy or discordancy of AV or ventricular–arterial connections may be important. Although AV alignment and ventricular arterial alignment abnormalities and segments are defined in the Van Praagh system, the common conventional usage of concordant and discordant relationships may also aid in communication.

It is also important to recognize that the embryologic development of the heart is not completely understood, and specific gene defects identified with congenital heart malformations are rare. Thus, the anatomic classification system, surgical syndromes, and embryologic development are not necessarily consistent.

It is obviously fundamentally important that cardiologists and surgeons dealing with congenital heart disease be able to communicate accurately about cardiac diagnoses and anatomy. The multiple classification systems and descriptions cloud the ability to create databases that can accurately collect data on large numbers of patients internationally with congenital heart disease. Because of this problem, there has been a very active international effort among cardiologists, surgeons, and pathologists to create standard nomenclature for congenital heart disease diagnoses and surgery and to cross-map these diagnoses to other databases, such as the European Congenital Heart Database. The Herculean efforts involved in creating these common nomenclatures has now provided a standardized list of anatomic diagnoses and operative procedures and enable data acquisition internationally and benchmarking of outcomes for congenital heart disease from one congenital heart center to another.

As noted by Dr. Weinberg, the International Society for Nomenclature of Pediatric and Congenital Heart Disease (ISNPCHD) has created the international pediatric and congenital cardiac code (IPCCC). This code maps terms from one nomenclature system to another so that entities have a single code or group of codes regardless of the original terms used. This approach recognizes that different groups continue to use different morphologic nomenclature systems. The importance of this work is hard to underestimate since having the ability to have all nomenclature systems cross code to one another such that data entry can be uniform across multiple different databases around the world is critical in establishing large multinational databases to collect information on the prevalence, significance, and outcomes in complex congenital heart disease. As databases become more and more important for our activities, these remarkable efforts of committed individuals to standardize and cross-reference data systems are of extraordinary importance.

Many different anatomic classification schemes can describe similar entities as has been noted in this chapter by Dr. Weinberg. The classification of a “simple” congenital defect such as ventricular septal defect can be completely different between different morphologic schemes. For example, the geographical scheme Dr. Weinberg describes is quite different from the border scheme described by Robert Anderson. Nevertheless, these schemes result in similar descriptions of the types of ventricular septal defects that are encountered and each might be considered complementary for consideration by surgeons.
Methodologies using ultrasonic imaging have been developed over the last three decades that allow for accurate and timely assessment of the form and the function of the heart. Echocardiography is noninvasive and portable; thus, it has become the imaging modality of choice in the initial diagnostic evaluation of the patient suspected of having congenital or acquired heart disease. Structural abnormalities as well as alterations in flow and hemodynamics may be quickly and easily identified with minimal disturbance to the patient. Unlike angiography, in which images of opacified blood are radiographically exhibited and in which structural form is assumed from the visualization of nonopacified regions, echocardiography allows for direct, real-time imaging of cardiac structures based on their ultrasonic reflective properties. Multiple advantages are inherent in this diagnostic tool. Echocardiography is safe, portable, and radiation free. Views and sweeps of the heart from different angles and positions may be performed freely to conceptually reconstruct a three-dimensional (3D) image. Presently, 3D echocardiography can also be performed to better define valve abnormalities as well as define all of the rims of atrial septal defect (ASD) and ventricular septal defect (VSD). Serial assessments can be performed at different points in time or used continuously as a monitoring tool during procedures or interventions. Familiarity with the principles used to generate the echocardiographic image and its limitations will aid in the appropriate interpretation and clinical application of ultrasound in the surgical management of infants and children with congenital heart disease.

**PRINCIPLES OF ULTRASOUND PHYSICS AND APPLICATIONS**

**Ultrasonic Frequencies**

Ultrasonic energy is generated by the delivery of electrical impulses to piezoelectric crystals, which resonate at a set frequency. The range of ultrasound frequencies used for conventional cardiac imaging is 2.0 to 10 MHz. The choice of a particular frequency for imaging is based on its tissue penetration and resolution characteristics. High-frequency ultrasound is dissipated quickly in tissue and can be propagated only for short distances but allows for greater resolution of structure, whereas low-frequency ultrasound penetrates greater distances before attenuation but resolution is sacrificed. This concept is illustrated by the formula: wavelength = velocity/frequency, where the velocity of ultrasound in biologic tissue is constant at 1,540 m/sec. To ultrasonically resolve two points in space, they must be a distance of at least one wavelength from each other; hence, the higher the frequency, the smaller is the wavelength and the greater is the ability to resolve points that are in close proximity. For example, using 2.0-MHz ultrasound, one can resolve two points that are a minimum of 0.78-mm apart. If the objects are any closer, they will not be resolved and will appear as one. At 7.5 MHz, two points can be resolved at a minimum of 0.21-mm apart, hence resolution is greater. In practice, high-frequency transducers are chosen for use in newborns and small children to maximize resolution, whereas in older children and adolescents lower frequencies are used to maximize penetration. Higher resolution can also be used in transesophageal probes because penetration is not a major obstacle.

The Doppler Principle

In 1842, Christian Johann Doppler described the change in frequency of energy emission of an object in motion in relation to its velocity of motion toward or away from a stationary observer as follows:

\[ F_o = 2VF_d \cos Y / c \]

where \( F_o \) is the frequency shift, \( F_d \) is the emitting frequency, \( Y \) is the angle of incidence between the direction of motion of the object and the emitted frequency, \( V \) is the velocity of motion of the object, and \( c \) is the velocity of the energy in the medium (a constant). In the setting of reflected ultrasound, this principle can be used to assay for the velocity of blood flow moving through the chambers of the heart. Rearranging the equation, we obtain

\[ V = F_o F_d \cos Y / c / 2 \]

Hence, the velocity of blood flow can be derived from the Doppler frequency shift of reflected ultrasound from moving blood if the emitting frequency and the angle of incidence between the direction of motion of blood and the interrogating ultrasound beam are known. In the clinical setting, it is cumbersome to measure the angle of incidence between flow direction and the ultrasound beam. Every effort is therefore made to align the ultrasound beam parallel to the direction of blood flow; angle \( Y \) is thereby assumed to be 0 (cosine of \( Y = 1 \)). Doppler velocity assessments based on this assumption continue to be valid for angles of incidence of \( \leq 20 \) degrees because the cosine of 20 remains close to unity; however, at angles \( > 20 \) degrees this assumption is not valid, and Doppler-derived velocities may be underestimated.

Information relating to velocity and direction of blood flow can be obtained by several methods including pulsed-wave, continuous-wave, or color Doppler techniques. Pulsed-wave and continuous-wave Doppler quantify the blood flow velocity. In the pulsed-wave Doppler technique, ultrasound crystals fire pulses of energy and then stop to “listen” for reflected sound. This technique permits the spatial determination of velocity by allowing for interrogation of flow within a selected region of interest. Distance is calculated from the time it takes for reflected ultrasound to return to the transducer during the listening phase. Pulsed-wave Doppler is limited by its inability to assess peak velocities when there are significant disturbances of flow and velocities are high. Once a region of disturbed flow is identified, continuous-wave
Doppler may be applied to determine the peak velocity in the region. Continuous-wave Doppler emits and listens simultaneously. Thus, continuous-wave Doppler will assess all velocities within a line of interrogation—velocities within as well as proximal to and distal to the site of interest. Combining pulsed-wave and continuous-wave Doppler when assessing disturbed flow patterns is ideal to give the location of the turbulence and the maximum velocity.

Color Doppler is a pulsed-wave method in which flow within a region is assigned a color based on velocity and direction and is displayed as an overlay onto the two-dimensional image. By convention, flow toward the transducer is designated as varying shades of red, whereas flow away from the transducer is blue. Color flow is a pictorial indicator of blood flow direction and velocity but does not quantify the maximum velocity of a flow jet.

**Modified Bernoulli Theorem**

Based on the concept of exchange of potential energy into kinetic energy, the velocity of flow between cardiac structures can be used to calculate the pressure difference, thereby providing hemodynamic information. Bernoulli showed that the difference in potential energy, or pressure, between two sites is equal to the kinetic energy loss in addition to the energy losses caused by inertial and frictional forces. If the loss of energy because of inertia or friction is assumed to be minimal, as can be done when assessing flow across a discrete, short segmental narrowing (such as a valve or VSD), then these contributing variables may be ignored and the modified Bernoulli formula can be applied to calculate the pressure difference between upstream point 1 (proximal point) and downstream point 2 (distal point):

\[ P_1 - P_2 = 4(V_2^2 - V_1^2) \]

If the proximal blood flow velocity is \( \leq 1.0 \text{ m/sec} \), as is the case within most of the structures of the normal heart, the formula can be further simplified to

\[ \text{Pressure difference} = 4V_2^2. \]

Hence, the pressure difference across an area of discrete stenosis can be calculated based on the peak velocity across the region of narrowing obtained by Doppler echocardiography (Fig. 72.1A, and 72.1B). Systolic pressure gradients derived from peak velocity data reflect the peak instantaneous pressure gradient, which usually occurs during the upstroke of systole and not at peak systole. This is why Doppler-derived gradients may be higher than cardiac catheterization gradients in which peak-to-peak pressure gradients are measured. Lesions in which the time for reaching peak pressure is delayed in one chamber relative to the other will add to a further exaggeration of differences between the catheter-derived and Doppler-derived gradients. For example, in aortic stenosis, peak ascending aorta pressure is reached much later than peak left ventricular pressure. Hence, whereas the peak-to-peak (catheter) gradient may be 40 to 50 mmHg when comparing the two time-delayed peaks, the peak instantaneous (Doppler echocardiography) gradient, which will likely occur during early systole when aortic pressure is low and left ventricular pressure is rapidly on the rise, may be up to 30 to 40 mmHg higher, providing an echo-derived gradient of 70 to 80 mmHg. The mean gradient, which can be calculated from the echocardiogram by integrating the sum of the peak instantaneous gradients within the systolic cycle, is most likely the best reflection of the afterload work imposed on the ventricle; however, clinical correlates were developed in the era before echocardiography, and the standard for grading and treatment of valvular stenosis of a congenital cause today is still based on the peak-to-peak catheter-based gradient assessment.

**Fig. 72.1.** (A) The Bernoulli principle defines the relationship between kinetic energy (velocity) and potential energy (pressure drop) across a discrete stenosis such that inertial and frictional forces can be ignored. (B) Practical example of the use of the Bernoulli principle. Continuous-wave Doppler measurement across a stenotic right ventricular to pulmonary artery conduit in a patient with L-transposition of the great arteries after atrial switch operation and Rastelli procedure. The peak velocity is 4 m/sec generating a peak instantaneous gradient across the conduit of 65 mmHg.
CONGENITAL HEART DISEASE

Echocardiographic evaluation of a child with potential heart disease should be performed in a standardized, systematic manner with identification of all segments of the anatomy from multiple planes. In addition to the identification of all structural defects, physiologic information via the Doppler methodologies is also obtained. To facilitate the study, patients ranging from 3 months to 3 years of age should generally be sedated. A complete echocardiographic study consists of two-dimensional views and sweeps (incremental views obtained while rotating the transducer through a plane or on an axis), starting with subcostal imaging in which the liver is used as an acoustic window to the heart and ending with the suprasternal windows (Table 72.1). These standardized views and tomographic sweeps are acquired in a sequential manner during the pediatric echocardiogram, and synthesized into a comprehensive picture of cardiac anatomy, function, and blood flow (Fig. 72.2A–72.2G).

Abdomen and Situs

The echocardiographic study commences with a determination of situs. A transverse or coronal view of the abdomen just below the sternum at the level of the diaphragms displays the position of the liver, stomach, inferior vena cava, and descending aorta. In situs solitus, the following should be noted: (1) the liver and the inferior vena cava traversing throughout the body of the liver are to the right of the spine; (2) the stomach is to the left of the spine; and (3) the aorta is retroperitoneal and lies just anterior and slightly to the left of the spine (Fig. 72.3). In situs inversus, the mirror image is found, whereas in heterotaxy syndrome (asplenia or polysplenia), the liver is often in the midline, and the inferior vena cava and aorta may be juxtaposed on the same side of the spine either to the right or the left. In heterotaxy syndrome, systemic venous anatomy is clinically important as the majority of associated cardiac defects require single-ventricle palliation. In polysplenia, the inferior vena cava may be interrupted at the infrarenal level, with no inferior vena cava seen at the level of the diaphragms. In this case, a dilated azygos vein should be sought in the retroperitoneal space adjacent to the spine, which carries inferior vena caval blood to the superior vena cava (Fig. 72.4). A dilated superior vena cava helps confirm this finding. In addition to interruption of the inferior vena cava, the hepatic venous drainage into the aorta should be identified. Occasionally, the hepatic veins drain to both atria particularly when there is a common atrium. The size of the hepatic veins should also be noted because inordinate dilation may be a sign of (1) right atrioventricular valve insufficiency, stenosis, or atresia or (2) infradiaphragmatic total

Chapter 72: Echocardiographic Evaluation of Congenital Heart Disease

Fig. 72.2. (A) Subcostal frontal sweep. Coronal plane with sweep from anterior (position 1) to posterior (position 3). At position 1, structures visualized include the right ventricular outflow tract and the apex of the left ventricle. At position 2, the left ventricular outflow tract is seen. At position 3, the right and left atria and atrial septum are highlighted. Ao, aorta; LA, left atrium; LV, left ventricle; MPA, main pulmonary artery; RA, right atrium; RV, right ventricle; SVC, superior vena cava. (All tomographic sweep and view figures are reproduced with permission from Lai WW et al. Guidelines and standards for performance of a pediatric echocardiogram: a report from the Task Force of the Pediatric Council of the American Society of Echocardiography. J Am Soc Echocardiogr 2006;19:1413-1430.) (B) Subcostal sagittal sweep. Sagittal plane sweep from right to left. At position 1, the entry of the superior vena cava is seen. At position 2, the right ventricle inflow and outflow is visualized. At position 3, the short axis of the left ventricle and the right ventricle cavity wrapping around anteriorly are seen, and at position 4, the apex of the left ventricle. Ao, aorta; LV, left ventricle; RA, right atrium; RPA, right pulmonary artery; RV, right ventricle; SVC, superior vena cava. (C) Apical four-chamber view demonstrates the atria, ventricles, and atroventricular valves. Posterior angulation visualizes the coronary sinus; anterior angulation visualizes the left ventricular outflow tract and proximal aorta. Ao, aorta; CS, coronary sinus; LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle. (D) Parasternal long axis views with sweep from rightward/inferior (position 1), which focuses on the tricuspid valve and right ventricle inflow to leftward/superior (position 2) with visualization of the right ventricular outflow and pulmonary valve. At position 2, the mitral valve, left ventricle inflow, left ventricular outflow tract, and aortic valve in long axis are well seen. Ao, aorta; LA, left atrium; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RV, right ventricle. (E) Parasternal short-axis sweep from superior (position 1) to inferior (position 3). Structures viewed in sequence in this sweep include the aortic valve in cross section with the identification of valve leaflets, course of the coronary arteries, conal septum, pulmonary valve, ventricular septum, mitral valve, papillary muscles, muscular septum, right ventricle cavity, and left ventricle cavity. LA, left atrium; LV, left ventricle; MV, mitral valve; PMs, papillary muscles; RA, right atrium; RV, right ventricle; TV, tricuspid valve. (F) Suprasternal frontal view. Structures well seen include the innominate vein, superior vena cava, pulmonary arteries, and pulmonary vein entry into the left atrium. Ao, aorta; Innom V, innominate vein; P Vs, pulmonary veins; RPA, right pulmonary artery. (G) Suprasternal arch view, also known as the "candy cane view" as the ascending and descending aorta are displayed with the origin of cephalic vessels. Ao, aorta; Innom V, innominate vein; RPA, right pulmonary artery.

Chapter 72: Echocardiographic Evaluation of Congenital Heart Disease

Fig. 72.2. (Continued)

Fig. 72.3. Coronal view used to determine situs. Situs solitus or normal situs is seen with the aorta to the left of the spine and the inferior vena cava (IVC) running through the liver on the right.

Fig. 72.4. Coronal view in a patient with polysplenia type of heterotaxy syndrome. The stomach is left-sided, the aorta runs to the right along the spine, and there is interruption of the inferior vena cava such that the azygos runs adjacent to the aorta and inserts into the left superior vena cava (not seen).

anomalous pulmonary venous connection (TAPVC). A left superior vena cava has no hemodynamic significance in the structurally normal heart. Typically, this vessel crosses anterior to the left pulmonary artery and enters the coronary sinus posteriorly. However, bilateral superior venae cavae are common in heterotaxy syndrome. Identification of this anomaly becomes important particularly if single-ventricle palliation is planned (Fig. 72.5). Without a bridging vein between the superior venae cavae, a bilateral bidirectional superior cavopulmonary anastomosis is necessary in single-ventricle palliation; when a large enough bridging vein is present, the left superior vena cava can be ligated rather than connected to the pulmonary artery. In heterotaxy syndrome, the left superior vena cava may empty directly into the left atrium or by way of an unroofed coronary sinus resulting in a right-to-left shunt.

Atria, Ventricles, and the Atrioventricular Connection

Identification of atrial and ventricular morphology is an important part of the echocardiographic examination. The atria are identified by their appendage morphology as well as the attachments of the septum primum to the septum secundum. The atria should not be defined by the connected venous structures because they can be variable (i.e., anomalous pulmonary venous connection to the right atrium, and left superior vena cava to left atrium). The right atrial appendage has a wide inlet and a broad-based triangular appearance; the
left atrial appendage has a narrow inlet and a long, fingerlike appearance. In heterotaxy syndrome, the atrial appendages may be mirror image; thus, identification of the right and left atria can be challenging.

The right and left ventricle have anatomic features that distinguish them, and these can usually be seen by echocardiography barring circumstances of severe hypoplasia or hypertrophy. The right ventricle is identified by the presence of (1) coarse septal trabeculations, (2) a single papillary muscle, (3) a trileaflet atrioventricular valve, and (4) chordal attachments to the ventricular septum. The left ventricle is identified by the presence of (1) smooth trabeculations along the septal surface, (2) two papillary muscles, and (3) no chordal attachments to the ventricular septum. When the ventricles are “D-looped” (concordant atrioventricular connection), the right and left atria connect normally to their respective right and left morphologic ventricles. When the ventricles are “L-looped” (discordant atrioventricular connection), the right atrium connects to a morphologic left ventricle and the left atrium connects to a morphologic right ventricle. In an L-looped heart, Ebstein’s anomaly of the left-sided right ventricle is frequently seen.

THE ATRIAL SEPTUM AND ATRIAL COMMUNICATIONS

The atrial septum is comprised of three components; septum primum, septum secundum, and canal septum. Additionally, the sinus venosus septum is adjacent to the atrial septum.

1. Ostium secundum ASD is a deficiency in the septum primum. These defects are usually located centrally, may be of varying size, and, if small, may be difficult to distinguish from a patent foramen ovale (Fig. 72.6). A defect measuring >6 mm in diameter on a subcostal long axial oblique or sagittal sweep should be considered one of significance. Defects <5 mm may be considered a large patent foramen ovale and may spontaneously become smaller over time. Occasionally, even an anatomically small defect may be physiologically significant (large left-to-right shunt), and surgical or catheter-directed closure may be indicated. Identification of the rims of an ostium secundum ASD have become important in the era of device closure. Some defects have minimal rim at the level of the venae cavae or pulmonary veins making surgical closure a better option.

2. Ostium primum ASD is part of the spectrum of common atrioventricular canal defects. It is also called an incomplete or partial atrioventricular canal defect. In addition to the atrial septal deficiency, there is by definition a “cleft” in the left atrioventricular valve and possibly a VSD of varying sizes. The cleft is where the superior and inferior bridging leaflets meet at the ventricular septum. Valve regurgitation in this region is quite common. The atrial septal deficiency is typically large, located inferiorly and anteriorly, and best seen in the subcostal left axial oblique sweep and in the apical view.

3. Coronary sinus septal defects have the same physiologic effect as an ASD. There can be partial or complete unroofing of the coronary sinus with obligatory left-to-right shunting through the ostium into the right atrium. Often, the coronary sinus ostium is enlarged. It can be challenging to diagnose a coronary sinus septal defect when there is a left...
superior vena cava to coronary sinus (thus, the coronary sinus is enlarged already) or in patients with complex congenital heart disease. Contrast injection can sometimes be helpful to make the diagnosis.

4. Sinus venosus defects are in fact not true ASDs because the sinus venosus portion of the heart is not a component of the true atrial septum. However, from a clinical standpoint, the defect results in a left-to-right shunt at the atrial level and causes the same right ventricular overload seen in other ASDs. Sinus venosus defects are generally large and usually occur in association with the superior vena cava; less frequently, these defects are associated with the inferior vena cava. A superior defect is located at the orifice of the superior vena cava into the right atrium, hence echocardiographically, the defect creates the appearance of the superior vena cava overriding the atrial septum (Fig. 72.7). The right upper pulmonary vein is often either overriding the defect or connected anomalously to the superior vena cava. In an inferior defect, the inferior vena cava overrides the septum and the flow may be directed toward the left atrium resulting in cyanosis. The right lower pulmonary vein may drain anomalously in this setting.

Because it is a thin structure and false image drop-out is possible, the atrial septum should always be imaged in multiple planes perpendicular to the ultrasound beam. When an ASD is present, the right atrium, right ventricle, and pulmonary arteries will often appear dilated, and pulmonary artery flow velocities may be elevated in relation to the right-sided volume load. Echocardiography generally provides all of the information that is sufficient to refer patients for catheter-directed or surgical intervention.

**THE VENTRICULAR SEPTUM AND VENTRICULAR COMMUNICATIONS**

The ventricular septum is a complex 3D structure made up of tissue of varying morphologies as well as embryologic origin; hence, there are a variety of VSDs. In some cases, multiple defects can be seen in the same patient.

1. The conoventricular or perimembranous VSD is the most common and is located in the region adjacent to the septal leaflet of the tricuspid valve and just under the aortic valve (Fig. 72.8). It may be of varying sizes and in fact may be partially filled in with tricuspid valve tissue, forming an “aneurysm.” The presence of aneurysm tissue on echocardiographic examination may indicate a high likelihood for spontaneous diminution or closure. Prolapse of the right coronary cusp of the aortic valve may occur over time, particularly with a small defect, and may be an indication for surgery.

2. Displacement of the conal or infundibular septum results in a malalignment-type VSD. Malalignment defects are generally large and unrestrictive and do not undergo spontaneous closure. With anterior displacement of the conal septum, the aorta overrides the ventricular septum and the right ventricular outflow tract becomes smaller resulting in tetralogy of Fallot (TOF). The conal septum can also be displaced posteriorly, impinging on the left ventricular outflow tract. This type of defect is commonly associated with arch obstruction or interruption.

3. Deficiency of the infundibular septum may occur with or without displacement, resulting in a conosetal hypoplasia or doubly committed subarterial VSD (Fig. 72.9). In contrast to the more common conoventricular or perimembranous defect, this VSD is located just under the pulmonary valve. The proximity of this defect to the aortic valve annulus makes it a substrate for prolapse of the right aortic cusp with deformity of the aortic valve architecture and subsequent aortic insufficiency. Though these defects may be small, they do not close spontaneously.

4. An atrophicventricular canal or inlet-type VSD may be part of the common atrophicventricular canal anomaly in which a primum ASD and a common atrophicventricular valve are present. In rare cases, a canal-type VSD occurs without common atrophicventricular canal defect but with an associated conotruncal anomaly such as double-outlet right ventricle (DORV). A canal-type VSD is usually large and located posteriorly at the “inlet” portion of the right ventricle. In the common AV canal spectrum, the VSD may be filled in with valve tissue, which may partially or completely occlude the defect.

5. A muscular VSD may exist in the anterior trabecular zone or in the middle portion, apex, or posterior aspect of the septum. Muscular defects are rimmed circumferentially by muscular tissue and may be of varying sizes. These defects may also undergo spontaneous closure over time, particularly if they are small. In the presence of a large VSD such as in TOF, an additional small or moderate-sized muscular defect has been reported in up to 5% to 10% of cases and may be difficult to detect because flow is preferentially across the larger defect. Once the larger defect is closed, the smaller defects may then play a greater physiologic role and cause morbidity related to increased left-to-right shunt in the postoperative period. Hence, a careful search for additional muscular defects, particularly in

---

**Fig. 72.7.** Subcostal sagittal view in color compare mode demonstrating a superior vena cava (SVC)-type sinus venosus defect. The SVC appears to override the atrial septum and flow across the defect can be seen. The right pulmonary veins are not seen in this image but connect anomalously to the SVC. RA, right atrium; RPA, right pulmonary artery.
the anterior trabecular zone of the right ventricle, should be undertaken in all patients with a large VSD.

A part of the assessment of the physiologic effect of a VSD is an estimate of the right ventricular pressure. Assessing the velocity of tricuspid regurgitation will allow for the calculation of the peak gradient between the right ventricle and the right atrium. By adding the value of right atrial pressure, which in the absence of direct monitoring may be assumed to be 5 to 10 mmHg, one can obtain an estimate of right ventricular pressure. In addition, a less accurate but somewhat useful method of assessing right ventricular pressure is to measure peak velocity across a native VSD or a residual defect after repair. Because the Doppler technique measures the peak instantaneous pressures within the cardiac cycle, a right bundle-branch block, common after closure of a VSD, may create a period in early systole in which a large pressure gradient is present, and a high peak velocity will be obtained. This may create the spurious finding that the right ventricular pressure is low. Cardiac catheterization is at times indicated before referral for surgery of patients with VSDs. If a defect appears anatomically large on echocardiography in conjunction with signs and symptoms of congestive heart failure and if there is no suspicion of pulmonary vascular disease (i.e., the patient is <6 months of age), cardiac catheterization is unnecessary and repair should be undertaken. Invasive catheter assessments are indicated when calculation of the degree of shunt helps in decision-making and in circumstances in which a calculation of the vascular resistances is useful.

**ABNORMAL ATRIOVENTRICULAR CONNECTION**

In atrioventricular discordance, the right atrium is aligned with the left ventricle and the left atrium is aligned with the right ventricle. The most common defect with atrioventricular discordance is congenitally corrected transposition of the great arteries (ccTGA) where there is also ventriculoarterial discordance. With these anatomic findings, the circulation remains in series (“congenitally corrected”). ccTGA is frequently associated with Ebstein-like malformation of the tricuspid valve with associated tricuspid regurgitation (Fig. 72.10). Additional cardiac defects are common such as VSD, pulmonary outflow obstruction, or systemic outflow obstruction. These findings often lead to early presentation, although presentation in adulthood has been reported. Surgery to align the left atrium to the left ventricle and the left ventricle to the aorta requires a “double switch” approach including an atrial switch along with an arterial switch or a Rastelli-like procedure if a VSD and pulmonary stenosis is present.

**SINGLE-VENTRICLE LESIONS**

Single-ventricle lesions or univentricular hearts are defined as anatomical abnormalities with a single-ventricular chamber or a large dominant ventricle with a diminutive opposing ventricle that cannot support its circulation. Functional single ventricles include patients with lesions such as hypoplastic left heart syndrome (HLHS, Fig. 72.11), pulmonary atresia with intact ventricular septum, and tricuspid atresia. True anatomic single ventricles typically have two atrioventricular valves (though one may be atretic) or a common atrioventricular valve connected to a single ventricle. The most classic example of true single ventricle is double-inlet left ventricle (Fig. 72.12). The single-ventricular chamber can usually be recognized as being a right or a left ventricle by its anatomic features. Important echocardiographic features that require elucidation in patients with
single-ventricle lesions include (1) systemic and pulmonary venous anatomy, (2) anatomy and function of the atrioventricular valve(s), (3) anatomy and function of the semilunar valve(s) and outflows, (4) arch sidedness, and (5) assessment for coarctation of the aorta. In conditions of one atrioventricular valve being hypoplastic or atretic, it is also important to determine if there is an adequate atrial communication to prevent high pressure in the affected atrium. In single-ventricle lesions, there may be one atretic or obstructed great vessel, or both may be unobstructed. Bilateral outflow tract obstruction is usually fatal in fetal life.

Anatomic features of single-ventricle lesions are important to help determine if a neonatal surgery is required. Neonatal surgeries include Norwood procedure (classically for HLHS), modified Blalock–Taussig shunt placement for patients with pulmonary atresia or severe pulmonary stenosis, or pulmonary artery banding for those with unobstructed pulmonary outflow. Some patients have just enough pulmonary outflow obstruction that an initial surgery is not required. After neonatal surgery, staged palliation is similar for all patients with single-ventricle lesions. By 4 to 7 months, bidirectional cavopulmonary anastomosis is performed followed by the Fontan procedure at 2 to 4 years of age. Important features of the echocardiographic evaluation of patients after staged palliation include (1) evaluation of atrial septal communication, (2) assessment of presence and severity of atrioventricular valve regurgitation, (3) assessment of ventricular performance, (4) assessment of semilunar valve function, (5) assessment of aortic arch (if reconstruction has been performed), and (6) reassessment of venous anatomy to identify a left superior vena cava or pulmonary venous anomaly.

Ventriculoarterial Connections and Conotruncal Anomalies

Conotruncal anomalies involve defects of the infundibulum (conus) and the great arteries. The conus is a smooth-walled region of muscle normally situated beneath the pulmonary valve, raising it above the level of the aortic valve and positioning it anterior and to the left of the aorta. When
the conotruncal anatomy is normal, the aortic valve annulus is in fibrous continuity with the mitral valve. This relationship is easily visible in many different echocardiographic planes. Conotruncal defects arise when displacement of the infundibular septum is present and when the normal relationship of the great arteries is disturbed. Isolated aortic and pulmonary valve disease will not be covered in this chapter.

**TETRALOGY OF FALLOT**

TOF is the most common form of conotruncal anomaly. In TOF, there is a large anterior malalignment VSD with displacement of the infundibular septum into the right ventricular outflow tract (Fig. 72.13). In addition, distal pulmonary artery stenosis and hypoplasia are present. The key parts of the echocardiographic evaluation include an examination of (1) the nature and degree of the infundibular and pulmonary arterial narrowing, (2) the branch pulmonary artery architecture, (3) the presence of additional muscular defects, (4) the location and course of the coronary arteries, and (5) aortic arch anatomy to assess for right aortic arch and/or vascular ring. If all five aforementioned points of anatomy are well delineated by echocardiography, diagnostic cardiac catheterization is not necessary prior to surgical intervention. If TOF occurs in association with a right aortic arch, genetic testing to identify 22q11 deletion is highly recommended.

There is a wide spectrum within the diagnosis of TOF. TOF with pulmonary atresia has a wide range of anatomical presentations including plate-like atresia of the pulmonary valve with well-developed and confluent pulmonary arteries, discontinuous pulmonary arteries (Fig. 72.14), and the most severe form with markedly hypoplastic pulmonary arteries and aorto-pulmonary collateral vessels perfusing various lung segments. By echocardiography, assessment for confluence of the branch pulmonary arteries can be challenging. Identification of a ductus arteriosus in the setting of tetralogy with pulmonary atresia generally indicates a less severe form of the disease. It is important to identify coronary anomalies in these patients. In approximately 5% to 10% of cases, the anterior descending artery arises from the right coronary artery and courses across the infundibulum in the region where a surgical incision may be anticipated. If this coronary variant is present, an infundibulotomy or transannular patch may not be possible and a right ventricle to pulmonary artery conduit may be considered as a surgical option. The other common variant of TOF is absent pulmonary valve syndrome, whereby the pulmonary valve is hypoplastic but essentially unguarded with dysplastic and hypoplastic leaflets. On echocardiography, there is usually not only significant pulmonary stenosis but also severe pulmonary regurgitation. The branch pulmonary arteries tend to be markedly enlarged in this clinical setting. TOF can also be seen associated with common atrioventricular canal defect. This is seen typically in children with Down syndrome.

**TRANSPOSITION OF THE GREAT ARTERIES**

TGA is a defect in which the aorta arises from the right ventricle and the pulmonary artery from the left ventricle (Fig. 72.15). Preoperative echocardiographic evaluation should include determination of (1) the nature and size of the interatrial communication as a source of mixing, (2) the presence or absence of left ventricular outflow tract obstruction, (3) the relative position of the great arteries to one another, and (4) the coronary artery anatomy, in order to anticipate the technique of coronary reimplantation at the time of arterial switch repair. TGA can be seen with intact ventricular septum or in association with any type of VSD. With malalignment-type VSD, outflow tract obstruction is common. In the classic association of TGA with posterior malalignment VSD and pulmonary stenosis, a set of surgical procedures can be performed with the goal of baffling the left ventricle to the aorta. In most circumstances, echocardiographic evaluation is sufficient to refer infants with this lesion for surgery without cardiac catheterization. Balloon atrial septostomy, which may be needed to increase the degree of intercirculatory mixing and raise the arterial oxygen level, can be done under fluoroscopic guidance or under echocardiographic guidance at the bedside.

**DOUBLE-OUTLET RIGHT VENTRICLE**

DORV is not a specific congenital malformation but rather refers to an abnormal ventriculo arterial alignment, whereby both great vessels arise from the right ventricle (Fig. 72.16). By most criteria, both great vessels must sit more than 50% over the right ventricle to be defined as DORV. Typically, there is a bilateral conus with myocardium separating both great vessels from the atroventricular valves; however, other conal anatomy may be present. Associated lesions dictate a wide spectrum of variability in the physiologic presentation of this lesion. A VSD is almost always present, and in addition there may be (1) left ventricular hypoplasia with mitral stenosis or atresia (physiologically similar to HLHS), (2) infundibular narrowing of the pulmonary outflow tract with VSD flow directed toward the aorta (physiologically similar to TOF), or (3) infundibular narrowing of the aortic outflow tract with VSD flow directed toward the pulmonary artery (physiologically similar to TGA and typically called the Taussig–Bing anomaly). The key points
that must be delineated echocardiographically are (1) the relative position of the great arteries one to the other, (2) the presence or absence of conus beneath either of the great vessels and the associated degree of outflow obstruction, (3) direction of flow from the VSD to the great vessels, (4) the location of the VSD, which may be under one or both great vessels or may be remote (canal type or muscular type), (5) the size of the VSD, which may be restrictive, and (6) chordal attachments of the AV valves, which may be to the infundibular septum or across the VSD. DORV is one of the most challenging defects to image because of the 3D complexity. In some cases, additional imaging with 3D echocardiography, cardiac magnetic resonance, or cardiac catheterization may be helpful in anticipation of surgical reconstruction.

**TRUNCUS ARTERIOSUS**

Truncus arteriosus is a conotruncal defect characterized by the following criteria: a solitary great vessel arises from the heart giving rise to the aorta, at least one pulmonary artery and at least one coronary artery. Almost invariably, there is a malalignment-type VSD. The truncal valve is often abnormal; truncal stenosis and/or regurgitation is common (Fig. 72.17A). Though a tricuspid truncal valve is the most common anatomic subtype, other variations can occur including (in order of frequency), quadricuspid, bicuspid, and rarely valves with five leaflets (Fig. 72.17B). Approximately 25% of patients with truncus arteriosus have a right aortic arch and it can be associated with 22q11 deletion. There have been rare reports of truncus arteriosus with single ventricle. Truncus arteriosus has two classifications: the Colette Edwards and the Van Praagh classification. We describe here the Van Praagh classification.

1. **Type 1:** It is the most common type. There is partial absence of the aorto pulmonary artery septum: the main pulmonary artery arises from the common trunk giving rise to the branch pulmonary arteries.
2. **Type 2:** There is a total absence of the aorto pulmonary septum, and the
Fig. 72.17. (A) Subcostal left anterior oblique view of a patient with type 1 truncus arteriosus. The aorta (Ao) and pulmonary artery (PA) arise from the same trunk. The truncal valve in this patient is thickened and doming with truncal regurgitation seen (truncal regurg). LV, left ventricle; RA, right atrium. (B) Parasternal short-axis view in the same patient demonstrating that the truncal valve is thickened and quadricuspid. LA, left atrium.

PULMONARY VENOUS ANOMALIES

TAPVC occurs when all four pulmonary veins join as a confluence and connect to a cardiac structure other than the left atrium. There are three subtypes including:

1. **Supracardiac**: A pulmonary venous confluence connects by way of a vertical vein to the innominate vein or to a superior vena cava.
2. **Cardiac**: A pulmonary venous confluence connects either directly to the right atrium or to a coronary sinus (Fig. 72.18).
3. **Infracardiac**: A pulmonary venous confluence connects to a vertical vein that travels through the diaphragm and eventually connects to the ductus venosus or inferior vena cava.

The mediastinum should be carefully interrogated for left-sided vertical venous flow. TAPVC with obstruction is generally a surgical emergency. Thus, quick identification of the pulmonary venous confluence adjacent to the left atrium and the venous drainage is important for prognosis. The mixed type of TAPVC (pulmonary veins connect to multiple other structures) appears to carry a higher mortality than other forms. In addition, TAPVC in association with single ventricle generally has a poor prognosis; recurrent pulmonary venous obstruction is common. Echocardiography can usually identify the connection of all pulmonary veins and the location of the confluence in relation to the left atrium. The etiology of the pulmonary venous obstruction, if present, can also be identified by echocardiography using color and spectral Doppler. An atrial communication (which shunts exclusively from right atrium to left atrium in the setting of TAPVC (Fig. 72.18)) is a typical associated finding. When obstruction is severe, the left-sided structures may appear hypoplastic because of compression from the distended right ventricle.

AORTIC ARCH ANOMALIES

Aortic arch sidedness is determined by identifying each of the branches arising off the arch from proximal to distal. In a left aortic arch, the first vessel arising off the arch is the right innominate artery bifurcating into the right carotid and subclavian arteries, followed by the left carotid, and then left subclavian arteries. In a suprasternal frontal sweep, if the first vessel off the arch is the left innominate artery, the arch is right-sided. The branching pattern of the first vessel should be noted to
Chapter 72: Echocardiographic Evaluation of Congenital Heart Disease

be sure that it bifurcates into a carotid and subclavian artery. If it does not bifurcate, the possibility of an aberrant subclavian artery should be entertained. A right aortic arch with an aberrant left subclavian artery is a substrate for a potential vascular ring. Double aortic arch can also be suspected on echocardiography. However, if one arch is atretic, the diagnosis is more challenging. Any patient with a right aortic arch without mirror imaging branching should be suspected of having a vascular ring. Such patients should undergo further investigation, usually using cardiac magnetic resonance imaging.

PATENT DUCTUS ARTERIOSUS

Patency of the ductus arteriosus may be an isolated defect or in association with other lesions, whereby its function is to augment the systemic or pulmonic circulation. Doppler sampling of the flow patterns in the ductus arteriosus aids in understanding the physiology. In an isolated patent ductus arteriosus or when associated with lesions in which there is impediment to pulmonic flow (TOF, pulmonary atresia), the direction of flow will be from the aorta to the pulmonary artery (left to right) continuously throughout the cardiac cycle (Fig. 72.19). In lesions in which severe left-sided obstruction is present (critical aortic stenosis, coarctation of the aorta, HLHS), the role of the ductus arteriosus is to support the systemic circulation; hence, flow in systole will be from the pulmonary artery to the aorta (right to left); reversed flow into the pulmonary circulation will be observed during diastole because of lower pulmonary vascular resistance relative to systemic vascular resistance. Right-to-left flow across the ductus without an associated lesion is an ominous sign reflecting the presence of abnormally elevated pulmonary vascular resistance.

INTRAOPERATIVE TRANSESOPHAGEAL ECHOCARDIOGRAPHY AND POSTOPERATIVE IMAGING

As a result of the miniaturization of ultrasound probes, transesophageal echocardiographic (TEE) imaging may be performed in infants as small as 2 kg in weight. TEE may be utilized before and after surgical repair in the operating room. Preoperative TEE may identify previously unrecognized additional lesions. However, it is most often used to assess valve and ventricular function that can then be compared with postoperative studies. Postoperative imaging provides instantaneous information in the operating room prior to chest wall closure. TEE is useful to assess for residual lesions after closure of a septal defect, repair of an outflow tract obstruction, and repair of an atriointerventricular valve or a semilunar valve. TEE can also identify myocardial dysfunction after cardipulmonary bypass. Quantitative hemodynamics such as pressure gradients and degrees of valvular insufficiency, however, must be interpreted cautiously in the operating room because body temperature, cardiopulmonary bypass, inotropes, and an open chest wall may be variables that transiently influence the vascular resistances and/or myocardial mechanics. Information obtained in this setting may not always predict the patient’s steady-state outcome under different conditions in the intensive care unit or beyond.

Conventional transthoracic echocardiography has been shown to be effective in detecting residual lesions in the majority

Fig. 72.18. Subcostal left anterior oblique view in color compare mode of a patient with total anomalous pulmonary venous connection to the coronary sinus. The coronary sinus (CS) is markedly dilated with a dilated ostium. The pulmonary veins entering the CS have a “whale’s tale” appearance that is typical of this disease. The atrial septal defect (ASD) shunts exclusively right to left as is shown by the blue jet crossing into the left atrium. The flow in the CS does not appear to be obstructed based on the color scale. RA, right atrium.

Fig. 72.19. A high parasternal (ductal) view in color compare mode demonstrating a moderate-sized patent ductus arteriosus (PDA) shunting blood from the aorta to the pulmonary artery. The left pulmonary artery is out of the plane of the image. MPA, main pulmonary artery; RPA, right pulmonary artery.
of children who have had cardiac surgery. In addition to assessment for residual lesions, postoperative echocardiography can help identify ventricular dysfunction and important pericardial and pleural effusions. It is standard of care to perform a postoperative echocardiogram on patients who have undergone cardiac surgery to identify these potential complications.

It is also important to emphasize that TEE findings in the immediate postoperative period as the patient is separating from cardiopulmonary bypass may identify less or more severe residual disease than that seen several days after repair. The hemodynamic state as the anesthetized patient emerges from circulatory arrest and cardiopulmonary bypass is quite different than that in the awake child in the intensive care unit. Assessment of residual left atrioventricular valve regurgitation after atrioventricular canal repair is an excellent example of this phenomenon. Often, the regurgitation appears mild in the operating room, but is more severe on the study performed before hospital discharge. Correlation of the intraoperative assessment of the severity of neo-aortic regurgitation after the Ross procedure with postoperative assessment is also poor.

**THREE-DIMENSIONAL ECHOCARDIOGRAPHY**

Three-dimensional echocardiography has emerged in the past decade as an important imaging tool in patients with congenital heart disease. Three-dimensional echocardiography captures a thick sector of echocardiographic information which can then be cropped in any angle to obtain unique views of the heart. Septal defects can now be seen as would be seen on an autopsy specimen, in relation to all of the surrounding structures. Atrioventricular valves can also be viewed and the image can be cut into planes readily recognized by surgeons (Fig. 72.20). In some cases, the etiology of valvular regurgitation may be identified using this technique. The resolution of the image remains an obstacle especially in those with poor two-dimensional acoustic windows. Recently, a TEE probe has been developed that has 3D capability. The resolution is superior to transthoracic 3D and the probe can be used to help guide catheter-directed interventions such as ASD device closure. At present, the 3D TEE probe is large and can only be used in patients >40 kg.

**SUGGESTED READINGS**

An understanding of the standard views and methods of evaluation by echocardiography and a good understanding of echocardiographic imaging are important for congenital cardiac surgeons not only for preoperative diagnosis but also for postoperative evaluation of surgical repairs. Intraoperative echocardiography, usually by the transesophageal technique, has now become a common source of information on the suitability of cardiac repairs. Although in some centers echocardiography is used selectively to evaluate VSD patches for the presence of residual leaks or for evaluation of residual valvular insufficiency after AV canal repairs or tricuspid valvuloplasties, in other centers echocardiography is used routinely in all cardiac cases to assess the quality of the operative intervention and to rule out any additional hemodynamic lesions. (RM Ungerleider, JA Kislo, WJ Greeley, et al. Echocardiography during congenital heart operations, experience from 1000 cases. Ann Thorac Surg 1995;60:S539.) The hypothesis associated with the use of intraoperative echocardiography in the immediate evaluation of postoperative anatomy is that if residual lesions are identified, then addressing these at the initial operation would improve the morbidity or mortality in the postoperative period. Our experience with intraoperative echocardiography for assessing AV canal defects has shown that its routine use is associated with a significant reduction in the rate of reoperation for AV canal defects over time because significant residual valvular regurgitation can be addressed promptly. This approach has also decreased the risk of pulmonary hypertensive problems after repair. (CE Canter, TL Spray, CB Huddleston, E Mendoloff. Intraoperative evaluation of atrioventricular septal defect repair by color flow Doppler echocardiography. Ann Thorac Surg 1997;63:592.) The argument certainly can be made that intraoperative TEE is an integral part of any congenital cardiac operation as more complex repairs are being performed frequently in newborns and infants.

Recent echocardiographic techniques, including three-dimensional imaging, have improved the ability to provide anatomic information on mechanisms of valvar regurgitation and more three-dimensional

---

(continued)
geometric information that can aid in guiding cardiac surgical repair.

There have been multiple studies looking at use of postoperative transesophageal echocardiography that have shown that the identification of residual lesions in the operating room with prompt repair decreases the overall morbidity and mortality of cardiac operations. Thus, the use of postoperative transesophageal echocardiography in the operating room prior to decannulation from cardiopulmonary bypass is becoming routine in most centers except in the most straightforward of congenital heart defects where the anatomy is simply visualized at the time of the operation (secundum ASD, patent ductus arteriosus).

The argument certainly can be made that intraoperative transesophageal echocardiography is now an integral part of any cardiac operation as more complex repairs are being performed frequently in newborns and infants. As noted in this chapter, recent echocardiographic techniques, including three-dimensional imaging, have improved the ability to provide anatomic information on mechanisms of valvar regurgitation and more three-dimensional geometric information that can aid in guiding cardiac surgical repair.

As noted by the authors in this chapter, postoperative transthoracic echocardiography can show lesions that are different from those seen in the operating room environment. It is frequent for the magnitude of AV valve regurgitation to be greater postoperatively than in the operating room under conditions of general anesthesia with significant afterload reduction. Thus, in the majority of cases, a predischarge transthoracic echocardiogram is performed to evaluate the overall surgical repair.

As echocardiography has now become more available and portable and with the use of small portable probes, ultrasound-guided care in the Cardiac Intensive Care Unit is becoming increasingly standard. It is common for patients after cardiac surgical procedures to have multiple echocardiograms performed during their intensive care unit course to evaluate myocardial function, rule out residual shunts, assess diaphragm function and the presence of pleural or pericardial effusions, and to interrogate for evidence for thrombosis or valvular vegetations. There has been an increasing interest in training cardiac intensivists in the use of cardiac ultrasound for routine postoperative intensive care unit management and this trend is certainly likely to continue. Ultimately, echocardiography will become a standard monitoring tool in the cardiac intensive care unit, which will be used with increasing frequency.  

TLS
Cardiac Magnetic Resonance in Congenital Heart Disease
Mark A. Fogel and Yoav Dori

INTRODUCTION AND GENERAL COMMENTS

Cardiac magnetic resonance (CMR) has made incredible advances in the past 10 years and has become integrated into the management and care of the patient with congenital heart disease (CHD) in the 21st century. Its role in pre- and postoperative management of the patient with CHD is a useful adjunct to echocardiography and cardiac catheterization, adding significant clinical information which the other imaging modalities cannot and many times, supplanting the need for those techniques. Many times, this information can change the care of the child. In most instances, all anatomic data necessary for diagnosis and much of the physiologic information needed can be obtained through CMR. With all the choices today with regard to imaging type, choosing the correct modality or combination of modalities is important.

Table 73.1 displays the distinct advantages CMR has over both echocardiography and cardiac catheterization as well as its limitations. For example, because patient size plays an important role in the ability of echocardiography to visualize structures, CMR has a distinct advantage in the older child, adolescent, and adult. On the other hand, patients with pacemakers, in general, and some types of coils and stents cannot be placed in the scanner due to patient safety issues (although patients with pacemakers can be studied in selected patients in highly specialized centers). Some coils can give major artifacts. There is a lot to sort out in the choice of imaging modalities.

Anatomically, in complex CHD, the overlapping of structures in angiography or the “sweeps” utilized in echocardiography may not be sufficient to conceptualize the total anatomic picture. CMR is inherently a three-dimensional (3D) imaging technique and as such, whether they are a stack of steady-state free precession (SSFP) images obtained in contiguous, parallel slices, or a 3D slab obtained with a gadolinium (CMR contrast agent) injections, software can reformat the volumetric data set in any desired plane to demonstrate the salient points of the anatomy. Even “curved plane’s” are utilized clinically. Volume rendering of the 3D slab can create a 3D image which can be rotated, sliced, and manipulated in a myriad of ways to view the anatomy. Routine use of “dynamic” 3D contrast-enhanced CMR, where a 3D image slab can be obtained in just over a second, adds temporal information to a formerly static technique; gadolinium is injected in the periphery and its path is visualized as the bolus courses through the cardiovascular system (similar to a peripheral injection of iodinated contrast dye and fluoroscopy). The technique of T₁ prepared SSFP utilizing the navigator technique, generally utilized for coronary imaging, can be utilized at times for 3D imaging of the entire thoracic cardiovascular tree.

Another strength of CMR lies in its ability to delineate physiology and function in 3D. Using through plane phase-contrast velocity mapping, flows in any vessel rather than simply velocities (as in echocardiography) are obtained. Using cine imaging, ventricular volumes rather than simple linear dimensions (as in echocardiography) can be measured; CMR is the “gold standard” for measuring ventricular volumes and mass. In addition, a CMR image is typically averaged over multiple heartbeats (unlike echocardiography and angiography, a single CMR image can be averaged over two to many hundreds of heartbeats) and therefore, the functional analysis by CMR reflects many heartbeats embedded in the image yielding a much more realistic reflection of the physiologic state of the patient. In echocardiography, for example, the physician would have to perform this averaging “in his head”; it would be as if an echocardiographer would need to measure 75 Doppler velocities to be the equivalent of one velocity by CMR. It should be noted, however, that “real time” as well as “interactive” CMR is in routine clinical use, and this allows for instantaneous imaging typical of echocardiography and cardiac catheterization. Exercise and functional CMR makes much use of this technique.

In addition, CMR has the ability to “tag” myocardial tissue to calculate regional wall motion and strain, similar to speckle tracking by echocardiography and “tag” blood to visualize its course. Furthermore, myocardial velocimetry, the application of phase-contrast velocity mapping, is similar to Doppler tissue imaging by echocardiography where myocardial velocities can be measured. The advantage of both these CMR techniques over echocardiography, once again, is in its ability to determine all these parameters in 3D.

In a third broad category of CMR ability, tissue characterization plays a major role (the other two categories being anatomy and physiology/function). Viability, also called delayed enhancement, allows for identification of myocardial scar tissue and surgical patches after injection of gadolinium and a delay of approximately 10 minutes. In contrast to an injection and a subsequent delay in imaging, first pass myocardial perfusion imaging utilizing gadolinium can be used in conjunction with adenosine and is equal to nuclear techniques, which involve ionizing radiation and have less tissue contrast and resolution (“dynamic” 3D contrast-enhanced CMR mentioned above can be used to assess regional lung perfusion). Using a whole host of CMR techniques, cardiac tumors can be evaluated highly accurately (including delayed enhancement) and the “Lake Louis Criteria,” which utilizes T₂ imaging for myocardial edema, T₁ imaging before and after gadolinium injection for hyperemia/capillary leak and delayed enhancement for myocardial scar, has a high sensitivity and specificity for the diagnosis of myocarditis. T₁* imaging is a technique that allows for the determination of iron deposition in the myocardium, useful in disease states such as thalassemia and sickle cell disease to monitor and alter chelation therapy.
**CARDIAC MAGNETIC RESONANCE PHYSICS AND CARDIAC MAGNETIC RESONANCE TECHNIQUES**

The detailed physics of CMR image generation is beyond the scope of this text; however, the general concept is not. A powerful magnet, most commonly on the order of 1.5 Tesla and sometimes 3 Tesla, is used to align the spins of the hydrogen atoms in the body and a radiofrequency pulse (electromagnetic energy) combined with a special magnetic field which creates a magnetic “gradient” is used to perturb a small percentage of these molecules in a specific part of the body into a higher energy state. When the radiofrequency pulse is turned off, the hydrogen atoms from that part of the body return to their normal state, releasing energy in the process. This energy is then collected and analyzed by a complex series of mathematical computations to yield one line of data in what is called “K-space.” By repeating this process many times, many lines of K-space are obtained and through a process involving “Fourier transformation,” the lines of K-space are translated into lines in an image. The image itself is divided into a checkerboard [matrix] with each box called a voxel (the image is of a slice thickness and, therefore, is a 3D element). Generally, there are 128 to 256 lines of data in an image; however, this can vary from 64 to 512 lines. To allow for “noise” in the system (false data) as opposed to “signal” and to alleviate artifacts from breathing, each line can be obtained three or more times and averaged (with breathholding techniques, this is typically not necessary). To image the heart, the scanner uses the ECG (or much less commonly, pulse recording) to determine what part of the heartbeat to obtain the image.

By timing the radiofrequency pulses differently and changing their magnitude, different types of images are generated. There are many types of CMR in clinical use as shown in Figure 73.1. To define anatomy (Figs. 73.1–73.3), double inversion (DI) dark blood CMR yields high-resolution images of myocardial tissue and blood vessel walls while the blood remains signal poor. SSFP imaging also yields high-resolution images of myocardial tissue and blood vessels; however, the blood is bright and signal intense, without the use of contrast agents. Cine MR (see below) can be used to delineate morphology as well, including valve morphology (shown).

Although static noncontrast images used to be the mainstay of CMR, many other techniques have come into clinical use for morphology including contrast-enhanced imaging. A contrast, typically a gadolinium-based agent, is injected and a T1 weighted, 3D sequence is utilized to obtain a 3D image of the cardiovascular system (Fig. 73.2). Dynamic imaging is used and follows the contrast through the cardiovascular system; each phase is a 3D image in itself. These images can then be formatted as multiple two-dimensional images or a volume-rendered object (VRT) (Fig. 73.3) from any phase of the dynamic imaging; these images can be “added” or “subtracted” from each other to delineate the salient point of the anatomy. Shaded surface displays (SSD) and maximum intensity projections (MIP) are rarely used today but played a role in CMR in past years.

CMR goes beyond anatomy, however (Figs. 73.4 and 73.5). Cine CMR (Figs. 73.1 and 73.4) produces a high signal from blood in the myocardium and a low signal from blood in the blood vessels. This difference can be used to identify areas of perfusion and movement in the body. 4D flow imaging (Figs. 73.6) provides a way to examine velocity at different points across the ventricular cavity or blood vessel (Fig. 73.6) and allows for quantification of volume and flow.

**Chapter 73: Cardiac Magnetic Resonance in Congenital Heart Disease**
Fig. 73.1. Types of cardiac magnetic resonance in common use for anatomy. The upper left panel is a double-inversion dark blood image of a patient with a coarctation of the aorta (Ao) with residual aneurysm (An). Note that the blood is "black" and myocardial and vascular tissue give off signal. The upper middle image is a steady-state free precession (SSFP) image of a patient with pulmonary atresia with intact ventricular septum after Fontan (F); note how bright the blood is compared with the rest of the anatomy. SSFP depends upon this signal contrast for quality imaging. The upper right image is a patient with bicuspid aortic valve and mild aortic insufficiency using a spoiled gradient echo (SGE) sequence; note the turbulence underneath the aortic valve from the narrow jet. The lower left image is a three-dimensional maximum intensity projection of the Fontan baffle in a patient with hypoplastic left heart syndrome outlining the baffle, the branch pulmonary arteries and lungs; note the perfusion defect in the right upper lobe (arrow). The lower middle image is a magnitude image from phase-contrast velocity mapping depicting the trileaflet aortic valve in the Fontan patient mentioned in this figure; note how easily the valve leaflets are seen. The lower right image is the phase image in through plane-phase contrast velocity mapping of the aortic valve in the Fontan patient mentioned in this figure; flow, not just velocity, can be measured from this type of imaging.

3D echocardiography compares the data with CMR; why use a surrogate, however, when a "gold standard" can be used? This is extremely important in CHD where bizarre, misshapen cardiovascular structures cannot be modeled by geometry. Further, CMR is exquisitely sensitive to turbulence and can detect even small amounts of regurgitation or stenosis. If turbulent blood flow is present, cine CMR will show a signal void in the region of turbulence, used to detect valvular regurgitation, valve stenosis, blood vessel stenosis, or baffle leaks/fenestrations (Figs. 73.1 and 73.4). Alternatively, cine CMR can obtain static images at various levels of the body, "labeling" blood as signal intense regions. This may be used, for example, to find collateral vessels off the aorta in a patient with tetralogy of Fallot and pulmonary atresia. Cine CMR can be of the spoiled gradient echo type (SGE) or of the SSFP type.

The CMR signal generated contains both the amplitude information of the signal as well as "phase" information. Phase-contrast (also known as phase-encoded) velocity mapping (Figs. 73.5 and 73.7) uses this phase information to encode velocity similar to Doppler imaging in echocardiography. The difference is that with...
Chapter 73: Cardiac Magnetic Resonance in Congenital Heart Disease

Fig. 73.2. Types of cardiac magnetic resonance in common use for anatomy—dynamic three-dimensional gadolinium imaging: The series of images, progressing from left to right, depicts the injection of gadolinium as it traverses the cardiovascular system in a patient with hypoplastic left heart syndrome after Fontan (F). Each phase is a 3D image in itself. In the left image, gadolinium is injected in the left arm and enters the superior vena cava (SVC) and the branch pulmonary arteries. In the image second to left, the gadolinium has lit up the F as well as the right (RPA) and left pulmonary arteries (LPA); note the perfusion defect in the right upper lobe (arrow). In the second image from the right, the left-sided phase of the injection depicts the aorta (Ao) and in the image on the right, the recirculation phase is seen with flow back into the RPA and LPA.

Fig. 73.3. Types of CMR in common use for anatomy—volume-rendered three-dimensional imaging: These volume-rendered images are from the patient in Figure 73.2. The advantage of dynamic 3D gadolinium imaging is that various phases can be separated out to highlight various structures. The upper left and middle panels are 3D volume renderings of the Fontan baffle (F) and right (RPA) and left pulmonary arteries (LPA) from anterior (left) and posterior (middle) views. The right upper and right lower panels are volume renderings of the ventricle and aorta (Ao) from the systemic phase of the dynamic 3D gadolinium injection; note how both the native (nAo) and neoaortas (neoAo) and the connections can be easily seen. The lower middle and lower left panels are a combination of the pulmonary and systemic phases demonstrating the entire heart intact. DAo, descending aorta.
Fig. 73.4. Types of cardiac magnetic resonance in common use for physiology/function—cine CMR and myocardial tagging. The upper left and right panels are two images from the “three-chamber” cine of a patient with hypoplastic left heart syndrome after Fontan at end diastole (ED) and end systole (ES), respectively. Temporal resolution can be 20 milliseconds or less. The lower left and middle images are myocardial tagging (SPAMM—SPAtial Modulation of Magnetization) imaging of a single-ventricle patient at ED and ES; note how one can visualize the myocardial deformation of each “cube” of myocardium. Myocardial wall motion and three-dimensional strain can be measured. The right lower image is also myocardial tagging but of the one-dimensional version, used to tag thin walls such as at the right ventricle in this four-chamber view; regional myocardial wall shortening fractions can be measured.

CMR, velocity can be encoded in “through plane”—that is into and out of the plane of the image—the result being that actual flow can be obtained. If a blood vessel is imaged in cross section, all the voxels that encode velocity in the vessel can be summed over the entire cross section of the vessel and integrated over the entire cardiac cycle to obtain flow (as in liters/minute, not just velocity). This can be done in nearly any vessel in the body—arterial or venous, arterial to pulmonary collateral flow, regional flow to each lung, caval return can all be measured. CMR has the further advantage of performing internal checks—such as flow in the main pulmonary artery equaling the sum of the flows in the branch pulmonary arteries or the flow in the aorta equaling the sum of caval return in the absence of aortic to pulmonary collaterals; this is unique to CMR as a noninvasive imaging modality. Generally, an upper limit to the velocity to be measured is set, similar to the Nyquist limit in echocardiography, called the VENC (Velocity EN Coding). Also similar to echocardiography, velocity direction can be encoded in grayscale or color scale with “white” in one direction and “black” in another (or red and blue). Similar to Doppler echocardiography, velocity can also be encoded in the plane of the image—called “in-plane” velocity mapping. This can be encoded in either x- or y-directions of the image. The resulting three orthogonal planes that velocity can be measured in enable CMR to measure four-dimensional (4D) velocities when a “slab” is obtained, which encodes all three velocity vectors (three dimensions of velocity and one of time; Fig. 73.7). Much work is now being done in this area. Finally, phase-contrast CMR can be used to determine myocardial velocities similar to Doppler tissue imaging.

Myocardial tissue tagging (Fig. 73.4) is another CMR technique, which “magnetically labels” the walls of the myocardium and divides it into “cubes of magnetization.” This allows for the calculation of regional wall strain, radial motion, and torsion. This can be of the two-dimensional tagging type, where a “grid” is laid down on the myocardium (spatial modulation of magnetization or SPAMM) or of the one-dimension type, where just a series of parallel lines are laid down. Finally, blood tagging is similar to tissue tagging except that the blood is labeled, allowing for visualization of velocity profiles as well as calculation of cardiac index (Fig. 73.8). This can be of the bolus tagging variety, where only a thin stripe is laid down on the blood vessel to label it (Bolus tagging); this has largely been supplanted by phase-encoded velocity mapping. Nevertheless, the ability to actually visualize a flow profile directly without postprocessing is still an appealing approach. Alternatively, a large stripe can be laid down on the blood to aid in shunt detection (Fig. 73.8).

Coronary imaging, as with perfusion and viability, is an important issue in CHD. Coronary issues that the imager needs to address can be divided into three broad categories: (1) congenital coronary abnormalities such
Phase-encoded velocity mapping

Fig. 73.5. Types of cardiac magnetic resonance in common use for physiology/function—velocity mapping. Each pixel has a velocity measurement associated with it and encodes velocity into and out of the plane of the image for the through-plane version and in the plane for the in-plane version. Direction is encoded as either increased signal (white) in one direction and decreased signal (black) in the other direction. Summation of the multiplication of pixel areas by their respective velocities yields flow in the through-plane version. Through-plane velocity mapping—the upper left image is a velocity map across the atrioventricular valves in a patient with transposition of the great arteries, whereas the upper middle panel is an axial phase-encoded velocity map of the descending aorta (DAo). The upper right and lower right panels demonstrate the velocity map and anatomic image, respectively, across a normal trileaflet aortic valve. In-plane velocity mapping—the lower left and second from left images are in-plane velocity maps and the anatomic image (third from left) of the left ventricular outflow tract of a patient with aortic stenosis and insufficiency. The lower left image is in systole, the second and third from left in diastole.

Regional myocardial perfusion and viability are now in routine clinical use in CMR (Fig. 73.10). Utilizing gadolinium enhancement, CMR assesses regional wall perfusion by using a “first pass” injection technique. Typically, short-axis views of the ventricle are obtained and the sequence set up is such that the heart is imaged relatively motionless. Gadolinium is injected intravenously while the scanner continuously images the ventricle (up to 4 to 5 short axis slices may be imaged at once) and the gadolinium bolus is followed from right ventricular cavity to left ventricular cavity to ventricular myocardium. Defects in perfusion show up as dark portions of the myocardium while the rest of the ventricle is signal intense (Fig. 73.10). It is usually used in conjunction with a coronary vasodilator, such as adenosine, although other agents such as dipyridamole can also be used. Lung perfusion can also be assessed qualitatively using time-resolved gadolinium techniques (Fig. 73.2).

Infarcted myocardium is less of a known issue in CHD than it is in adults; however, native lesions such an anomalous left coronary artery from the pulmonary artery or operations, which scar the myocardium (e.g., repaired tetralogy of Fallot or single ventricles), may manifest myocardial infarction and scarring. Gadolinium is avidly taken up in the extracellular space by scarred myocardium and can remain in the scarred tissue for an extended period of time while it is subsequently “washed” out by coronary blood flow in perfused myocardium. Put another way, the signal intensity–time curves separate, with the infarcted myocardium gadolinium curve remaining highly signal intense after 5 minutes, whereas normal myocardium becomes much less so. CMR sequences take advantage of this property to be able to image infarcted myocardium using an inversion
**Section III: Congenital Cardiac Surgery**

Ao flow = 4.3 l/min/m²
MPA flow = 7.8 l/min/m²
\( Q_p/Q_s = 1.8 \)

![Flow vs Time](image)

**Fig. 73.6.** Types of cardiac magnetic resonance in common use for physiology/function—velocity mapping analysis example—\( Q/Q_s \); velocity mapping can determine complex or simple flows. For example, in a patient with an atrial or ventricular septal defect, \( Q/Q_s \) may be determined by placing a velocity map across the aortic (Ao) valve (top left and top middle panels) and the main pulmonary artery (MPA) (lower left and lower middle panels). The left panels are the anatomic images for reference, and the middle panels are the velocity maps with the cross section of the vessel contoured (green for Ao and red for MPA). The resultant measurements are graphed in a flow versus time curve (right panel). In this particular patient with partial anomalous pulmonary venous connection, \( Q/Q_s \) was 1.8.

pulse; this ability of CMR to detect myocardial scar is unique in noninvasive imaging. Signal intensity differences between normal and infarcted myocardium of up to 500% have been achieved. The technique has been shown to accurately delineate the presence, extent, and location of acute and chronic myocardial infarction as well as fibrous tissue (Fig. 73.10). Ventricular septal defect patches, right ventricular outflow tract patches as with repaired tetralogy of Fallot also demonstrate signal intensity with this technique. In addition, various cardiac tumors can take up gadolinium, whereas others will not and cardiac MR uses this property, along with T₁-weighted images, T₂-weighted images, and fat saturation to predict what type of tumor is present (Fig. 73.11).

Viability, myocardial edema, and tumor characterization are all examples of a third major function of CMR, which is "tissue characterization"—the ability of CMR to differentiate various forms of tissue from others and to make a diagnosis based on this and other characteristics. Other tissue characterization techniques rely on the T₁, T₂, and T₂* properties of the myocardium to determine the presence of excessive water or iron. T₂* imaging, which has a long TR and TE, is sensitive to water and is used to detect edema in, for example, myocarditis (Fig. 73.10). T₁* imaging, which quantifies the decay of signal at different TEs, will be lower in patients with iron deposits in the myocardium (after all, iron is ferromagnetic) than in patients without; this is used in patients with thalassemia or sickle cell disease to monitor chelation therapy (Fig. 73.11).

There are many other specialized techniques within CMR; the two that will be explored in greater detail in this chapter are:

1. X-ray magnetic resonance (XMR)—the use of CMR in combination with cardiac catheterization. The uses range from superimposition of 3D images generated by CMR onto the fluoroscopy of the catheterization laboratory to act as a "roadmap" for the physician performing the catheterization to performing interventions in the CMR suite—and everything in between.

2. Computational fluid dynamic modeling is the application of the Navier–Stokes equations, which is the governing equations of fluid flow in the body, to the cardiovascular system. With anatomy from CMR and blood flow measured at the inlets and outlets of the system (e.g., cavae and branch pulmonary arteries of the systemic venous pathway of Fontan patients or the main and branch pulmonary arteries in tetralogy of Fallot), a model of fluid flow can be created and tested at different flow conditions.

This chapter cannot delve into all the specialized CMR techniques although the reader should be aware they exist:

1. Exercise CMR—Performing exercise in the CMR suite itself with a CMR-compatible ergometer. Ventricular function, blood flow, and perfusion at exercise can be obtained by utilizing "real time" cine CMR and "real time" phase-contrast velocity mapping (Fig. 73.12).

2. Fetal CMR—Utilizing "real time" and ultrafast single shot CMR, fetal cardiac anatomy and ventricular function can be obtained. Newer techniques utilize "Metric Optimized Gating" (MOG) allow for measuring flow in fetal vessels (Fig. 73.12).

3. Tissue characterization: BOLD imaging, still being developed, can measure tissue oxygen levels as deoxygenated blood
has different magnetic properties than oxygenated blood. \( T_1 \) mapping utilizing gadolinium can measure “diffuse” myocardial scarring.

4. Three-dimensional printing is a technique that enables creation of physical 3D models of the cardiovascular system from gadolinium images, which the surgeon or the cardiologist can actually hold in their hands (Fig. 73.12).

5. \( T_1 \) mapping: The new and emerging field of “diffuse” myocardial scarring has been developing for a few years. As opposed to viability imaging, which generally detects discreet areas of scar, \( T_1 \) mapping techniques utilizes gadolinium to detect diffuse scarring not readily apparent on the viability images.

CARDIAC MAGNETIC RESONANCE IMAGING APPROACH

The imaging approach to the patient with CHD is the same in CMR as it is in echocardiography, which was outlined previously in this chapter. However, there are various approaches that are used in the CMR evaluation of CHD, which any physician in the care of children with heart disease should be aware of. The following is a delineation of the conduct of the CMR examination and the various techniques that are performed.

The reader should understand that not all techniques are run on every patient and that the study is tailored to the individual patient.

The initial images obtained are contiguous, tomographic slices in the transverse (also called “axial”) plane (images are oriented anteroposterior and right–left). This allows for one complete volumetric data set to be obtained so that if the study is terminated prematurely (e.g., patient instability), multiplanar reconstruction, and 3D data manipulation can still be generated offline and used in the analysis of the anatomy. This view depicts the following structures (preoperatively): short axes of the ascending and descending aorta, pulmonary and aortic annulus, venae cavae, axygyous vein, trachea, and esophagus, the long axes of the transverse aortic arch, main and branch pulmonary arteries, pulmonary veins, and a slightly off-axis apical four-chamber view.

The next set of images obtained are determined by the region of interest.
For example, if a coarctation of the aorta or the systemic venous pathway of a Fontan patient is being imaged, an off-axis sagittal image is used to obtain the “candy cane” view of the aorta or the long axis of the systemic venous pathway (parallel to the path of flowing blood). If on the other hand, a double aortic arch is being imaged or the left ventricular outflow tract is assessed, a set of straight or slightly off-axis coronal images are obtained to yield the short axes of the right and left aortic arches, the long axes of the amalgamation of these structures into ascending and descending aorta, and the long axis of the left ventricular outflow tract. This can be performed using either dark or bright blood techniques.

It is the author’s strong belief that physiology and function must be interpreted in light of the prevailing anatomy. Therefore, once the anatomy is sorted out, cine CMR is the next performed to determine ventricular performance (end-diastolic volume, ejection fraction as examples), valve function (e.g., aortic insufficiency or stenosis), shunts that may be present and to aid in determining stenosis of great vessels. This series of scans is also used to confirm the anatomic information obtained by static imaging (e.g., hypoplasia of the branch pulmonary arteries should show the signal void of turbulence on cine CMR). The static images are used as a localizer for cine CMR imaging (e.g., using the four-chamber view on the static images to obtain the left ventricular short axis for shortening), another reason why the static images are obtained first.

Three-dimensional gadolinium imaging is then performed to obtain a 3D volumetric set of the cardiovascular system. The author prefers to use a dynamic technique such as TWIST, which follows the peripheral injection through the cardiovascular system, creating a 3D image every 2 to 3 seconds. The reader should note that other techniques that are “static” can be performed as well utilizing (1) bolus tracking—a special sequence is used to track the bolus of contrast through the cardiovascular system in real time and when it reaches the region of interest (e.g., branch pulmonary arteries in a patient with tetralogy of Fallot), the 3D gadolinium sequence is run automatically or (2) test dose technique—a sequence is used to determine how long a small test dose of contrast takes for the contrast to reach the region of interest from the time of injection. The 3D gadolinium sequence is then run after the full dose of contrast is injected, delayed by the amount of time determined by the test dose.
Chapter 73: Cardiac Magnetic Resonance in Congenital Heart Disease

Fig. 73.9. Types of cardiac magnetic resonance (CMR) in common use—coronary imaging: CMR has come into its own with whole heart, steady state free precession (SSFP) imaging for coronaries that have compared favorably to catheter and CT (although resolution is less). The upper three images are of a patient with a left ventricular fibroma. The top left panel is an SSFP image of the left coronary artery (LCA) specifically the left anterior descending coronary artery—coursing just above the tumor. The middle and right panels are 3D reconstructions demonstrating the courses of the right coronary artery (RCA), LCA and the left circumflex coronary artery (LCx); because the tumor is nearly avascular, it is not imaged on the 3D reconstruction. The middle left, second from middle and the lower left panels are taken from a patient who is after heart transplantations with large coronary aneurysms of both the right and left systems. The lower middle panel and lower right panel are from a patient with anomalous origin of the RCA from the left coronary cusp.

After the gadolinium portion of the study, phase-encoded velocity maps are obtained and these are used for flow and velocity information. The vessel to be interrogated is dependent upon the lesion, but typically, velocity maps across the aorta and main pulmonary artery are a minimum which is obtained. This serves two purposes: (1) with no shunts present, the cardiac output of the aorta should equal the cardiac output of the main pulmonary artery and (2) with a shunt present, a $Q_r/Q_l$ may be obtained (Fig. 73.6). This author recommends obtaining right and left pulmonary artery flow when calculating a $Q_r/Q_l$ as well since both flows should add up to flow in the main pulmonary artery. In addition, caval flows are also obtained which should equal flow in the aorta in the absence of aortic to pulmonary collaterals or a systemic to pulmonary artery shunt. These quantitative internal checks are usually performed in CMR and is one of the unique features of CMR as an imaging modality. In addition, ventricular pressure estimates and gradients can be calculated utilizing through-plane and in-plane velocity mapping as one would in Doppler echocardiography.

In a typical scenario, in a patient who is after surgery, delayed enhancement (viability) is the final portion of the study. Since velocity mapping was performed after gadolinium was injected, the requisite 10 to 15 minutes would have passed and the patient would be ready to have scar imaging performed; in this way, little time is wasted during the examination. Generally, delayed enhancement imaging is performed in a stack of contiguous short- and long-axis views of the ventricle; if a questionable region is present, other views are obtained through that region. To ensure that the questionable region is not artifact, images may be obtained with different parameters (e.g., swapping phase and frequency-encoding directions, etc.).

A number of other techniques can be performed in between these sets of sequences, in place of them, or the sequences would be performed in a different order, tailored to the individual patient's
disease and history. Myocardial tagging or blood tagging can be done after the cine sequences. Coronary imaging can take anywhere from 7 to 10 minutes and if that was the goal, it would be performed after the initial static images and some cine imaging. If perfusion is the goal of the study, this is usually done close to the beginning of the exam but after dark blood sequences are needed. If myocardial iron imaging (T₁ imaging) was the goal, that would be performed first. In the case of perfusion, the following sequence of events would be used, taking 60 to 70 minutes:

- Static bright blood imaging
- Cine imaging to obtain a gestalt for myocardial shortening prior to adenosine
- Adenosine perfusion imaging with gadolinium (adenosine 140 μg/kg/minutes for 4 to 6 minutes)
- Cine imaging for function (ventricular volumes and mass)
- Velocity mapping for flows
- Resting perfusion imaging with gadolinium (15 to 20 minutes after adenosine perfusion)
- Coronary imaging
- Delayed enhancement

With this sequence of events, a full functional exam, coronary and perfusion imaging can be obtained efficiently and distinctions can be made between normal perfusion, artifact, ischemia, and infarction.

CARDIAC MAGNETIC RESONANCE: MAJOR USES FOR ANATOMY

In certain situations, CMR is so vastly superior to other imaging modalities that it is the standard of care. There are five broad categories for which CMR has found an important role (both pre- and postoperatively) in the anatomic diagnosis of CHD which, because of the varied and flexible nature of the imaging modality, are not all-encompassing but take into account the vast majority of uses. They are (1) great artery anatomy, (2) imaging extracardiac conduits and intracardiac baffles, (3) complex spatial relationships, (4) venous connections both preoperative and postoperative, and (5) general morphologic evaluation and miscellaneous, but important individual diseases are not included in the other categories. This also includes subsections, such as (5A) valve morphology, (5B) tissue characterization (such as characterizing right ventricular dysplasia, identifying myocardial scar tissue or cardiac tumors), and (5C) coronary imaging.

Great Artery Anatomy—Preoperative and Postoperative
Aorta
Lesions of the aorta commonly evaluated by CMR are classified as either (a) ring or
Fig. 73.11. Types of cardiac magnetic resonance in common use for tissue characterization—$T_2^*$ for myocardial iron and tumor characterization. (A) The $T_2^*$ approach uses the fact that iron alters a magnetic field and how much of that iron is present will determine how that magnetic field is altered. The top three panels going from left to right are $T_2^*$ images with increasing echo times (TE) from a patient with thalassemia—note how dark the myocardium and liver become and this darkness increases with increasing TE. A $T_2^*$ $<20$ milliseconds puts a patient at risk for decreasing ventricular performance. (B) For tumor characterization, there are multiple techniques used by CMR to determine a tumor type. SSFP (middle left panel), HASTE imaging (lower left panel), $T_1$ dark blood with and without fat saturation (second from middle left and second from lower left, respectively), perfusion (second from middle right), $T_1$ after gadolinium administration (lower right), and viability (middle right) are just a few in this patient with a right ventricle (RV) tumor (T). There is a pericardial effusion (PE) and there is obvious RV compression. The heterogeneity of the tumor’s signal intensity on different types of imaging and the avascular nature of the tumor on perfusion with a rim of neovascularization suggested a mixed type of tumor with fibrous material. This patient’s biopsy showed a mixed cellular fibroma.

(b) non-ring abnormalities (Figs. 73.1–73.3, 73.7, 73.13, and 73.14). A vascular ring is an aortic malformation where vascular structures (or former vascular structures) completely surround the trachea and esophagus, possibly compromising these structures (diverticulum of Kommerel). An advantage of CMR is that imaging the trachea and bronchi as it relates to the vascular ring allows the physician to examine the bronchoarterial relations and find the reason for and assess the amount of airway compression.

In the CMR evaluation of a vascular ring, the initial axial images can almost always make the diagnosis and a set of contiguous coronal images complements the axial ones as an orthogonal view (useful in assessing the diameter of the vascular structures which may ultimately affect the surgical management). Three-dimensional reconstruction is now the standard in assessing the size of the various components of the vascular ring, the geometry, and in the evaluation of tracheal or bronchial compression.

In a double aortic arch, the ascending aorta splits into two arch vessels, which cross over both bronchi and branch pulmonary arteries coalescing behind the trachea and esophagus to form the descending aorta. The aorta totally surrounds the trachea and esophagus and surgical management entails ligation and division of the smaller of the two arches, which is more commonly the left one. Since this is performed by thoracotomy, CMR is crucial in determining the surgical management by assessing which arch is smaller to know which hemithorax to enter.

Right aortic arch complexes may form rings, depending upon where regression in the embryonic aortic arches occurs. For example, in a right aortic arch with a retroesophageal diverticulum of Kommerel and an aberrant left subclavian artery (Figs. 73.13 and 73.14), the components
**Fig. 73.12.** Other types of cardiac magnetic resonance—exercise CMR, fetal CMR, and three-dimensional printing: left image is of a volunteer on a CMR compatible ergometer about to be scanned. The right upper panel is a four-chamber view of a fetus with pulmonary atresia and intact ventricular septum. The right lower panel is a 3D model fabricated from CMR images of a patient with pulmonary atresia and intact ventricular septum with a hypoplastic right ventricle from posterior; only the left-sided structures were printed for this example. DAo, descending aorta; LV, left ventricle; RV, right ventricle.

**Fig. 73.13.** Right aortic arch with a diverticulum of Kommerel and aberrant left subclavian artery (LSCA)—bright blood images: The upper left, upper middle, bottom left, and bottom middle are static bright blood axial images of a child with a right aortic arch (RAo) with a diverticulum of Kommerel (D) and aberrant LSCA. Images progress from superior to inferior as the numbers progress from one to four. The panel on the right is an off-axis bright blood coronal view demonstrating the D. A Ao, ascending aorta; DAo, descending aorta; LCC, left common carotid artery; RCC, right common carotid artery; RSCA, right subclavian artery; LSCA, left subclavian artery.
Fig. 73.14. Right aortic arch with a diverticulum of Kommerell and aberrant left subclavian artery (LSCA) — trachea and three dimensions: The left upper and lower panels are images of the trachea (T) from off-axis coronal and sagittal views from the patient in Figure 73.12, respectively. The middle and right panels are two views from the 3D imaging demonstrating the right aortic arch, diverticulum of Kommerell (D), and the aberrant left subclavian artery.

of the ring are as follows: anterior and right lateral portions formed by the aorta, posterior portion from the diverticulum, and left lateral portion formed by the left ligamentum arteriosum and left pulmonary artery (LPA). The right panels of Figure 73.14 is a volume-rendered image of such a lesion.

It should be noted that echocardiography can generally not totally rule out the diagnosis of a vascular ring. A small retroesophageal ductus (ligamentum) will cause a ring whether right or left aortic arch, and this can almost never be diagnosed by echocardiography. In addition, echocardiography relies on the rule of thumb that the first branch of the aorta is contralateral to the sidedness of the arch (although technically, this branch needs to be visualized to bifurcate before this rule can be applied; even then, an early bifurcation of the carotid cannot be ruled out). There are significant exceptions to this rule that can occur such as a right aortic arch with an aberrant left innominate artery or a right aortic arch with an atretic/absent left carotid artery, and aberrant left subclavian artery both of which would have the first branch being the right carotid artery; the echocardiographer would then assume this was a left aortic arch when indeed it was a right aortic arch.

With nonring aortic arch abnormalities, as with ring abnormalities, the initial axial images can generally yield the diagnosis or at least lead one in the correct direction. Instead of a set of coronal images, a set of oblique sagittal images are obtained parallel to the path of flowing blood allowing the whole arch to be visualized in one picture. In both ring and nonring abnormalities, 3D imaging with gadolinium or noncontrast techniques (T2 prepared, navigated SSFP) is nearly always obtained.

Of the nonring aortic arch abnormalities, assessment of the aortic arch for coarctation (Fig. 73.1, upper panel on left) is one of the most frequent referrals seen. Four extremity blood pressures and an image of the coarctation by CMR are all that are necessary for the diagnosis and referral for surgery CMR will also be used to assess for a bicuspid aortic valve and other associated abnormalities. Preoperatively, by measuring aortic flow immediately distal to the coarctation and then at the level of the diaphragm, CMR can be utilized to determine and quantitate collateral flow seen in this disease. In a normal aorta, the flow at both levels would be approximately the same or the flow in the descending aorta at the level of the diaphragm slightly lower than just distal to the isthmus; in a coarctation, because of collateral flow, aortic flow at the level of the diaphragm would be higher than that just distal to the coarctation. Postoperatively, CMR is used to assess the presence of coarctation in patients with aortic arch reconstruction or may be used a follow-up in patients who have had coarctation repair, monitoring for recurrence of coarctation or aneurysm formation. Other nonring aortic abnormalities include interruption of the aortic arch, supravalvar aortic stenosis (e.g., caused by Williams syndrome) or dilation of the ascending aorta because of
valvar aortic stenosis (Fig. 73.1), postoperative assessment of the adequacy of an aortic to pulmonary anastomosis in patients who require left ventricular outflow reconstruction, or ascending aortic aneurysm formation such as after a ‘wrap’ procedure.

**Pulmonary Artery**

Initial assessment of the pulmonary arteries is performed from the axial images, followed by long-axis views of the individual branch pulmonary arteries. Pulmonary artery lesions that were imaged by CMR fall into three basic categories. Stenosis or hypoplasia of one or both branch pulmonary arteries or main pulmonary artery (e.g., pre- and postoperative tetralogy of Fallot or tricuspid atresia) is one category, in which the data are important preoperatively to help predict outcome and may affect the conduct of the surgery as pulmonary artery augmentation may be necessary. Pulmonary artery size is thought by some to be one of multiple prognosticators of surgical outcome in patients with single-ventricle lesions leading to Fontan reconstruction.

CMR can characterize the geometry and size of the arteries, determine branch pulmonary artery discontinuity (ideally imaging in three orthogonal planes), the amount of collaterals present from the aorta, and if pulmonary atresia is present, to determine how far the main pulmonary artery extends to the base of the heart.

Aneurysmal dilatation of the pulmonary arteries is the second category. This occurs classically in the patient with tetralogy of Fallot with absent pulmonary valve leaflets but may also occur in patients with pulmonary artery hypertension or the poststenotic dilatation of pulmonic stenosis. CMR will yield the size and geometry of the pulmonary arteries and the amount of respiratory compromise. The last category is anomalous origin or course of the pulmonary arteries (Fig. 73.15). This category includes, for example, anomalous origin of the LPA from the right pulmonary artery (a pulmonary artery ‘sling’) where tracheal embarrassment may occur, anomalous origin of the right pulmonary artery from the ascending aorta (hemitruncus), or when one great artery arises from the base of the heart and gives rise directly in its ascending portion to the systemic, pulmonary, and coronary circulations (truncus arteriosus). In addition, postoperative assessment of patients after arterial switch procedure and the Lecompte maneuver falls into this category. In all cases, CMR can and should be used to delineate size, geometry, and site of origin.

**Extracardiac Conduits and Baffles**

Echocardiography may be hampered in imaging these structures because extracardiac conduits frequently pass immediately underneath the sternum or near the lungs, and parts of the intracardiac baffle are posterior in the atria or ventricle. CMR can usually succeed where echocardiography fails.

Extracardiac conduits fall into a few categories. A right ventricular-to-pulmonary artery conduit (e.g., a Rastelli procedure), an apical left ventricular-to-pulmonary artery conduit (e.g., [I,L,L]), severe pulmonic

---

**Fig. 73.15.** Pulmonary artery sling: The top panels demonstrate a three-dimensional image of a pulmonary artery sling from various views of anterior (left panel), lateral (middle panel), and posterior (right panel) where the left pulmonary artery (LPA) arises from the right pulmonary artery (RPA). The lower panel is a transverse (axial) view. Because there was narrowing of the LPA, velocity mapping was performed across the main (MPA) and branch pulmonary arteries to determine the relative flows to both lungs. Note how close the MPA flow measurement is to the sum of the RPA and LPA flows.
stenosis, and two good size ventricles), or an apical left ventricular-to-descending aorta conduit (e.g., severe aortic stenosis) are examples of ventriculoarterial conduits. An example of a venoatrial conduit is a Baffes procedure, whereas an example of an arterio-arterial conduits is in the case of an aortic-to-aortic conduit in reconstructing the heart of thoracopagus conjoined twins.

Intracardiac baffles can also be categorized. Atrial baffles, which function to channel venous blood to arteries or the ventricles, include the Fontan reconstruction for single ventricle complexes (Figs. 73.2–73.4), an atrial baffle to direct pulmonary venous blood to the left atrium in anomalous venous connection, and the Mustard and Senning procedures (which have been performed in the past) for the transposition of the great arteries. The Rastelli procedure, performed for transposition of the great arteries with ventricular septal defect and pulmonic stenosis, is an example, which has a ventricular baffle placed.

After contiguous axial images are performed, which can be used to follow the conduit and baffle in short axis, double oblique-angled 2D images are usually necessary to obtain the long axis of the conduit or baffle in one image. Sometimes, this may be impossible and although the physician must be satisfied with two to three 2D images of the conduit in long axis to obtain its full extent, 3D imaging with gadolinium, or T2-prepared SSFP imaging will nearly always enable visualization in long axis. Stenosis, regurgitation, or leaks across the baffle can be detected by cine CMR.

**Complex Spatial Relationships**

The orientation of various cardiovascular structures relative to each other and the rest of the body can be sorted out by CMR easier than other imaging modalities. The ability of CMR to obtain parallel, contiguous, tomographic slices, creating 3D volume-rendered displays and the use of multiplanar reconstruction gives the physician a powerful tool with which to analyze the complex geometry.

As with conduits and baffles, contiguous axial images are performed, which can be used to follow the various cardiovascular structures and, in general, to yield a first approximation of the anatomy. Afterward, double oblique-angled images (coronal angled to sagittal angled to axial) are usually necessary to further delineate the morphology and regions of interest identified on the axial images. Confirmation of certain diagnoses can be made using cine CMR.

Superoinferior ventricles with criss-cross atrioventricular relations is one example of complex spatial relationships (Fig. 73.16). In this lesion, the two ventricles are oriented superoinferiorly instead of anteroposteriorly and right–left with the ventricular septum lying parallel to the axial plane. Further, in connecting atria to ventricles, the atrioventricular valves appear to cross each other, hence, the

![Fig. 73.16. Complex spatial relationships: The left panel is an off-axis sagittal view of a patient with superoinferior ventricles after Fontan (F). The top middle panel and top right panel are bright blood images of thoracopagus conjoined twins (designated as twin "A" and twin "B") from the axial and sagittal views (relative to the babies), respectively. The middle and lower panels are three-dimensional reconstructions from the sagittal and axial views, respectively. All structures could not be labeled as the figure would get too complex. Ao-A, aorta from twin A; Ao-B, aorta from twin B; LV-A, left ventricle from twin A; LV-B, left ventricle from twin B; PA-A, pulmonary artery from twin A; PA-A, pulmonary artery from twin B.](image-url)
name criss cross. To depict the ventricular relationship, coronal or sagittal images are utilized while the criss cross of the atrio-ventricular valves can be shown by the standard axial images. Off-axis coronal and sagittal images can be used the delineate the criss cross in the superoinferior plane.

Thoracopagus conjoined twins is another example of a complex spatial relationship (Fig. 73.16). The twins are joined at the thorax and cardiac fusion may occur at one or multiple levels. Echocardiography may be difficult postnatally because of acoustic windows, whereas prenatal imaging may be better in this scenario. CMR is used to sort out the various cardiac structures, including the complex venous anatomy (e.g., status of the inferior vena cavae), ventricular morphology (e.g., fused central [usually left ventricular morphology] ventricle), and abdominal viscera (status of the liver). For all lesions in this category, 3D volume-rendered displays as well as multiplanar reconstruction is useful in conceptualizing the anatomy. Time-resolved 3D gadolinium imaging can be utilized to determine if vascular connections exist between the twins and if so, at which level.

**Venous Connections—Preoperative and Postoperative**

At times, these may be difficult to visualize by echocardiography because of their position in the chest or poor echocardiographic windows (Fig. 73.17). Many times, it may take a long time for this to be sorted out by echocardiography where 10 to 15 minutes in the scanner is all that is needed, especially with the use of gadolinium (assuming anatomy is the sole goal of the study). CMR is a useful tool in delineating these connections.

**Systemic Veins**

Sometimes, isolated lesions of the systemic veins may have marked physiologic consequences, such as when the right or a persistent left superior vena cava connects to the left atrium, causing cyanosis (Fig. 73.17, left panel). Other anomalies of the systemic veins may be associated with intracardiac lesions and will affect the conduct of surgery, necessitating the need to be aware of these lesions preoperatively (e.g., if a patient with hypoplastic left heart syndrome has a persistent left superior vena cava not identified prior to Fontan reconstruction, deoxygenated blood will enter the pulmonary venous pathway, mixing with the oxygenated blood and causing cyanosis). The necessity for identifying this lesion is obvious and, therefore, important to diagnose at CMR. Since most systemic veins run in a superoinferior plane, coronal images are obtained after the contiguous axial images, delineating the vein along its long axis. This allows confirmation of the connections, assessment of the size of the vessel, and identification of any areas of stenosis.

---

**Fig. 73.17.** Venous anomalies: The left panel is an off-axis coronal view of a cine image of a newborn with a left superior vena cava (LSVC) connected to the left atrium (LA) without a right superior vena cava. The other images are three-dimensional reconstructions of a patient with complex total anomalous pulmonary venous connections—the left pulmonary veins (LPVs) connect to a vertical vein (VV), which descends on the left below the diaphragm, makes a hairpin turn superiorly into the right hemithorax to ascend and accept the right pulmonary veins (RPVs), and connects to the innominate vein (Inn vein) which connects to an LSVC. The top images isolate the RPVs, LPVs, and VV in two different views; the bottom image has the whole cardiovascular tree visualized from anterior.
Pulmonary Veins

Axial images can delineate the pulmonary venous anatomy and can also follow a vertical plane, allowing visualization of the pulmonary veins in the thoracic cavity (Fig. 73.17, middle and right images). Off-axis coronal images can then be obtained to confirm the diagnosis by visualizing the pulmonary veins in long axis.

The number of anomalies of pulmonary veins is myriad and their importance is obvious and are dealt with elsewhere in this textbook. Examples include Scimitar syndrome, which has an anomalous large, single right pulmonary venous connection to the right atrium, total and partial anomalous pulmonary venous connection.

General Morphology and Miscellaneous Diseases

CMR can also be used for general morphologic evaluation as well. It can be of great utility in the older child, adolescent and adult for this and because of the wide field of view, a single CMR study may serve the purpose of multiple other studies. For example, in heterotaxy syndrome, where defining the morphology and sidedness of the trachea, liver, gastrointestinal tract, and finding a spleen is important, a CMR may suffice. A chest X-ray, abdominal ultrasound, echocardiogram, abdominal CT scan, and possibly a liver–spleen scan may have to be performed otherwise.

CMR may also add another dimension to the lesion under study because of its reliance on the magnetic properties of the tissue. For example, in an intracardiac myxoma or tumor (Fig. 73.9, top left panel), the acoustic contrast (by echocardiography) may not be the same as the contrast on CMR (utilizing different pulse sequences and injecting gadolinium [which magnetically enhances vascular structures] to demarcate the extent of the tumor and its water content).

Other examples of common lesions CMR is used for, or have been diagnosed incidentally, are shown in all figures of this chapter. A pericardial effusion (Fig. 73.11) and single ventricle lesions (Figs. 73.2–73.4), for example, are fairly straightforward to recognize on CMR. Some other examples not shown include an aortic–pulmonary window, which is visualized by the turbulent jet of blood shunting from aorta to pulmonary artery in the coronal and axial views by cine CMR. Occasionally, a dark blood scan can identify this lesion as well and the shunt can be quantified using phase-encoded velocity mapping. Finally, left juxtaposition of the atrial appendages can be visualized in the coronal and axial (less well) plane of which whose findings generally include a ventricular and/or atrial septal defect, tricuspid atresia or stenosis, a hypoplastic right ventricle, pulmonary stenosis, and bilateral infundibulum.

With the advent of faster imaging sequences and improvements in hardware as well as software, capabilities of CMR for uses of generalized anatomy have expanded greatly. For example, valve morphology (category 5A referred to above) can be performed by CMR now coming close to and many times equaling echocardiography. Examples of how easily these are seen are shown in Figures 73.1 and 73.5. CMR can use en-face imaging to view this type of morphology using either SSFP or SGE sequences with a high flip angle. Even phase-encoded velocity mapping can be used to determine valve morphology.

In addition to valve morphology, tissue characterization plays an important role in CMR (category 5B referred to above). The tool has been advocated to be used to identify patients with right ventricular dysplasia by characteristics such as (1) fatty substitution of the myocardium, (2) ectasia of the RVOT, (3) dyskinetic bulges or dyskinesia of RV wall motion, (4) a dilated RV, (5) a dilated RA, and (6) fixed RV wall thinning with decreased RV wall thickening. Tumor characterization is also an important function of CMR and is based on the tissue characteristics by T1 and T2 weighting (with and without fat saturation), its signal intensity during and after gadolinium injection (Figs. 73.9 and 73.11), and the contraction pattern on myocardial tissue tagging. Finally, identification of myocardial scar tissue by the use of delayed enhancement 5 to 10 minutes after gadolinium injection (Figs. 73.10 and 73.11) is useful to determine ventricular performance, myocardial perfusion (see below), or as an etiology for arrhythmia as just a few examples.

Coronary imaging by CMR (Fig. 73.9) is a major emphasis in adults with heart disease; however, there is much applicability in pediatrics and CHD as well (category 5C referred to above). This is typically performed by obtaining a 3D volume data set using SSFP or (much less commonly) SGE sequences utilizing the Navigator technique, which monitors diaphragmatic motion and allows acceptance of data from only one part of the respiratory cycle (i.e., no need for breath-holding). There are the more well-known coronary anomalies found in pediatrics and CHD such as anomalous left coronary artery from the pulmonary artery, but others such as single coronary arteries, origin of the left coronary artery from the right sinus of Valsalva, or its mirror image which also need to be delineated. The status of the coronary arteries in coronary transplantation in surgeries such as the Ross procedure or the arterial switch procedure for transposition of the great arteries can also be assessed with this technique. Other CMR techniques can be used in conjunction with structural imaging of the coronaries such as delayed enhancement to evaluate for myocardial infarction (see above) or perfusion imaging (see below), once again demonstrating CMR as a “one-stop-shop” in imaging.

CARDIAC MAGNETIC RESONANCE: MAJOR USES FOR PHYSIOLOGY AND FUNCTION

Some of the uses of CMR for physiology and function are extremely clinically useful (e.g., accurate measurement of ventricular volume in a patient with borderline left ventricular size to determine whether it can support the systemic circulation) and play an important role in the management of patients (Figs. 73.4–73.8). Others are in physiology or ventricular function/fluid mechanics research or are still in the experimental or development stage clinically. And still others are on the verge of acceptance (e.g., computational fluid dynamics). Nevertheless, the physician taking care of patients with CHD should be aware of all of these capabilities as the research ones will no doubt enter clinical practice in the near future. Presented are just the most common uses in practice and in research.

The various techniques may be used in conjunction with each other. For example, to obtain the mitral regurgitant fraction in a patient with mitral insufficiency, cine CMR is used to obtain left ventricular end-diastolic volume, stroke volume, and total cardiac output. Phase-encoded velocity mapping in the aorta measures forward stroke volume, and the subtraction of this forward stroke volume from the total stroke volume measured by cine is the mitral regurgitant volume (which if divided by the total stroke volume is the mitral regurgitant fraction). Alternatively, velocity mapping across the mitral valve in diastole combined with forward flow across the aortic valve in systole allows for another method to calculate mitral insufficiency.

A feature unique to CMR is the capability of internal checks used in quantitative data, which is unique to noninvasive imaging. To use the example above, phase-encoded
velocity mapping across the mitral valve in diastole should yield the same flow volume as the mitral regurgitant volume calculated by cine imaging of the ventricle. Similarly, in patients without intracardiac shunting, velocity mapping across the main pulmonary artery should equal velocity mapping across the aorta, flow in the branch pulmonary arteries should match flow in the main pulmonary artery, and flow in the cavae should match flow in the aorta in the absence of aortic to pulmonary or veno-veno collaterals. All these strengthen the accuracy of CMR for the assessment of physiology and function.

Another unique feature of CMR is that the image can be built over multiple heartbeats and averaged (unlike echocardiography and angiography, a single CMR image can be averaged over two to many hundreds of heartbeats). Some might call this a disadvantage; however, it should be noted that using this approach, functional analysis by CMR can give a better handle on long-term performance. The image itself is an average and this average over many heartbeats is built into the image—the physician does not have to do this averaging “in his head” as in echocardiography.

Cine Cardiac Magnetic Resonance Uses

As noted in the Introduction, cine CMR (SSFP, SGE sequences) is used to image cardiac motion and blood flow (Figs. 73.1, 73.4, and 73.8). Blood is signal intense in this pulse sequence and myocardial tissue is less so and turbulence yields a signal void in the blood.

To assess ventricular shortening, a single-level short-axis view or multiple levels of the short axis of the ventricle can be obtained. This may be complemented by cine in the apical four-chamber view or the ventricular long-axis view. Regional wall motion abnormalities can be grossly visualized in this manner. Furthermore, some investigators have been using dobutamine infusions to assess the myocardium in a stressed state and determining regional wall motion abnormalities. Most software on present day scanners can give a temporal resolution of about 20 milliseconds. Neuer techniques now allow for “real time” visualization of ventricular performance or “interactive scanning,” where the real-time technique can be used and the user can change planes instantaneously, similar to echocardiography. ECG gating is not a requirement in these instances and, therefore, makes it very useful in patients with arrhythmias. Modifications of existing techniques use “arrhythmia rejection” algorithms to successfully image the heart in patients with arrhythmias. Clearly, a physician versed in all the nuances of CMR is needed to choose the best imaging for the particular task at hand.

Ventricular volume, mass, stroke volume, ejection fraction, and cardiac index may be accurately assessed by cine CMR. As mentioned earlier, this technique does not rely on any geometric assumptions, which are an advantage with the bizarre ventricular shapes found in CHD. Multiple contiguous cine CMR runs are performed throughout the entire ventricle at the same temporal resolution (scans usually take approximately 5 to 10 minutes) and the data then sorted by time. The results are multiple full volume data sets as low as 20 millisecond intervals. Ventricular volume at a given time (usually end-diastole and end-systole are the times of interest) is obtained by tracing the endocardial borders on all images at that time (done on computer with a cursor and mouse), planimeterizing the areas, multiplying by the slice thickness, and summing the result. Ventricular mass is obtained by tracing the epicardial borders on all images, planimeterizing the areas, multiplying by the slice thickness, summing the result, and then subtracting the ventricular volume. Stroke volume is simply the ventricular volume at end-diastole minus the ventricular volume at end-systole (usually defined by closure of the semilunar valve). Once this is known, ejection fraction is calculated in the usual manner. Cardiac index is simply the stroke volume multiplied by heart rate during the study divided by body surface area. Software packages today make this process easy, and the results may be obtained in a few minutes with minimal user interaction.

Cine CMR, as noted above, may also be used to visualize turbulence of blood flow. This is especially useful when valvar regurgitation or stenosis is present. Grading the regurgitation is similar to color Doppler echocardiographic imaging although the “volume amount” of regurgitation may be calculated using phase-encoded velocity techniques alone or in combination with cine CMR techniques as noted below. Similarly, valvar stenosis may be detected using cine CMR, and peak velocities may be measured using phase-encoded velocity techniques. Caution must be used when using the signal void, as this can be made greater or smaller by manipulation of CMR parameters (such as the echo time); this is similar to echocardiography where the Nyquist limit and color Doppler gain (to name just a few parameters) may be manipulated to change the “aliasing” in the image.

Cine CMR is useful in many disease states in CHD. Postoperative ventricular performance is certainly a common application. Assessments of ventricular performance in patients with single ventricle, tetralogy of Fallot, and transposition of the great arteries are common referrals of cine CMR. Accurate assessment of regurgitant fraction in patients with left atrioventricular valve insufficiency in a postoperative endocardial cushion defect repair is another example. Visualization of dynamic obstruction to the left ventricular outflow tract in the older patient with transposition of the great arteries after an atrial inversion operation is also a useful application.

Phase-Encoded Velocity Mapping Uses

This technique makes use of phase information obtained at CMR to encode velocity (Figs. 73.5–73.7). This may be done in images perpendicular to flow or parallel to flow (see Figs. 73.5 and 73.6). In the images perpendicular to flow (e.g., obtaining a cross-sectional area of the vessel), summing all the velocities in each pixel in a given cross section of blood vessel and multiplying by the area of each pixel will yield flow at that given period of time. Summing all phases of the cardiac cycle will yield flow during one heartbeat. Multiplying by the heart rate will yield the cardiac output. As with cine CMR, most software on present day scanners can give a temporal resolution of up to 20 milliseconds. “Real time” velocity mapping, which can yield real-time flow measurements (i.e., flow vs. time, not just velocity vs. time as in echocardiography) is currently being tested. Cardiac output can be measured to assess ventricular function in such lesions as single ventricles or transposition of the great arteries after atrial inversion. Regurgitant fractions can be measured by simply placing a velocity map across a great vessel and measuring both forward and reverse flows. This would be important, for example, in a patient after tetralogy of Fallot repair with a transannular patch.

As with echocardiography, velocities obtained at CMR are useful to obtain a noninvasive estimate of the pressure using the Bernoulli equation (see above). Similarly, to obtain, for example, the amount of atrioventricular valve regurgitation, one needs only image perpendicular to the atrioventricular valve in systole to obtain volumetric data (as described above), although their can be fraught with error at times. Other alternative methods for the assessment of atrioventricular valve regurgitation are imaging perpendicular...
to the atrioventricular valve during dias-
tole (volumetric amount of inflow—see
Fig. 73.5) and perpendicular to the semi-
lunar valve during systole (volumetric
amount of outflow) and subtract outflow
from inflow to obtain the amount of regur-
gitation. In a similar vein, one can use a
combination of cine CMR techniques
(measure ventricular volume at end-
diastole and end-systole to obtain the total
amount of blood ejected by the ventricle)
and phase-encoded velocity mapping (the
amount of forward flow from the ventricle
to measure the volumetric amount of
regurgitation. Further, because CMR can
obtain velocities perpendicular to flow,
velocities in different regions of the blood
vessel at a given level may be obtained and
is used in fluid mechanics research of the
cardiovascular system.

Flow can be measured to different
organs or parts of organs. A Q/Q may
be obtained in patients with an atrial or
ventricular septal defect simply by placing
velocity maps across the aorta and pulmo-

nary arteries (Fig. 73.6). Internal checks
are used to validate the data (i.e., flow in
the branch pulmonary arteries should sum
to the main pulmonary artery and
flow in the cavae should sum to the flow
in the aorta in the absence of aortic to
pulmonary collaterals). Cerebral blood
flow can be measured by velocity mapping
across the jugular veins. Right and left
pulmonary blood flow can be measured by
placing velocity maps across the right and
left pulmonary arteries, respectively, and
the same information as a nuclear scan
can be obtained. This is useful in patients
with single ventricles, for example, or with
tetralogy of Fallot.

Four-dimensional flow (Fig. 73.7) has
began to play an important role and
multiple studies are being published in the
literature on this.

Myocardial Tissue and
Blood Tagging

A unique ability of CMR is to magnetically
tag tissue or blood (Fig. 73.4). This makes
use of cine CMR in combination with a
special technique, which destroys all the
spins in a given plane (resulting in a line
of signal void). The result is “slicing up” the
myocardium into “cubes of magnetization”
or labeling (with a signal void from it and
hence a black line on the cine image) the
blood. Once the slicing into “cubes of mag-
netization” is performed at end-diastole,
images can be obtained as much as every
20 milliseconds and the distortion of these
cubes (in systole or diastole) allows for
calculation of regional strain, ejection frac-
tion, and wall motion (Fig. 73.4). Quali-
tatively, regional wall motion can also be
assessed and this can be used in instances
where there are questionable areas of con-
traction on cine imaging. This is similar to
speckle tracking in echocardiography;
however, these “cubes of magnetization”
are in full 2D in the image (across the entire
myocardial thickness), can “visualize” qual-
itatively the deformation, and can be made
into a 3D strain map.

In blood tagging, however, the more
useful technique is to tag prior to each
image (similar to myocardial tagging,
images can be obtained as much as every
20 milliseconds) and cardiac index can be
calculated (although this has largely been
supplanted by phase-encoded velocity
mapping) and velocity profiles can be visu-
alized (Fig. 73.8). This can also be used for
shunt detection (e.g., isolation of atrial
septal defects, e.g., see Fig. 73.8). As with
phase-encoded velocity mapping, indi-
vidual regions of the blood vessel may be
isolated to evaluate for flow dynamics. It
may also be useful for measuring forward
flow (cardiac index) for valvular regurgita-
tion calculations (see above).

Myocardial Perfusion

Regional myocardial perfusion is an
important parameter in the assessment of
the myocardium in adults, and this plays
an important role in pediatrics and CHD as
well (Figs. 73.10 and 73.11). Manipulation
of the coronaries in diseases stated above
such as transposition of the great arteries
repair or the Ross procedure can lead to
perfusion abnormalities. Anomalies of the
coronaries such as in anomalous origin of
the left coronary artery from the pulmo-
nary artery or in hypoplastic left heart syn-
drome can also lead to perfusion defects.
Regional wall motion abnormalities, for
example, may be caused by a lack of blood
supply to a certain region of the myocar-
dium. CMR, utilizing gadolinium enhance-
ment, has the ability to assess regional wall
perfusion by using a “first pass” injection
technique. Typically, short-axis views of
the ventricle as described in the cine CMR
section are obtained and the sequence set
up is such that the heart is imaged rela-
tively motionless in diastole. Gadolinium
is injected intravenously while the CMR
scanner continuously images the ventri-
cle (up to 4 to 5 short-axis slices may be
imaged at once), and the gadolinium bolus
is followed from right ventricular cavity to
left ventricular cavity to ventricular myo-
cardium. Defects in perfusion show up as
dark portions of the myocardium while the
rest of the ventricle is signal intense. This
is typically performed with and without
an adenosine infusion and then followed 5
to 10 minutes later with delayed enhance-
ment imaging.

Other Uses of Cardiac Magnetic
Resonance for Ventricular
Function/Physiology

Time-resolved 3D gadolinium imaging
(Fig. 73.2), since temporal information is
embedded in the technique, can be uti-
ized to determine regional lung perfusion
(e.g., no blood flow to the right upper lobe
because of a pulmonary embolus) or to
determine stenotic versus atretic vessels
(e.g., continuity or discontinuity of the
branch pulmonary arteries). Newer tech-
niques such as exercise CMR is useful in
patients with tetralogy of Fallot which is
a disease state known to have decreased
exercise performance. Functional fetal
CMR may be used to determine ventricu-
lar volumes in the fetus with just recently
developed techniques enabling the evalu-
ation of fetal blood flow. XMR is being
used on a research basis not only to per-
form interventions in the CMR suite but
also to determine lung compliance and
plot ventricular pressure–volume loops
(see below).

Surgical Planning
AND CARDIAC MAGNETIC
RESONANCE

By virtue of obtaining and combining anat-
omy, physiology, and function, CMR can
be utilized to perform surgical planning in
a couple of ways—not solely by “showing”
the cardiac defect to the surgeon but by
actually performing “virtual” surgery and
predicting outcome. In addition, with the
advent of rapid prototyping and 3D print-
ing (Fig. 73.12), a 3D “physical model” of
the heart and a proposed surgery can be
created; the surgeon and cardiologist can
litera-

ly hold the heart of the patient in his/her
hand prior to surgery and actually create a
baffle or conduit to see how it looks. This
has obvious utility in making efficient use
of cardiopulmonary bypass and deep hypo-
thermic circulatory arrest times as well as
optimizing potential results.

Surgical Planning: Single-
vs. Double-Ventricle Repair

Not infrequently, neonates are born with
two ventricles where the suitability of

Chapter 73: Cardiac Magnetic Resonance in Congenital Heart Disease 735
separating the circulations with two pumping chambers is questioned (Fig. 73.18). The left (LV) or right ventricles (RV) may be borderline in size before surgery or after baffle creation. In a patient with double outlet right ventricle, a baffle placed between the ventricular septal defect to the aorta to direct LV blood to the systemic circulation may substantially decrease the right ventricular size below the limits of tolerability. The baffle may not even be feasible if atrioventricular valve chordal attachments are in the way. By utilizing a stack of cine SSFP images of both ventricles, a “virtual” baffle can be created and the ventricular volumes, ejection fraction, and cardiac index assessed; phase-encoded velocity mapping is used as a check on these data. If the cardiac index, end-diastolic volume, or ejection fraction from a ventricle are unacceptably low with the “virtual” baffle, a double-ventricle repair may not be feasible and the patient may progress toward the single-ventricle Fontan pathway. It is true that loading conditions postoperatively may change these parameters, however; quantitative preoperative information may be a better gauge to predicting clinical outcome than the current “eyeball” method currently in use preoperatively.

**Surgical Planning—Computational Fluid Dynamics and Modeling**

Work performed with Ajit Yoganathan and the bioengineering department at The Georgia Institute of Technology. The Navier-Stokes equations are the fundamental equations that govern fluid flow in the cardiovascular system (Figs. 73.19 and 73.20). By obtaining the geometry of blood vessels, baffles, conduits, and so on in conjunction with 2D or 3D flows at the inlets and outlets of these structures, assessment and visualization of the flows, streamlines, and power can be obtained by applying these mathematical formulae, hence, the term “computational” in the fluid dynamic part. The combination of phase-contrast velocity mapping and static SSFP imaging by CMR allows for just such computations. This has been mostly applied to modeling of the systemic venous (Fontan) pathway of single ventricles but has found application in other diseases such as coarctation of the aorta and tetralogy of Fallot. A number of investigations in single ventricle patients after Fontan have demonstrated the degree of “power loss” in the systemic venous pathway and the effect of geometry and flows on this. In addition, streamlines can be calculated and relative contributions of caval blood to the branch pulmonary arteries can be accurately assessed. This approach not only can evaluate the present status of the circulation in vivo but can also assess various structural modifications of the cardiovascular system that the surgeon or interventional cardiologist might perform. One study, published a few years ago, assessed the effect of LPA stenosis on flow and power loss in single ventricles; this was followed by a "virtual

---

**Fig. 73.18.** Single- versus double-ventricle repair: In patients where a baffle needs to be created by the surgeon, a "virtual” baffle can be created from the cardiac magnetic resonance images and quantitative data can be obtained to estimate whether the ventricles are of adequate size. The patient is 3-year old with double outlet right ventricle (SLL) with a ventricular septal defect, pulmonic stenosis, and Ebstein’s anomaly. The four-chamber view and short-axis cine images are in the upper left and upper middle panels, respectively. To repair this, the surgeon would baffle the ventricular septal defect to the aorta (upper right image with baffle drawn in red). The three-dimensional images of the ventricles before baffle creation (lower left and middle panels) and after baffle (B) creation (lower right panel) are shown. End-diastolic volumes, stroke volume, ejection fraction, and cardiac index are then calculated to determine if this approach is feasible.
angioplasty” and a reassessment of flow and power loss when the stenosis was removed. Other studies have looked at etiologies for the development of pulmonary arterial venous malformations (lack of streaming of hepatic venous blood to a lung) with possible alterations of the geometry to correct this (see below) while still other studies have investigated power loss in the systemic venous pathway during exercise.

With this notion, the idea that a surgeon, a cardiologist, or an engineer can create “virtual” systemic venous baffles and assess the effect of flow and power loss in various geometries has been implemented in select patients. One clinical application is the single ventricle heterotaxy patient with an interrupted inferior vena cava (IVC) with azygous continuation. A Kawashima operation and hepatic venous baffle with left-sided pulmonary arteriovenous malformations. In this figure, inferior vena cava (IVC) is used to signify hepatic venous blood and not IVC blood. Cardiac magnetic resonance derived anatomy of the systemic venous pathway alone (top left) and with the cardiac mass and aorta in place (lower left) is shown. The image on the right demonstrates the streamlines showing how much IVC blood gets to each one. Data are labeled and suggest why left lung arteriovenous malformations occurred; little hepatic flow gets to that lung. Figures are created in conjunction with Dr. Ajit Yoganathan and the bioengineering department at the Georgia Institute of Technology. CO, cardiac output; innominate, truly left superior vena cava; LPA, left pulmonary artery; RPA, right pulmonary artery; SVC, superior vena cava.

Kawashima who has yet to have a hepatic baffle placed; three options with their data are presented both visually and quantitatively.

Still in another application, Whitehead et al. utilized CFD in Fontan patients to determine the etiology for decreased exercise performance. With 10 patients of various systemic venous pathway geometries and various flow splits to the branch pulmonary arteries, the cardiac output was increased to two and three times baseline and power loss and flow profiles determined. They found a “dramatic increase in a non-linear fashion” of increasing power loss in the baffle, even when normalized for various parameters. One reason was an increase in the collision of flows between superior and IVC blood. A “resistance index” that takes into account resistance to flow increased during the increasing exercise simulations to such levels that exercise limitation was almost a certainty with pressure drops across the baffle at exercise becoming nonphysiologic (up to 52 mmHg) and therefore unachievable. The work showed the importance of CFD calculations and the possibility of designing various Fontan geometries, which might minimize the exercise limitation.

X-RAY MAGNETIC RESONANCE

Traditional fluoroscopically guided cardiac catheterization in CHD is sufficient to guide catheterization procedures with good results. However, fluoroscopy requires the use of ionizing radiation, has poor soft tissue definition, and only provides 2D projections of complex 3D anatomy. As interventional procedures have become more complex, it is becoming apparent that in many instances, this imaging modality is suboptimal. A different approach to image-guided interventional procedures is to perform the procedures inside the MRI scanner with real-time magnetic resonance imaging (rtMRI) for guidance. While this strategy has promise, certain technical issues, such as the lack of MRI compatible wires and catheters and difficulties with catheter tracking, have limited the current use of this modality although it is currently an active area of research.

Multiple types of cardiac interventions have been successfully performed in the cardiac MRI suite on a research basis. Utilizing XMR to perform electrophysiologic ablations has a special appeal; beside the anatomic capabilities of CMR to be used as a roadmap to place catheters for performing the procedure, the myocardial disruption caused by radiofrequency

![Fig. 73.19. Surgical planning—original anatomy and physiology of single ventricle after Kawashima and hepatic baffle: The patient is a single ventricle patient with interrupted inferior vena cava and azygous continuation after Kawashima operation and hepatic venous baffle with left-sided pulmonary arteriovenous malformations. In this figure, inferior vena cava (IVC) is used to signify hepatic venous blood and not IVC blood. Cardiac magnetic resonance derived anatomy of the systemic venous pathway alone (top left) and with the cardiac mass and aorta in place (lower left) is shown. The image on the right demonstrates the streamlines showing how much IVC blood gets to each one. Data are labeled and suggest why left lung arteriovenous malformations occurred; little hepatic flow gets to that lung. Figures are created in conjunction with Dr. Ajit Yoganathan and the bioengineering department at the Georgia Institute of Technology. energy can actually be visualized—on T1 imaging, the myocardium will turn from a “gray” signal to a “white” signal in a matter of minutes. If a line of scar tissue needs to be created to prevent an arrhythmia, this capability can be used to ensure the line is continuous and no breaks are present that might allow an impulse to pass.

Other interventions solely in the cardiac MRI suite include such procedures as stent placement (e.g., for coarctation), balloon dilation of stenotic branch pulmonary arteries, or valves and creation of atrial septal defects via either balloon or laser (Fig. 73.23). Further, additional physiologic and diagnostic information can be obtained by using a combination of pressure measurements with invasive catheters (either placed in the catheter lab and moved to the CMR suite or placed in the CMR suite itself) and flows of ventricular volumes by CMR simultaneously or near simultaneously. For example, pressure-volume loops or pulmonary arterial impedance can be obtained in this manner; this is an on-going active area of research.

An alternative to exclusive rtMRI-guided interventions or fluoroscopy only guided interventions is to use a hybrid approach where 3D data sets from either CT, rotational angiography, or MRI are fused to the X-ray images to provide the additional information needed while still taking advantage of the good spatial and temporal resolution offered by conventional fluoroscopy (Figs. 73.24–73.26). Fusion of CT and rotational angiography images has been reported in a number of EP studies. Registration is the process of accurately overlaying one imaging technique over the other. Registration of CT and rotational angiography to X-ray images has been reported in neurological interventions; however, this method requires significant radiation and can require a significant contrast load, which makes this modality suboptimal for interventions in children.

Fiducial marker-based registration has been shown to be accurate to high spatial resolution under certain conditions, but this method has several drawbacks. First, it requires that the MRI scan and catheterization procedure occur successively as the markers need to remain attached during both procedures. Second, skin mobility and movement of internal organs relative to the skin can make this method inaccurate. Third, the need to include the markers in the MRI images requires a larger scanned volume increasing imaging time and could result in reduced imaging resolution. Lastly, fiducial marker-based registration requires propriety software.
Chapter 73: Cardiac Magnetic Resonance in Congenital Heart Disease

Fig. 73.21. Surgical planning—computational fluid dynamic modeling for the top left option of this figure. The three rows are different global flow distributions of blood to the left pulmonary artery (LPA): 72% on top (initial conditions from the original cardiac magnetic resonance derived data from Fig. 73.19), 60% in the middle, and 50% on the bottom. The left-most column demonstrates the calculated pressure drop (color coded), the middle column demonstrates the global flow distribution (color coded), and the right-most column demonstrates just hepatic flow to each branch pulmonary artery (color coded). Legends for the color code are on the bottom row. Figures are created in conjunction with Dr. Ajit Yoganathan and the bioengineering department at the Georgia Institute of Technology. CO, cardiac output; Innominate, truly left superior vena cava; IVC, hepatic blood flow; LPA, left pulmonary artery; PL, power loss; RPA, right pulmonary artery.

Fig. 73.22. Surgical planning—computation fluid dynamic modeling for a single ventricle patient after Kawashima prior to hepatic baffle creation: Original three-dimensional model from cardiac magnetic resonance is shown on the left panel. The three rightward upper panels show three of the multiple anatomic options considered, while the images below show the streamlines. Data for each option (Op) are listed at the bottom of the figure. Figures are created in conjunction with Dr. Ajit Yoganathan and the bioengineering department at the Georgia Institute of Technology. GFD, global flow distribution; LPA, left pulmonary artery; %, percent.
Section III: Congenital Cardiac Surgery

Fig. 73.23. X-ray magnetic resonance (XMR)—intervention in the CMR suite: (A) The top three panels are real-time CMR images of advancing a stent mounted on a catheter in the aorta and then deploying the stent; images progress chronologically from left to right. In the top left panel, the catheter (C) in green is in the distal descending aorta (Ao). In the top middle panel, the C is advanced to the isthmus and in the top right panel, the balloon is inflated and the stent deployed. (B) The lower three panels are real-time cardiac magnetic resonance images of advancing a needle catheter across the atrial septum to create an interatrial communication. In the lower left panel, the needle (N) in green is in the right atrium (RA) and is abutting the atrial septum (AS). In the lower middle panel, the N is advanced across the AS and in the lower right panel, the needle is now in the left atrium (LA). Images are courtesy of Dr. Robert Lederman of the National Institutes of Health.

Fig. 73.24. This figure shows the anterior-posterior (AP) and lateral view as seen after the three-dimensional magnetic resonance imaging volume is fused to the fluoroscopy image in a patient with a superior cavo-pulmonary circuit and a stent in the proximal anatomic right pulmonary artery.
Fig. 73.25. This figure depicts X-ray magnetic resonance fusion to heart and vessel borders using volume-rendered MRI (VRT) image (B) and maximal intensity projection (MIP)-rendered image showing the largest cross section of the heart and great vessels (C). In (A), the dashed line traces the heart border and the left lateral border of the aorta on the X-ray image. (D) and (E) show the registered VRT and MIP images. All images are in the AP projection.

Fig. 73.26. This figure demonstrates the examples of internal marker-based registration. (A) and (B) depict XMRF to imaging artifact from sternal wires that resulted in indents on a RV-PA conduit. In (C) and (D) susceptibility artifact from a stent produced a gap in the MRI image of the LPA in a patient with a Glenn shunt. The inset in image (D) shows a close-up view of the stent registered between the two PA stumps. (E) and (F) depict registration to distal conduit calcification. The arrow in (E) points toward a ring of calcification that formed at the distal end of a RV-PA conduit. All images are in the AP projection.
that is not currently commercially available. A different approach is to use internal markers for the registration process (Fig. 73.26). This approach is potentially more accurate and overcomes some of the limitations of fiducial marker-based registration. Dori et al. have reported on an X-ray magnetic resonance fusion (XMRF) method to internal markers that can be performed quickly, with minimal radiation, without the need for contrast, and with high accuracy (Fig. 73.26). In addition, they have demonstrated the initial use of this modality in CHD interventions.

Internal marker-based registration offers several advantages over fiducial marker-based registration. Internal markers are inherently more stable. They allow for easy correction of patient motion and they do not interfere with contrast angiograms. Furthermore, internal marker-based registration alleviates the constraint imposed by fiducial marker-based registration, namely, the need to perform the MRI and the catheterization successively. The choice of internal marker depends on marker visualization in both modalities and the specific application. In CHD, catheterization registration to the heart and vessel borders is simple and in most cases sufficient to guide the procedure (Fig. 73.25). However, in some instances when the heart and vessel borders are not clearly visible, for example, in the presence of significant pulmonary edema or a pericardial effusion, or when there is a more distinct marker, other markers such as airways, bone, stents, devices, and calcification can be used (Fig. 73.26).

XMRF allows for roadmapping without the need for contrast load (Fig. 73.27). Furthermore, since MRI contrast angiograms provide 3D volume data of the entire circulatory system, roadmaps of an entire procedure can be created and stored as bookmarks prior to the start of the case. This offers a distinct advantage in certain cases because contrast is known to significantly affect hemodynamics. Furthermore, this has the potential to save time, reduce radiation exposure, and contrast load. An example of how XMRF was used for roadmapping is depicted in Figure 73.27. Whole volume-rendered images and images that were cut to delineate certain structures were utilized for this purpose (Fig. 73.27A–73.27C). The figure shows the heart of a patient with a small right ventricle-to-pulmonary artery conduit and LPA stenosis. A coronal cut-plane was created prior to the catheterization and used as a roadmap for navigation from the IVC to the conduit (Fig. 73.27B and 73.27E). After entering the conduit, an oblique cut-plane showing the LPA was loaded and used as a roadmap to enter the LPA (Fig. 73.27C and 73.27F).

There are two limitations to this roadmapping modality that need to be considered. First, the spatial resolution of MRI is on the order of 1 millimeter making contrast injections necessary for roadmapping in very small vessels. Second, the presence of stiff wires or catheters can alter the local geometry of vessels rendering the registration inaccurate. Lastly, dynamic errors due to respiration and heart motion also can influence registration accuracy and need to be taken into account. Consequently, although device positioning with fused images is possible in most cases, local hand injections are needed for final confirmation of device position prior to deployment.

In addition to roadmapping, the MRI data in the catheter lab can be used for procedure planning including preliminary device sizing, camera angle selection (Fig. 73.28), and hemodynamic and...
When the camera is at the desired angle, the visualization using the 3D MRI data prior to multiple heart cycles and other imaging panning to the desired camera angles. There is nothing on the fluoroscopy image the procedure allowing for optimal camera angles. The anatomy is shown in the conventional camera angles (A, B, E, and F) and in the angle that was chosen for the contrast angiogram (C) and (G). The corresponding contrast angiograms are shown in (D) and (H).

Camera angle selection is an important utility of MRI volume data sets and XMRF (Fig. 73.28). This is especially true in CHD interventions, where complex 3D anatomy is often encountered. Complex 3D vessel anatomy visualization with fluoroscopy often requires repeated angiograms to fully delineate the anatomy. This is essentially eliminated with this new technology as the anatomy at the different angles can be visualized using the 3D MRI data prior to the procedure allowing for optimal camera angle selection, which can be entered into the C-arm control system for automatic panning to the desired camera angles. When the camera is at the desired angle, the fused image can then be used to assure that there is nothing on the fluoroscopy image that could interfere with the angiogram and to confirm that the chosen angle produced the desired result. In addition, XMRF allows for continuous visualization of the region of interest throughout the catheterization procedure. The 3D map follows the C-arm and the table such that optimal visualization of the region of interest can always be maintained. An example of how camera angle is selected to visualize a complex pulmonary artery anatomy is shown in Figure 73.28.

Clearly, 3D MRI has had a significant impact on the way in which CHD is diagnosed and managed (Figs. 73.24–73.28). Although it is customary to acquire 3D MRI data on many patients with CHD for a variety of clinical indications, the ways in which these data can be used to reduce catheterization time, radiation exposure, and contrast load are under investigation. We have recently reviewed data from our institution of 15 patients who had a purely diagnostic pre-Fontan catheterization in 2010. Seven of the patients had a cardiac catheterization following an MRI evaluation. We compared radiation exposure, contrast load, and catheterization time with the remaining eight patients who underwent a complete diagnostic pre-Fontan catheterization during the same time period without an accompanying MRI. Table 73.2 summarizes the results of a comparison between the two groups. In this small cohort of patients undergoing diagnostic pre-Fontan catheterization, we have been able to show that if the data from a precatheterization MRI are utilized correctly, this can significantly reduce radiation exposure while providing the needed diagnostic information. For this study, we chose patients undergoing a diagnostic pre-Fontan catheterization because the uniformity of this catheterization makes comparison of these patients simpler. Patients who had an interventional procedure were excluded from the study because the heterogeneity in intervention types, lengths, and complexity would make it difficult to compare these patients.

In addition to reduction in radiation, we also found that utilization of the MRI data significantly reduced catheterization time and exposure to contrast compared with subjects receiving a standard diagnostic pre-Fontan catheterization without accompanying MRI. The reduction in contrast exposure is almost certainly a direct effect of the decreased need to perform cine angiograms, as anatomic information is obtained by MRI. The reduction in radiation exposure is likely due to the combined beneficial effects of a decreased total catheterization time and a decreased number of cine angiograms performed (where a disproportionate amount of radiation exposure occurs). Although in the MRI group, the total fluoroscopy time is lower than in
the control cases, this difference did not reach statistical significance. A more significant difference in the total fluoroscopy times will likely be seen in cases where more complex cardiovascular anatomy increases the utility of XMRF and roadmapping.

Although this study looked only at one specific group of patients, it seems quite likely that extending this strategy to many others will result in similar benefits. In any circumstance, obtaining at least some of the required diagnostic information by MRI prior to catheter entry will decrease the time needed for the catheterization, with resultant decrease in contrast and radiation exposure. Furthermore, beyond the simple matter of reducing the time a patient spends under the fluoroscopy cameras, XMRF may allow for catheter manipulation to be performed at very low fluoroscopy pulse rates, further lowering radiation exposure.

It is likely that multimodality imaging techniques including MRI will significantly alter the way we perform catheterization procedures in the future. This new technology where 3D imaging data can be incorporated into live fluoroscopy images holds great promise to improve catheterization outcomes and reduce radiation exposure. Further studies into the effect of MRI and XMRF on catheterization outcomes are currently underway in our institution.

### PARTING THOUGHTS

CMR has advanced considerably in the last 30 years and the next 30 years holds even more promise for additional capabilities to come on line. It is gaining widespread use but clearly, there is a long way to go. It is an extremely useful and complementary technique to other imaging modalities and has supplanted some to become the gold standard. Recognition of this fact should play a role in practicing 21st century medicine.

Cardiac MRI imaging has become extremely sophisticated, and with new techniques, much additional hemodynamic information can be added to the morphologic information from MRI scanning. In addition, the ability to threedimensionally reconstruct MRI images has provided a very useful anatomic description of cardiac anomalies, including abnormalities of the aortic arches and vascular rings. The MRI scan is now the most useful imaging modality for evaluation of these lesions, and barium swallow determinations are now most commonly used as screening modalities. The ability to assess not only great vessel anatomy but also airway and esophageal anatomy by MRI has distinct advantages in assessment in these patients. In addition, assessing abnormalities of chest wall anatomy may be useful in determining whether simple division of vascular rings or more complex vascular reconstruction or aortopexies may be necessary to completely relieve obstruction.

One of the greatest limitations to cardiac MRI is the fact that it is somewhat cumbersome in the management of very small infants, who require anesthesia to prevent motion during the scans. The limits of resolution of the scans also are important for imaging in very small children, although technology is improving rapidly in this area. Nevertheless, the unique ability of MRI to create threedimensional images of cardiac anatomy with associated images of blood flow and ventricular function, make hemodynamic evaluations of ejection fraction and blood flow velocity, and assess regurgitant volumes, is making this modality an increasingly important tool in the assessment of congenital heart disease.

Recently, fast multislice computed tomography angiography has been added to MRI as a good modality for threedimensional reconstruction of vascular images in children with congenital heart disease. This technique has the advantage of very rapid acquisition times, making anesthesia less important. An additional advantage is excellent resolution even in relatively small children and the ability to evaluate the airways, including the possibility of virtual bronchoscopy. A disadvantage of this technique is the relatively large radiation dose necessary to acquire the images, and this concern has significantly limited its use.

As noted by Dr. Fogel in this chapter cardiac MRI is becoming increasingly used as the primary imaging modality in congenital heart disease. The images being obtained today are of superior quality to those of only a few years ago and increasing hemodynamic and flow distribution images have been obtained, which now make echocardiographic studies and cardiac catheterization studies less and less important. One might argue that cardiac MRI will become the primary imaging modality and echocardiography will be used primarily as a surveillance tool in Cardiac Intensive Care Units or for initial screening examinations. The ability to calculate cardiac shunts and cardiac valve regurgitant volumes in addition to assessing ventricular function and flow distributions in vessels along with cardiac output and shunt calculations has made cardiac MRI virtually supplant hemodynamic cardiac catheterization except in rare cases where pulmonary vascular resistance needs to be calculated. The combined use of cardiac catheterization and cardiac MRI as has been done in our center permits the possibility to define cardiac anatomy and pulmonary flow distribution and assess collateral pulmonary blood flow with subsequent intervention to eliminate extra sources of pulmonary blood flow or shunts, and then recalculate the remaining shunt flows and distributions. In addition, cardiac MRI has become useful in preoperative planning in baffle reconstruction and complex single-ventricle repairs such as those with heterotaxy syndromes and systemic and pulmonary venous abnormalities. Defining the capabilities of, and indications for, the various imaging modalities now available to us in congenital heart surgery will be very important to prevent unnecessary duplication of imaging and to achieve the maximum possible information for surgical planning on our patients.

TLS
Advances in noninvasive imaging have done away with the need for preoperative cardiac catheterization in the management of many heart lesions. Thus, cardiac catheterization is not indicated prior to operative intervention for transposition of the great arteries, hypoplastic left heart syndrome (HLHS), truncus arteriosus, complete common atrioventricular canal defect, a simple paramembranous ventricular septal defect, or tetralogy of Fallot, unless particular concerns arise. This discussion of heart catheterization in children, therefore, focuses not on which lesions require a heart catheterization for a complete evaluation but rather what information is desired when it has been decided that a heart catheterization should be undertaken.

**BASIC PRINCIPLES OF HEMODYNAMIC EVALUATION**

Invasive hemodynamic assessment involves calculation of flows and resistances, shunt calculations, and measurement of pressure and flow gradients.

### Calculation of Flows

The simplest method of measuring flow is to use a thermodilution catheter. This method is a variation on the dye dilution method using temperature decrement to determine blood flow. However, the method is only applicable in the absence of intracardiac shunting when there is a mixing chamber between the proximal and distal ports. Since most children with congenital heart disease do have either right-to-left, left-to-right, or bidirectional shunting, thermodilution is not an appropriate method of determining cardiac output in these patients.

More often, the Fick principle is used for calculation of flow. The essence of the Fick principle is that flow can be calculated by the use of a measurable indicator, which is added or subtracted at a known rate. In practice, the indicator is oxygen.

\[
F = \text{unknown flow rate (ml/min)}
\]

\[
I_1, I_2 = \text{indicator concentrations (mg/ml) at the two ends of the flow pathway}
\]

\[
R = \text{rate at which indicator is added or subtracted (mg/min)}
\]

\[
F (ml/min) = R (mg/min)/I_2 - I_1 (mg/ml)
\]

In a hemodynamic study, the unknown flow rate is systemic or pulmonary blood flow, the indicator is oxygen, and the rate of change of the indicator is the oxygen consumption. Oxygen content is determined by multiplying the hemoglobin concentration times the spectrophotometrically measured percentage of oxygen saturation of hemoglobin; dissolved oxygen must be included in the calculation when patients receive supplemental oxygen. Oxygen consumption is either measured or assumed on the basis of age and heart rate, using standardized tables. The equation for calculation of pulmonary blood flow is as follows:

\[
Q_p = \frac{O_2 \text{ consumption}}{(\text{pulmonary vein } O_2 \text{ content} - \text{pulmonary artery } O_2 \text{ content})}
\]

and the equation for calculation of systemic blood flow is as follows:

\[
Q_s = \frac{O_2 \text{ consumption}}{(\text{aortic } O_2 \text{ content} - \text{venous } O_2 \text{ content})}
\]

**Effective flow** describes the quantity of deoxygenated blood that flows through the pulmonary circuit, which is also equal to the volume of oxygenated blood that flows through the systemic circuit. Effective equals effective and is calculated by taking the difference between the mixed systemic and pulmonary venous oxygen content and dividing that into the oxygen consumption:

\[
Q_{eff} = \frac{O_2 \text{ consumption}}{(\text{pulmonary venous } O_2 \text{ content} - \text{mixed venous } O_2 \text{ content})}
\]

### Calculation of Shunts

Shunt flow can be thought of as the ineffective flow in the system: the left-to-right shunt is the volume of oxygenated blood flowing through the lungs and is equal to the total pulmonary flow minus the effective pulmonary flow \((Q_p - Q_{eff})\). The right-to-left shunt is the volume of deoxygenated blood flowing through the systemic circulation and is equal to the total systemic flow minus the effective systemic flow \((Q_s - Q_{eff})\).

Because of the great variation in size among pediatric patients, flows are always indexed to body surface area.

### Calculation of Resistance

Resistance is the change in mean pressure divided by the flow. Thus, pulmonary vascular resistance \((R_p)\) is the difference between the pulmonary venous and pulmonary arterial pressures divided by the total pulmonary flow.

\[
R_p = \frac{(\text{mean pulmonary vein pressure} - \text{mean pulmonary arterial pressure})}{Q_p}
\]

and the systemic vascular resistance is the difference between the systemic arterial and right arterial pressures divided by systemic flow.

\[
R_s = \frac{(\text{mean arterial pressure} - \text{mean right atrial pressure})}{Q_s}
\]

The resulting units, liters per minute per millimeters of mercury, are termed *Wood’s units*, after the cardiologist Paul Wood. As with flows, vascular resistance is indexed to body surface area in pediatric patients.

### Flow Gradients

In the cardiac catheterization laboratory, gradients across stenotic valves or vessels are generally measured as “peak-to-peak” gradients. This measurement is often inaccurately referred to as the PSEG or peak systolic ejection gradient. The peak-to-peak gradient is a different entity than the maximal instantaneous gradient that is estimated noninvasively by Doppler studies. Whether a gradient is expressed as peak-to-peak, maximal instantaneous gradient, or mean gradient, it is not a
meaningful number unless one has some idea of the amount of flow that is producing the gradient. For example, a patient with critical aortic stenosis who is in low cardiac output may have a relatively low measured gradient across a severely narrowed valve orifice.

**HEMODYNAMIC EVALUATION OF PATIENTS WITH A LEFT-TO-RIGHT SHUNT LESION**

Patients with left-to-right shunt lesions (ventricular septal defect, complete or partial common atrioventricular canal defect, patent ductus arteriosus [PDA]) undergo cardiac catheterization in order to address the following related questions:

1. What is the magnitude of the left-to-right shunt? Does it justify surgical repair?
2. What is the status of the pulmonary vascular bed? Is the pulmonary vascular resistance sufficiently low that a complete repair is possible?

**HEMODYNAMIC EVALUATION OF PATIENTS WITH A RIGHT-TO-LEFT SHUNT LESION**

In patients with right-to-left shunt lesions (critical pulmonary stenosis status post-surgical or transcatheter correction, pulmonary atresia with intact ventricular septum status postaortopulmonary shunt, Ebstein’s anomaly, tetralogy of Fallot with pulmonary atresia status postright ventricular outflow reconstruction with an open ventricular septal defect, single ventricle status postenfenestrated Fontan palliation), there is often some uncertainty as to the adequacy of the right heart or pulmonary vascular bed. Specifically, the question is whether one normal cardiac output can pass through the right heart with acceptable systemic venous and right ventricular pressures. If not, the presence of an atrial or ventricular level combination will often permit adequate cardiac output with acceptable hemodynamic values at the expense of oxygenation. Often, an attempt will be made to temporarily occlude the site of right-to-left shunting during the heart catheterization in order to assess the hemodynamic sequelae. Increased heart rate, increased systemic venous pressure, and decreased cardiac output with occlusion of an atrial level communication are all signs of right heart insufficiency.

**HEMODYNAMIC EVALUATION OF PATIENTS WITH COMPLETE MIXING LESIONS AND FUNCTIONAL SINGLE VENTRICLE**

Currently, the “ideal” surgical palliation for children with functional single ventricle lesions is the modified Fontan operation, with or without an atrial level right-to-left shunt. This type of surgical palliation requires that the pulmonary vascular resistance be low (<4 Wood’s units), as the separation of the circulations is accomplished by using the functional single ventricle to pump systemic blood flow, while pulmonary blood flow occurs passively across a pressure gradient. Early in life (i.e., in the first year), the goal of management is to provide adequate but limited pulmonary blood flow. In cases of functional single ventricle with pulmonic stenosis, no intervention may be needed in the first few months of life. More often, the desired hemodynamics will be achieved via placement of a pulmonary artery band or an aortopulmonary shunt. Typically, this arterial to pulmonary flow is altered to veno pulmonary flow by 6 months of age with a bidirectional cavopulmonary anastomosis (bidirectional Glenn or “hemi-Fontan” procedure). Completion Fontan procedure (total cavopulmonary anastomosis) is usually performed by 3 years of age. Traditionally, cardiac catheterization has been performed prior to the second and third stages of surgical palliation though the need for routine diagnostic catheterization at these times has been called into question. When diagnostic catheterization is performed prior to the Fontan operation, its purpose is to assess whether “Fontan physiology” will be well tolerated in a given patient. The important questions to be evaluated at cardiac catheterization include:

1. What is the pulmonary vascular resistance? Patients with pulmonary vascular resistance >3 to 4 Wood’s units are much more likely to manifest high central venous pressures and low cardiac output.
2. What is the pulmonary artery pressure? Elevated pulmonary artery pressure is not necessarily a contraindication to a modified Fontan operation provided that it is measured in the setting of elevated pulmonary blood flow. However, if the mean pulmonary artery pressure greater than about 15 mmHg in the setting of normal or diminished pulmonary blood flow bodes poorly for the outcome after conversion to Fontan physiology.
3. What is the ventricular filling pressure? After a modified Fontan operation, blood flows passively across the pulmonary vascular bed. The central venous pressure will, therefore, be determined by the ventricular filling pressure and the pulmonary vascular resistance. Elevated ventricular filling pressure may be present as a result of chronic volume overload or ventricular hypertrophy, the latter case in particular is associated with poor outcome after Fontan palliation.

**HEMODYNAMIC ASSESSMENT OF SEMILUNAR VALVE STENOSIS OR INSUFFICIENCY (WITHOUT SHUNT)**

**Pulmonary Valve**

The severity of pulmonary valve stenosis is graded according to the peak-to-peak gradient across the valve (trivial, <25 mmHg; mild, 25 to 49 mmHg; moderate, 50 to 79 mmHg; severe, >80 mmHg). In general, the presence of a peak-to-peak gradient of ≥40 mmHg is an indication for treatment. Pulmonary insufficiency is difficult to assess quantitatively in the cardiac catheterization laboratory. A ventricularized pulmonary artery tracing—that is, one in which the diastolic pressure approximates that of the right ventricle—indicates severe pulmonic insufficiency.

**Aortic Valve**

Although cardiologists will generally grade aortic stenosis in adults according to the calculated effective valve area, in the pediatric population indications for intervention are based on catheter-measured peak-to-peak systolic pressure gradients. Because gradients across a stenotic valve will vary depending on flow and heart rate, cardiac output, left ventricular function, and mitral and aortic valve insufficiency all must be evaluated to arrive at an accurate assessment of left ventricular outflow tract obstruction. Left ventricular outflow tract obstruction may be subvalvar, valvar, or supravalvar.

Aortic valve insufficiency is assessed in a semi-quantitative manner in the cardiac catheterization laboratory by angiography. A wide arterial pulse pressure not only may represent important aortic valve insufficiency but may also be seen with aggressive afterload reduction.
HEMODYNAMIC ASSESSMENT OF ATRIOVENTRICAL VALVE STENOSIS OR INSUFFICIENCY

Tricuspid Valve

Isolated tricuspid stenosis is extremely rare; more often, tricuspid stenosis is seen in the context of right heart hypoplasia and pulmonic stenosis or atresia. Tricuspid stenosis cannot be assessed in the presence of pulmonic atresia because there will be little or no flow across the tricuspid valve in these cases. The presence of a patent foramen ovale that allows right-to-left shunting or right ventricular diastolic dysfunction (both of which are common in right heart hypoplasia) makes assessment of the degree of tricuspid stenosis problematic. Complete evaluation requires balloon occlusion of the atrial communication and simultaneous measurement of right atrial and right ventricular pressures; this may not be technically feasible particularly in neonates and small infants (e.g., the atrial communication is too large to be occluded). However, the maneuver may be quite useful in evaluating right heart competency in older children noting any resultant changes in right atrial pressure, cardiac index, and heart rate with balloon occlusion.

Angiographic assessment of tricuspid insufficiency can be difficult because the catheter in the right ventricle of necessity crosses the tricuspid valve; if the catheter stents the valve open or if some of the holes of the catheter are in the right atrium at the time the injection is made, artifactual insufficiency will result. In addition, ectopic beats will often be associated with induced atrioventricular valve insufficiency.

Mitral Valve

Mitral stenosis is generally graded in terms of calculated valve area by cardiologists treating adults and in terms of anatomy and valve gradient by cardiologists treating children. Both the mean valve gradient (arrived at by digitizing the area between the left atrial or pulmonary artery wedge pressure tracing and the left ventricular pressure tracing during the period when the mitral valve [MV] is open) and the gradient between the a-wave and the left ventricular end-diastolic pressure as well as the absolute left atrial pressure are generally considered in assessing mitral stenosis. Because gradients are meaningful only when considered in association with flow, cardiac output must be assessed to appropriately interpret the severity of obstruction. A mean left atrial pressure >25 mmHg is generally associated with moderate-to-severe reactive pulmonary hypertension.

Mitral insufficiency is assessed in a semi-quantitative manner by angiography. This is more reliably accomplished than in the case of the tricuspid valve because the catheter with which the picture is taken usually does not cross the MV and the shape of the left ventricle is such that it accommodates a catheter more easily than does the right. However, entanglement of the catheter in the MV apparatus or stimulation of ventricular premature contractions can result in induced mitral insufficiency.

TRANSCATHETER THERAPY FOR CONGENITAL HEART DISEASE

Introduction

Catheter-directed treatments have assumed a major role in the care of patients with congenital cardiovascular defects. These techniques have replaced surgery as the primary mode of therapy in some instances. In many others, optimal treatment combines staged transcatheter and surgical intervention. It is, therefore, essential that the congenital heart surgeon has a working knowledge of interventional cardiology. This section introduces current catheter interventions for patients with congenital cardiovascular defects, highlighting therapies particularly useful in combination with surgery.

Catheter interventions for congenital heart defects are quite varied, but in simplistic terms can be classified into: (1) procedures to create or enlarge communications and vessels (septostomies, dilations, and stents); (2) procedures to close vessels or defects (device closures, vascular occlusions); and (3) other (thrombectomy, vascular retrievals). Another commonly performed intervention, radiofrequency ablation, is more appropriately dealt with as part of a discussion of cardiac dysrhythmias.

Creation and Enlargement of Atrial Communications

Balloon atrial septostomy described in 1966 by Rashkind and Miller for palliation of cyanosis in D-transposition of the great arteries is often considered the first intervention for congenital heart defects. Even with the use of prostaglandin E1, many infants with transposition require septostomy procedures to ameliorate compromising cyanosis. The procedure is also performed to relieve left atrial hypertension in infants with left atrioventricular valve stenosis or atresia. The basic technique has changed little since first described. A septostomy catheter is advanced through either umbilical or femoral vein into the right atrium and across the foramen ovale. The balloon is filled with fluid and the catheter pulled quickly across the foramen tearing septum primum. Balloon septostomy is often performed at the bedside under echocardiographic guidance (Fig. 74.1).

In many situations, balloon septostomy is not the best way to create an atrial communication. Balloon septostomy is ineffective in patients over 6 weeks of age because the atrial septum is too thick. In most newborns with HLHS and restrictive or intact atrial septum, balloon septostomy is not feasible or ineffective because the left atrium is too small or posterior deviation of septum primum is present. In these populations, an atrial communication is best created by other means. The intact atrial septum may be traversed either by the standard transseptal puncture technique (Brockenbrough procedure), or with the aid of a specially designed radiofrequency perforation system (Nykanen Catheter, Baylis Medical Corp., Mississauga, ON). Once the atrial septum has been crossed, a hole may be created by static balloon angioplasty, or in the case of the very thick atrial septum, endovascular stent deployment. When the procedure is performed for relief of cyanosis in patients with mixing lesions and left atrial outlet obstruction (such as the newborn with HLHS born with intact atrial septum), the goal should be the creation of an unrestricted atrial communication. In other circumstances (i.e., augmentation of systemic blood flow in patients with right heart failure, or for left atrial decompression in patients on extracorporeal support for left heart dysfunction), smaller atrial communications suffice. In fact, when these techniques are used to palliate right heart failure (transient right ventricular dysfunction after repair of tetralogy of Fallot, or primary pulmonary hypertension, or fenestration creation for Fontan failure), the procedure results in systemic arterial desaturation; thus, the size of communication created must be carefully titrated to arterial oxygen saturation. The goal is to create a restrictive ASD to augment systemic output without excessive cyanosis. In tetralogy of Fallot or pulmonary hypertension patients, this is best accomplished by graded balloon angioplasty of the atrial septum. In Fontan patients requiring fenestration creation, the optimal strategy depends on the type of Fontan. It may include the use of standard or cutting balloon dilation (lateral
tunnel-type Fontan), or transseptal puncture followed by bare metal or covered stent deployment (extracardiac Fontan).

**Valve Repair and Replacement Procedures**

**Balloon Valvuloplasty**

Inflation balloon angioplasty was developed in 1974 by Gruntzig for the treatment of atherosclerotic peripheral arterial stenoses. Advances in equipment and technique have allowed the application of balloon dilation to a variety of valvar and vascular stenoses in patients of all ages.

**Pulmonic Valve Stenosis and Atresia**

The first congenital lesion treated with balloon dilation was pulmonic stenosis. Balloon valvuloplasty for pulmonic stenosis is usually curative and generally regarded as the treatment of choice in patients of all ages. In older children and adolescents, the procedure is straightforward. After hemodynamic evaluation, a right ventricular angiogram is performed to assess anatomy and measure the pulmonary annulus dimension. Dilation is accomplished by advancing the balloon catheter over a guide wire positioned in the distal pulmonary artery tree through the stenotic valve. The balloon size is chosen to be 120% to 140% of the annulus.
Fig. 74.2. (A) Lateral projection of a right ventriculogram in a newborn with critical pulmonary valve stenosis demonstrates doming of the stenotic pulmonary valve in systole. (B) Inflation of a balloon catheter across the stenotic pulmonary valve. A waist develops on the balloon during inflation and subsequently resolves (C). The guide wire crosses the patent ductus arteriosus and is positioned in the descending aorta.

diameter. As the balloon is inflated, the stenotic valve creates a waist, which then disappears. Failures may occur (1) if the pulmonary valve is thickened, nondoming, and often muscularized (so-called dysplastic valve common in Noonan’s syndrome) or (2) where valvar stenosis is part of complex obstruction involving infundibulum, valve annulus, or supravalvar region.

Dilation for critical pulmonary stenosis in the newborn is successful in the majority of cases (Fig. 74.2). Moderate cyanosis is common after dilation due to atrial right to left shunting. Cyanosis diminishes as right ventricular compliance improves. Severe cyanosis after valvuloplasty should prompt further evaluation. Where inadequate relief of right ventricular outflow obstruction is present after technically adequate balloon valve dilation, right ventricular outflow patch augmentation may be required, particularly when there is hypoplasia of the pulmonary annulus.

Balloon valvuloplasty is also applicable to newborns with pulmonary atresia and intact ventricular septum. Prior to intervention, these children require diagnostic evaluation to determine that the right ventricle and particularly the infundibulum are of adequate size as well as to rule out the presence of a right ventricular dependent coronary circulation. If an infant is deemed a suitable candidate, the pulmonary valve is perforated with a radiofrequency catheter (see above) and then dilated in the standard manner (Fig. 74.3). Patients undergoing this intervention very frequently develop cyanosis after discontinuation of prostaglandin infusion as the ductus arteriosus closes. If cyanosis occurs, management is individualized. In cases where the right ventricle is deemed well developed, the patient may be maintained on prostaglandins for a time to allow improvement in right ventricular compliance. If the right heart is more significantly hypoplastic, a stable source of additional pulmonary blood flow is added usually by stenting of the ductus arteriosus (Fig. 74.4).

Aortic Stenosis

All treatments for aortic stenosis, including surgical or balloon valvuloplasty, valve replacement, or pulmonary autograft (Ross procedure), should all be considered palliative. Balloon dilation of aortic stenosis generally results in adequate gradient relief with a minimal increase in aortic regurgitation. Reported failure rates vary from 0% to 10%, and significant increases in aortic regurgitation occur in approximately 10% of patients. The duration of successful palliation varies from months to decades though most (if not all) patients will subsequently develop restenosis, progressive regurgitation, or both. Intermediate term results after balloon and surgical valvuloplasty are comparable, thus balloon valvuloplasty is generally recommended as the first treatment for patients with aortic stenosis and little regurgitation. Except in the newborn, aortic valvuloplasty is usually performed via a retrograde approach from the femoral artery. After measurement of the transvalvar gradient, aortic root injection and ventriculography are performed for valve anatomy, degree of insufficiency, and annulus measurement. The valve is dilated by advancing the angioplasty balloon over a guide wire positioned in the left ventricle (Fig. 74.5). Balloon size is chosen to be slightly less than the diameter of the aortic valve annulus. The risk of significant aortic insufficiency increases when the balloon-to-annulus ratio exceeds 110%.

Special considerations apply to critical aortic stenosis in the newborn. This lesion has traditionally been very difficult to treat with high mortality. However, improvements in stratifying patients to appropriate treatment as well as in the treatments themselves have resulted in markedly decreased mortality. The approach to such patients is primarily dependent on left ventricular function and anatomy. When the left ventricle is inadequate to support systemic circulation, patients require treatment as HLHS. Several reports have established criteria for stratification of patients to biventricular repair versus single ventricle palliation. Balloon aortic valvuloplasty is the treatment of choice where left ventricular size (including MV, ventricular volume, and aortic valve sizes) and function are deemed adequate to support systemic circulation. When the left ventricular volume and MV are adequate but the aortic valve hypoplastic, primary Ross procedure may be the optimal strategy. After successful balloon valvuloplasty, ventricular function generally recovers enough to allow discontinuation of ventilatory and intravenous inotropic support within a few days. When this cannot be accomplished, either left ventricular outflow obstruction persists or left heart size and/or function are(s) inadequate. When left ventricular outflow obstruction persists despite a technically
Chapter 74: Hemodynamic Assessment and Transcatheter Therapy for Congenital Heart Disease

Fig. 74.3. (A) Anteroposterior projection of a right ventricular injection in a newborn demonstrates a tripartite right ventricle with a well-developed infundibulum and valvar pulmonary atresia. (B) A lateral view of the same injection. (C) A Nykanen catheter (arrow; Baylis Medical, ON) has been advanced through a guide catheter to the atretic valve, which has been perforated by the application of radiofrequency energy. (D) Subsequent balloon valvuloplasty. The arrows mark the location of the atretic valve. RF, radio frequency.

Fig. 74.4. (A) Lateral projection of a descending aortogram in a patient with pulmonary atresia with an intact ventricular septum following prior RF perforation and balloon valvuloplasty. There is significant constriction of the patent ductus arteriosus at the pulmonary end (white arrow), resulting in hypoxemia. (B) Deployment of a stent via balloon inflation results in unobstructed flow through the ductus (C) and therefore improved oxygenation. MPA, main pulmonary artery; PDA, patent ductus arteriosus.

Adequate balloon procedure, it is usually the result of annular hypoplasia and may be successfully treated by autograft root replacement. In the latter circumstance, an alternative surgical palliative strategy is the only approach likely to lead to long-term survival. This strategy may be a Norwood operation committing the patient to subsequent single ventricle palliation. Alternatively, a so-called hybrid procedure (see below) may be undertaken. After the hybrid approach, subsequent anatomic
Section III: Congenital Cardiac Surgery

**Fig. 74.5.** (A) A left ventriculogram in a patient with aortic stenosis demonstrates systolic doming of the aortic valve leaflets. (B) A valvuloplasty balloon advanced over a guidewire through the aortic annulus is inflated across the stenotic valve. A pacing catheter is placed in the right ventricle to permit rapid ventricular pacing, used to transiently reduce cardiac output and therefore facilitate stable balloon positioning. LV, left ventricular.

and physiologic evaluation is performed to determine whether the patient is best served with a single or biventricular approach.

**Other Valvular Lesions**

Balloon dilation has been applied to mitral, tricuspid, and bioprosthetic stenoses. In contrast to the excellent outcome after balloon dilation for rheumatic mitral stenosis, results after dilation in infants and children with congenital mitral stenosis are mixed and restenosis common. Nonetheless, balloon valvuloplasty is an appropriate first-line treatment in certain anatomic subtypes of congenital mitral stenosis because these lesions respond poorly to surgical valvuloplasty. Dilation may be reasonably attempted in patients with either “typical” congenital mitral stenosis or multiple orifice MV. Neither parachute MV nor supravalvar mitral ring should be dilated; in the former because success has never been demonstrated and in the latter because surgical therapy is clearly superior. While results after dilation of bioprosthetic valves have by and large been disappointing, percutaneous valve therapy has emerged as an effective treatment.

**Catheter-Based Valve Repair and Replacement**

Over the last decade, advances in catheter-based technology have resulted in new minimally invasive therapeutic options for pulmonary and aortic valve replacement, and for MV repair. These advances have transformed the treatment of valvular and structural heart disease for both pediatric and adult patients.

**Pulmonary Valve Replacement**

The era of percutaneous heart valve replacement began in the earnest following the first published report of percutaneous pulmonary valve replacement (PPVR) procedure using the Melody Valve (Medtronic, Inc., Minneapolis, MN) in September 2000. Since that time, there have been approximately 3,000 procedures performed worldwide using either the Melody or the SAPIEN (Edwards Lifesciences LLC, Irvine, CA) device. Both devices consist of balloon-expandable stents, with a valve mechanism sewn into the center (Fig. 74.6). At present, due to size limitations, PPVR is mostly limited to postoperative patients with preexisting RV–PA conduits and/or bioprosthetic valves. Alternative devices and strategies for PPVR in patients with dilated RV outflow tracts are in development and will likely play a major role in the management of postoperative pulmonary insufficiency in the years to come.

Figure 74.7 shows an example of a typical PPVR procedure using the Melody valve in a patient with a stenotic and insufficient RV–PA conduit. Through femoral or jugular venous access, conduit stenosis is usually alleviated first by placement of a bare metal stent, with subsequent implantation of the Melody valve through a 22F delivery system. Figure 74.8 shows an example of Melody valve implantation into a dysfunctional bioprosthetic valve.

The early and intermediate results of PPVR have been reported, with high success rates, low morbidity and mortality, and acceptable reintervention rates. However, procedural complications, including coronary artery compression and RV–PA conduit rupture, can be life threatening, and stent fractures following implantation are common, necessitating ongoing medical follow-up.

**Transcatheter Aortic Valve Implantation**

Transcatheter aortic valve implantation (TAVI) was first performed in 2002; since that time it has evolved into a routine procedure for symptomatic aortic stenosis performed in specialized centers around the world. First introduced as an alternative to medical treatment for elderly patients deemed too high-risk for standard surgical valve replacement, TAVI has subsequently been proven to be equivalent to surgery in respect to mortality rates in randomized prospective clinical trial in a standard-risk population (PARTNER and PARTNER 2). Currently, two TAVI devices are commercially available: the SAPIEN valve (Edwards Lifesciences LLC, Irvine, CA) and
the CoreValve (Medtronic, Inc., Minneapolis, MN) (Fig. 74.9).

The role of TAVI in younger patients and in those with congenital heart disease is still evolving with the experience thus far limited to small case series using off-label devices. Next-generation devices are on the horizon, which may expand the indications for TAVI into younger, healthier individuals, including those with congenital defects.

**Mitral Valve Repair Technology**

Improved understanding of the mechanisms of MV dysfunction, combined with advances in catheter-based technologies, has resulted in the rapid development of percutaneous mitral valve repair (PMVR) techniques over the last decade. All of these new technologies are designed to mimic well-established surgical MV repair principles. These include therapies aimed at the MV leaflets, the MV annulus, and at the subvalvular apparatus (chordae). The most successful PMVR device to date is the MitraClip device, which mimics the surgical Alfieri technique by bringing the anterior and posterior leaflets of the MV together, creating a “double-orifice” MV. This approach re-establishes leaflet coaptation, thereby reducing mitral regurgitation. The MitraClip has been shown to be noninferior to surgery in randomized clinical trial (EVEREST and EVEREST2). Other technologies, including percutaneous annuloplasty devices and artificial chordae, are in clinical or preclinical testing.

Despite the many promising catheter-based MV repair technologies under development, one-stage percutaneous MV replacement remains elusive. However, surgical (transapical or transatrial) and transcatheter MV replacement via valve-in-valve (VIV) and valve-in-ring (VIR) (Fig. 74.10) procedures using the SAPIEN and Melody valves have been published in both preclinical and clinical reports. This early experience underscores the potential of repurposing “failing” surgical hardware (bioprosthesis valves and annuloplasty rings) as “landing zones” for subsequent minimally invasive valve replacement.

**Balloon Angioplasty and Endovascular Stenting**

Balloon dilation has been used for over a decade to treat native and postoperative aortic, pulmonary artery, and venous obstructions. Balloon-expandable endovascular stents are used to treat pulmonary artery stenoses, venous obstructions, and aortic coarctation. In balloon angioplasty, the vessel is dilated to a diameter significantly greater than the expected final size. Relief of obstruction is generally due to intimal and medial disruption at the site of stenosis. Vascular integrity after successful angioplasty is dependent on an intact adventitia. As a general rule, dilation should not be performed within 6 weeks to 2 months after surgical dissection of the region.

**Aortic Arch Obstructions**

Balloon angioplasty for native coarctation and postsurgical recoarctation has similar results with residual gradients
of <20 mmHg in 80% to 90% of cases. Restenosis is more common after dilation of native coarctation, largely due to a particularly high rate of restenosis when dilation is performed in young infants. Balloon angioplasty is the treatment of choice for recoarctation of the aorta after previous surgical repair. Given the high restenosis rate after dilation, current data suggest that surgery is the optimal treatment for native coarctation in the very young infant. For native coarctation in older infants and children, dilation is an acceptable alternative to surgery. Endovascular stenting for coarctation is now a widely used form of therapy for both native and recurrent coarctation in older children and adults. The early and intermediate-term results of this form of therapy have been documented in several series with very high success rates. In most reported series complication rates are low but not insignificant; aneurysm formation may occur even late after intervention and necessitates follow-up with scheduled CT or MRI arch imaging. Aortic wall complications are more prevalent in patients with aortopathies (such as William and Turner syndromes) and older adults. Covered stent angioplasty is generally the recommended catheter-based treatment approach for such patients and results in acceptable short- and intermediate-term outcomes. Given the increased surgical risk in many such patients, transcatheter treatment is often the optimal strategy. Results of dilation for recoarctation after Norwood procedures for HLHS are comparable to those in simple recoarctation though risks tend to be higher.

**Branch Pulmonary Artery Stenosis**

Balloon angioplasty for pulmonary artery stenosis is successful in 80% of instances, when success is defined as an increase in vessel diameter of more than 50%. In patients with complex or multiple pulmonary artery narrowings, angioplasty procedures may be lengthy and challenging. Wires are positioned in the largest distal branches and dilations performed with short balloons to minimize risk of aneurysm formation. Potential vascular complications include perforation, aneurysm formation, dissection, or thrombosis. Mortality rates for the procedure may be as high as 0.5% to 1%. Patients require careful follow-up, as restenosis after successful dilation is not uncommon. Endovascular stenting has proven to be a very effective treatment for branch pulmonary artery obstruction. Stents are deployed on
angioplasty balloons advanced through long sheaths to the site of the stenosis (Fig. 74.11). Disadvantages of endovascular stenting include the need for redilation to accommodate growth, restenosis from neointima formation (most significant in small diameter stents), and prothrombotic potential of the foreign body (particularly in low flow vessels). In general, stents are most effective in the treatment of proximal branch pulmonary artery obstructions where it is rare for angioplasty alone to completely relieve vascular obstruction.

Branch pulmonary artery narrowings may occur in isolation. More commonly, these lesions occur in association with other defects, either congenitally (tetralogy of Fallot—particularly with pulmonary atresia, truncus arteriosus) or as a result of prior surgery (pulmonary artery banding, shunt procedures, and arterial switch operations). Treatment of these complex lesions often requires a combination of catheter and surgical intervention. Dilation in the early postoperative period and surgery early after dilation may both be risky. Thus, it is essential that balloon angioplasty and surgery be planned and staged to minimize such risks. Catheter intervention should nonetheless be considered for the occasional patient who develops signs of right heart failure immediately postoperatively due to previously unrecognized or inadequately treated pulmonary artery distortion. Endovascular stenting is the preferred transcatheter treatment in these patients as the risk of vascular disruption is lower than with angioplasty.

Complex branch pulmonary artery obstruction due to multiple stenoses in series and parallel remain among the most difficult problems in the care of children with congenital heart defects. Current therapy includes standard balloon angioplasty, cutting balloon angioplasty, and the use of stents. While stents usually result in the most complete resolution of stenoses, their use in more distal vessels is limited because of the risk of “jailing” multiple branching segmental arteries effectively reducing the arborization of an already compromised pulmonary artery tree. Cutting balloon angioplasty is more effective than the standard static balloon dilation, however, probably carries an increased risk of vessel wall injury.

**Systemic and Pulmonary Veins**

Balloon angioplasty or stent placement for systemic venous obstructions may be very effective and has been particularly useful in patients with systemic venous pathway obstruction after atrial switch operations and cavopulmonary connections. Treatment of pulmonary vein stenoses by angioplasty has generally been disappointing. Though dilation often results in initial angiographic and hemodynamic improvement, restenosis is rapid and inevitable. Endovascular stenting of pulmonary vein stenosis has been somewhat more successful but only in select patient groups. The duration of success depends on the underlying disorder. Thus, some patients with discrete obstruction of large normal pulmonary veins after previous procedures (usually older individuals after lung transplantation or repair of partially anomalous pulmonary venous return with anastomotic narrowing, or stenosis after radiofrequency ablation for atrial flutter) will have lasting improvement with
stenting. However, infants with pulmonary vein stenosis invariably develop restenosis either from neointimal proliferation within the stent or progressive vascular disease in the more peripheral pulmonary veins. There has been interest in the use of adjuvant therapy with systemic antimetabolites or drug-eluting stents in this disease, but the efficacy of these methods has yet to be demonstrated.

**Conduits and Shunts**

Endovascular stents can be very useful for relief of obstruction in surgical conduits and shunts. Progressive obstruction in conduit reconstruction of the right ventricular outflow tract is to be expected as infants grow. However, in many cases the process is accelerated due to external compression or shrinkage of homograft conduit from host inflammatory response. In these instances, the conduit can often be stented back to near its original diameter prolonging the life of the prosthesis. In younger patients, this technique finds its most useful application for the treatment of cyanosis due to conduit stenosis after the Sano modification of the Norwood operation (Fig. 74.12). In the older patient population, it is in use of the percutaneous valve for conduit failure as described previously.

The wide availability of coronary stents mounted on very low profile balloons allows treatment of surgical shunt obstruction or occlusion even in very small children (Fig. 74.13).

**Closure Procedures**

A variety of techniques have been developed for closure of vascular connections and intracardiac defects. The versatility of these techniques has allowed their use in a wide range of congenital lesions.

**Embolizations**

A variety of catheter techniques are available for vascular embolization in patients with congenital cardiovascular defects. These include metal coils, synthetic particles, and self-expanding controlled delivery nitinol plugs (Amplatzer Vascular Plug). After careful angiographic definition of vessel size and anatomy, the delivery catheter is advanced into the structure to be embolized. The type of delivery catheter varies from small microcatheters for delivery of particles or microcoils to large guide catheters or sheaths for deployment of vascular plugs. Under angiographic guidance the embolization device or material is then placed. The most common complication of transcatheter embolization is misplacement of the embolization material. While errant coils or plugs can usually be removed by transcatheter retrieval, this is not possible in the case of particles. Other less common complications include vascular injury at catheter entry site, hemolysis from partially occlusive devices, and endovascular infection.

Embolization is definitive therapy for some lesions. The technique has been widely

used for the treatment of persistent PDA (see below) and has proven efficacious in the treatment of coronary cameral fistulae. In addition, transcatheter embolization is often performed as part of staged intervention in patients with complex defects. Examples include for redundant aortopulmonary collateral arteries in tetralogy of Fallot with pulmonary atresia and previously placed surgical shunts in patients with multiple sources of pulmonary blood flow. Patients with single ventricle heart disease often undergo embolization procedures. This may be for persistent left superior vena cavae or other decompressing veins in patients undergoing bidirectional Glenn or Fontan procedures, or for the treatment of systemic to pulmonary collateral arteries. The indications for and efficacy of this procedure in the latter circumstance remain poorly defined. All patients with single ventricle heart disease develop systemic to pulmonary collateral artery formation. In some patients, these collaterals may result in a substantial volume load, accounting for over 50% of total pulmonary blood flow. Embolization seems to result in acute decrease in this flow but preliminary evidence suggests that the effect may not be durable. Further work is underway to clarify this issue.

A small percent of patients with a variety of congenital heart defects including tetralogy of Fallot, transposition of the great arteries, and single ventricle defects are plagued by recurrent hemoptysis often years after surgical therapy. Catheter embolization is the main treatment modality in this situation. Bronchoscopy may be useful in localizing the side and lobe where hemorrhage originates. Selective digital subtraction angiography is performed to identify potential sources of bleeding. Though it is exceedingly rare to visualize extravasation of contrast (active hemorrhage), candidate vessels are identified by their characteristic appearance. These are usually bronchial arteries. The vessels are occluded with particle emboli. Typically, multiple feeder vessels must be embolized (Fig. 74.14).

Device Closures
Devices designed for closure of defects including PDA, atrial septal defects, and ventricular septal defects have been developed and tested for almost 40 years. Many such devices are in routine clinical use and several others are in clinical trials. The majority of transcatheter device procedures are performed for closure of PDA or atrial communications: either typical secundum atrial septal defects or patent foramen ovale in patients with prior stroke. Device closure of PDA is well established in young children and adults, and recent advances have made it possible in infants as small as 2 kg (Fig. 74.15).

The most widely used device for closure of atrial defects is the Amplatzer Septal Occluder. This device has been in use in tens of thousands of cases worldwide. It is composed of a woven frame of superelastic nitinol in which have been sewn three disks of woven Dacron (Fig. 74.16). The device is attached via a microscrew to a delivery cable. The assembly is advanced through a delivery sheath, which has been positioned through the defect to be closed. It is then deployed such that it straddles the defect (Fig. 74.17). The Helex Septal Occluder is currently the only other available device approved in the United States for ASD closure (Fig. 74.18). This device is composed of a Goretex patch sewn onto a single helical strand of nitinol. When advanced out of its delivery catheter, the device forms two disks—one on each side of the atrial septum (Fig. 74.18). This device is easily repositioned and retrieved but is not suitable for large defects. The Amplatzer PFO Occluder and the Gore HELEX device have Humanitarian Device Exemptions for closure of patent foramen ovale in patients who have had strokes and failed anticoagulant therapy.

The majority of secundum atrial septal defects can be successfully closed by catheter-delivered devices. Typically, the

procedure is performed with combined echocardiographic (transesophageal or intracardiac) and fluoroscopic guidance. Though less data have been accumulated for transcatheter closure of ventricular septal defects, results are encouraging for certain lesions. Because of impingement on atrioventricular or semilunar valves, the devices are not suited for closure of atrioventricular canal or malalignment defects. Transcatheter devices, such as the Amplatzer muscular VSD Occluder, have been used successfully for closure of muscular and postoperative peripatch septal defects (Fig. 74.19). In smaller children, intraoperative closure via a sheath placed periventricularly has been successfully used to close difficult defects. The Amplatzer Membranous VSD Occluder is in clinical trial for closure of membranous VSD.

**Retrievals**

Several specialized catheter systems have been designed for intravascular retrievals. These devices include snares, baskets, and grabber catheters. Most can be advanced through small introducers and are therefore applicable even in small infants. With the exception of large noncollapsible

endovascular devices (expanded stents), most errant catheters, and intravascular foreign materials can be successfully removed without the need for surgery. In children undergoing heart surgery, this approach is particularly useful for removal of fractured, retained lines.

**Combined Surgical and Catheter Interventions**

The last decade has witnessed a proliferation of procedures combining surgical and transcatheter techniques. The most commonly performed of these “hybrid” procedures include per-ventricular closure of ventricular septal defects and what has been referred to as the “hybrid stage I”: bilateral pulmonary artery banding combined with ductal stenting for palliation of HLHS or its variants. This alternative approach for HLHS avoids newborn cardiopulmonary bypass. There have been no concurrent controlled trials comparing outcome of hybrid with standard surgical palliation for HLHS. Contemporary results among centers suggest equipoise. There is great variability in approach; at some centers only one form of treatment is performed, but more commonly both are offered to patients. However, the reasons for stratifying patients to one treatment versus the other vary greatly. Choice of procedure may depend on concomitant risk factors deemed to increase the risk of cardiopulmonary bypass such as low birth weight or associated anomalies. Parental preference may also play a role. While there are as many different approaches to surgical stratification of HLHS patients as there are centers, it should be emphasized that there are clear anatomic risk factors for hybrid palliation. The most important is anatomy predisposing to coronary ischemia after ductal stent placement. Patients at risk are those with mitral or aortic atresia in whom there is anatomic substrate for retrograde coarctation of the aorta. Such patients should be treated with conventional Norwood operations.

The optimal environment for hybrid palliation is a specifically designed hybrid operating/catheterization suite but the procedure can be accomplished in a traditional catheterization laboratory. Bilateral pulmonary bands are placed by median sternotomy usually by using a cut ring of Gore-Tex shunt. Next, a purse string is placed into the most proximal portion of the main pulmonary artery through which a sheath is placed. Angiography is performed assessing the adequacy of the pulmonary bands as well as to evaluate ductal anatomy for stent placement. A guide wire is then advanced to the descending aorta and ductal stenting performed. After follow-up angiography, the wire and sheath are removed (Fig. 74.20). Prior to hospital discharge, the patient is brought back to the catheterization laboratory for balloon atrial septostomy.

Patients who have undergone hybrid palliation for HLHS require particularly close monitoring to screen for arch obstruction (either retrograde or anterograde) as well as the development of restrictive transatrial flow. They are typically referred for the subsequent stage palliation the so-called comprehensive stage II, at 3 to 4 months of age. This operation incorporates both the Norwood and the bidirectional Glenn procedures.

**Fetal Intervention**

A series of principles both medical and ethical must guide fetal intervention. The fundamental medical principles include the following: First, the condition in question occurs as a consequence of a relatively simple primary abnormality arising late in embryogenesis (or after). Second, this primary abnormality leads to subsequent changes that are either lethal or result in major morbidity. Third, that prenatal intervention is feasible at a stage where the above process can be interrupted. The guiding ethical framework includes (1) the proposed fetal intervention, which is reliably expected on the basis of animal studies to be life saving or prevent serious irreversible disease. (2) Among the alternatives, the intervention is designed to involve the least risk of death and morbidity to the fetus. (3) The risk of death or injury to the pregnant woman is very low. The application of these principles to cardiac malformations has been imperfect because investigators have failed in attempts to generate animal models for the relevant malformations.

Balloon dilation of aortic stenosis was the first fetal cardiac catheter intervention attempted, over two decades ago. The procedure was clearly groundbreaking and a technical tour de force, but unsuccessful in altering the clinical outcome. Approximately a decade later, other investigators rekindled interest in this method in dramatic manner. Approaching the same lesion at a substantially earlier stage...
in gestation, not only was the procedure technically successful, but also in some cases it appeared that therapeutic success was achieved by preventing the development of HLHS. It should be emphasized that only a small fraction of HLHS has even the potential to be averted in this manner, as most cases of HLHS are not due to fetal aortic stenosis. Nonetheless, over the years a substantial experience with fetal intervention has accrued for a small number of conditions. The majority of procedures have been for dilation of fetal aortic stenosis to prevent HLHS. As most infants born with HLHS now survive, the goal in this lesion is primarily to decrease morbidity rather than avert mortality.

Another condition for which fetal intervention has been performed is HLHS and intact atrial septum. In patients born with this combination of abnormalities, in utero left atrial outlet obstruction results in pathologic alteration of the pulmonary vasculature. Neonatal mortality is markedly increased compared with other cases of HLHS. Fetal intervention is performed to create an atrial septal communication with the goal of preventing pulmonary vascular disease and decreasing mortality (Fig. 74.21).

SUMMARY AND CONCLUSIONS

Transcatheter therapies are now available for many cardiovascular lesions. The patient with complex lesions may require several operations and interventional catheterizations. In these cases, outcome is optimal when surgeon and cardiologist, both educated in the range of therapeutic options, plan treatment strategies collaboratively.

SUGGESTED READINGS

Feldman T, Kar S, Rinaldi M, et al. Percutaneous mitral repair with the MitraClip system:
The advent of transcatheter approaches for the treatment of many cardiovascular lesions in children has resulted in the need for close cooperation between surgeons and interventional cardiologists in planning operative therapies. Because the results with balloon dilation of the aortic valve in critical aortic stenosis in newborns are similar to those of open surgical valvotomy, there is little added benefit to a surgical approach in these patients. It should be emphasized that the results are no better with transcatheter approaches, and there remains significant mortality in these newborns. A certain proportion of patients will have significant residual aortic valve stenosis or insufficiency and ultimately require additional intervention. Because of the success of balloon dilation of aortic stenosis in young patients, however, it is rare to require pulmonary autograft valve replacement or other surgical approaches to the aortic valve in infancy. Most patients can be at least satisfactorily palliated with balloon dilation, and then if significant insufficiency or recurrent stenosis not amenable to additional balloon dilation occurs, pulmonary autograft aortic valve replacement can be undertaken in early childhood. As noted by the authors of this chapter, the long-term results of even pulmonary autograft valve replacement are unknown, and therefore all of these procedures should be considered palliative at the present time.

Hemodynamic evaluation at cardiac catheterization is important for determining operability in many patients with complex congenital heart disease with significant shunts. A shunt calculation in many of these patients of 2:1 or greater is an indication for surgical repair. However, there is evidence that the presence of even modest shunts should prompt operative or transcatheter correction because the long-term effects on pulmonary vascular resistance of even a modest shunt are still variable. Therefore, in most situations a left-to-right shunt ratio of 1.5:1 or greater should be considered an indication for operative or transcatheter intervention, and even minor ductus arteriosus patency should be considered an indication for surgical or coil closure because subacute bacterial endocarditis is still a risk factor in these patients. Even ASD with a modest left-to-right shunt should not be considered a completely benign lesion because some of these patients will develop pulmonary vascular changes even with a relatively small defect. It appears that there are some patients who have a particular predisposition to vascular disease, and even a modest left-to-right shunt may exacerbate the development of progressive pulmonary vascular obstructive disease in these patients. In addition, as patients increase in size and age, shunts are not fixed; therefore, a significant shunt may be present in a patient with an ASD who at one isolated determination may have a relatively modest left-to-right shunt. As growth occurs, the shunt can increase significantly. With the relatively low risk of intervention in the current era, in my opinion, even modest shunts should be addressed.

The usefulness of occluder devices for ASD is established. It is of interest that the use of atrial septal occluder devices has not been associated with a significant incidence of pericardial effusion, which is the cause of the greatest morbidity after surgical closure of ASD. The reasons for this difference are not apparent. With surgical closure of ASD, no prosthetic material or mechanical struts are implanted, and the operative risk is extremely low. However, an incidence of pericardial effusion that requires treatment in approximately 5% to 20% of patients is noted in ASD closure, and the reason for this high occurrence of pericardial effusion is unknown. Transcatheter devices have resulted in high closure rates with a low incidence of recurrence or infection and have become the procedure of choice for small to moderate-sized secundum ASDs.

The larger Amplatz devices that have been used for larger-sized secundum atrial septal defects are quite large in the atrium. Some of the transcatheter devices have resulted in significant complications. There have been several reports of infection, thromboembolism, and erosion of the devices into the base of the sinus of the aortic valve or the atrial wall, resulting in rupture of sinus of Valsalva into the atrium. It appears that the incidence of these complications is low; however, the larger devices seem to occupy much more space in the heart, and therefore longer follow-up will definitely need to be obtained before these devices are proved to have similar safety and efficacy as the smaller devices for small to moderate-sized atrial septal defects.

Although results with dilation of the native infant coarctation are suboptimal and certainly no better than for surgical therapy, the long-term results remain to be determined. Balloon dilation of recurrent coarctation has become accepted standard therapy in most patients. The incidence of aneurysm formation and other long-term complications requires longer follow-up. It is certainly possible to argue that in an older patient with a normal-sized aorta, primary stenting of coarctation may result in relief of gradient and improvement in hypertension with no greater morbidity or mortality than surgical intervention. Stenting in younger patients, however, may be suboptimal because growth will frequently require additional dilation of the stent to prevent recurrent stenosis.

Catheter intervention for residual defects after surgical intervention is increasingly utilized. Patients with multiple ventricular septal defects are particularly amenable to this type of approach. Although most apical defects and perimembranous defects can be directly addressed with standard surgical (continued)
techniques, muscular ventricular septal defects (especially anterior defects) are often obscured from right ventricular or transatrial approaches. In patients with multiple defects, a primary surgical approach to the defects in the apical and perimembranous regions and then subse-
quent catheter closure if necessary of residual muscular defects is reasonable. Because most multiple ventricular septal defects are generally amenable to surgical and transcatheter closure, we have taken the approach that patients with multiple defects in general should not undergo pulmonary artery banding. Avoidance of banding may prevent hypertrophy of ventricular muscle, which can obscure margins of muscular defects and make later repair more difficult. Cooperation and communication between the catheterizing interventional cardiologists and surgeons can result in optimal outcomes in these patients.

An area of increasing interest is that of “hybrid” treatment options for various forms of congenital heart disease. In the hybrid approaches, transcatheter and surgical procedures are done simultaneously. There has been an increasing experience with the percutaneous approach to muscu-
lar VSD closure in the operating room, with excellent short-term results. The ability to access the VSD directly through the ventricular wall results in a very straight catheter course and ease of implantation of these devices. In addition, there has been increasing interest in the use of hybrid therapies for first-stage palliation in hypoplastic left heart syndrome. In these approaches, the ductus arteriosus is stented over its entire length and bands are surgically placed on the pulmonary arteries.

As noted by the authors of this chapter, the use of hybrid procedures for hypoplastic left heart syndrome has been variable. There are anatomic contraindications to the use of this therapy and unfortunately a significant number of patients with aortic atresia will have a substrate that is predisposed to retrograde coarctation of the aorta. In most centers, hybrid therapy is used selectively for patients who are con-
sidered at particularly high risk for surgical Stage I Norwood operation. As in many of the interventional techniques where stents are implanted in vessels, the stents are difficult to remove at the time of surgical intervention and often residual stent material must be left in place during sur-
gical reconstruction, making reoperation somewhat more complex. Thus, in any given patient it is particularly important that the long-term needs for staged sur-
gical reconstructions be recognized and the plans for surgical and interventional procedures coordinated between the sur-
geons and interventionalists to insure that the long-term treatment plan is optimal.

The availability of stents for maintain-
ing ductal patency has also led to greater interventional use as an alternative to aortopulmonary shunts in the newborn. Patients with pulmonary atresia and intact ventricular septum may undergo a radiofrequency perforation of the valve plate with balloon dilation and placement of a duc tal stent to avoid the need for surgery. Nevertheless, the long-term outcomes for patients with these strategies have not been determined, and in most cases the ductal stenting needs to be performed in a somewhat restrictive ductus to allow the stent to anchor ade-
quately. There have been cases of stent migration and stenosis, and the hemodynamic characteristics of a central stent may be suboptimal in terms of protection from pulmonary vascular resistance over the short term. Nevertheless, increased experience is being gained with the use of these interventional techniques.

There has not been a direct compari-
son of surgical versus catheter approaches for pulmonary atresia with intact ventricu-
lar septum with long-term outcomes. However, the intermediate stage results of catheter-based therapy seem to be quite good.

Although they are not yet readily available in the United States, the Amplatzer perimembranous VSD occluder devices are being used more extensively in Europe and Asia. Relatively large series of VSD closures with these devices are being reported and new devices are being studied. Although the closure rates appear to be quite good, there is an incidence of late development of complete heart block that needs to be addressed with additional long-term follow up and device modifications. Never-
theless, many VSDs could have device closure with appropriate patient selection.

As transcatheter interventions become more sophisticated, the communication between interventional cardiologists and surgeons becomes even more critical. In many cases, transcatheter interventions can be undertaken in conjunction with surgical therapy to occlude shunts that may be difficult to access intraopera-
tively, to occlude additional sources of pulmonary blood flow in patients who are undergoing the Fontan procedure, or to occlude decompressing veins after staged palliation for single ventricle. In some cases, intraoperative transcatheter interventions may be useful for stenting pulmonary arteries (e.g., in patients with compression of the left pulmonary artery after staged reconstruction for Hypoplas-
estic Left Heart Syndrome), which can sig-
ificantly improve flow to the lungs after the bidirectional Glenn or hemi-Fontan procedure or completion of Fontan pro-
cedures. In many cases, such as patients with discontinuous pulmonary arteries and a ductal source of pulmonary blood flow to one lung, early, complete operative repair can be undertaken but with a very high risk of stenosis of the pul-
monary arteries because of involution of ductal tissue after neonatal life. These patients should be referred for transcatheter dilation early and scheduling of these catheter interventional procedures should be considered part of the operative intervention.

It should be noted that diagnostic catheterization has particular value in patients with residual lesions after surgi-
cal intervention because many of these lesions cannot be directly identified by echocardiography. Postoperatively, echocardiographic windows may be inade-
quate, and therefore catheterization may be necessary to identify the exact anat-
omy of the residual lesion.

In our center, as in many others, patients who are not following a predicted postoperative course are referred for diagnostic catheterization if the echocardiographic information does not fit clearly with the patient’s clinical pro-
gression. We will very aggressively take patients for diagnostic and interven-
tional catheter procedures postopera-
tively to eliminate any potential residual defects that could influence the patient’s
hemodynamic course. It is not uncommon for residual VSDs or other significant shunts to be underestimated by postoperative echocardiography, and the risk of catheterization is low enough that it appears optimal to actually measure the hemodynamic situation to obtain the best overall outcome.

One of the areas of most active interest in interventional cardiology is the use of stent mounted valves. As mentioned by the authors of this chapter, this technology is rapidly increasing, and catheter-based valve implantation is being increasingly used in adult populations. The relative benefit of catheter-based valve implantation in children remains to be determined. The durability of these valves is not yet known since most have been placed in older patients who have contraindications to surgical intervention. It is well known that tissue valves deteriorate rapidly in very young patients and therefore it is difficult to know how useful this technology will be as primary therapy. However, implantation of catheter-based valves in the pulmonary outflow tract in conduits has clearly been effective, and on the right side of the heart these valves seem to last a reasonable period of time which may be comparable to homograft or other tissue valves. Nevertheless, it is inevitable that these valves will fail and require additional intervention. Placement of stent-mounted valves in the aortic position in children, while certainly feasible, is probably not the optimal therapy due to the poor durability of tissue valves in children at the present time. Nevertheless, there will certainly be instances, with careful patient selection where these technologies will be extended into the pediatric age ranges.

As noted in the previous chapter, MRI has supplanted diagnostic catheterization and to some extent echocardiography for many congenital heart lesions and much hemodynamic information can be obtained with MRI. Thus, the incidence of hemodynamic cardiac catheterization is significantly decreasing and interventional catheterization procedures are becoming increasingly prominent worldwide. Nevertheless, there are certain circumstances where hemodynamic catheterization is optimal, such as to evaluate postoperative repairs that are not responding as expected and in patients where filling pressures and vascular resistances need to be calculated. In addition, if the anatomic and hemodynamic information can be obtained at catheterization, the use of diagnostic catheterization permits the opportunity for interventional treatment of identified lesions without requiring an additional procedure (which would be true if MRI were used at the primary diagnostic modality). Thus, selection of the optimal procedure in each individual patient becomes an important consideration.

Finally, as emphasized by the authors, surgical outcomes in complex congenital heart disease with often multiple operative interventions are optimal when both surgeons and cardiologist construct treatment strategies in a collaborative and prospective manner.

TLS
Palliative Operations for Congenital Heart Disease

Hyde M. Russell and Carl L. Backer

With continuing advances over the years in neonatal cardiopulmonary bypass (CPB) and surgical techniques, the chapter on palliative procedures in all textbooks on congenital heart surgery has grown shorter and shorter. There seem to be progressively fewer indications for palliative operations, although there is a select, small group of patients for whom (at least with our current understanding of cardiovascular physiology) palliation apparently always will be required. Countering this trend, there has been a recent resurgence in the use of certain palliative techniques performed in conjunction with transcatheter procedures: the "hybrid" approach. The history of cardiac surgery has been one of an evolution from operations that were solely palliative to ones in which there is complete correction in the neonatal period with one procedure. Recognition of the complications associated with palliative operations and the realization that neonates and infants do not necessarily fare worse than older children during open-heart surgery have provided the impetus for primary corrective surgery at an earlier age. In this process, many previously commonly performed palliative procedures are now considered completely obsolete and are no longer indicated. It is important, though, for the practicing congenital heart surgeon to understand these palliative procedures because there are many patients who have had these operations in the distant past who require later surgical intervention. The two primary palliative procedures still frequently used are the aortopulmonary shunts (Table 75.1) for patients with diminished pulmonary blood flow and cyanosis and pulmonary artery banding for certain patients with excessive pulmonary blood flow and congestive heart failure. The pulmonary artery band has recently undergone a rebirth in its use as part of the hybrid approach to the treatment of infants with hypoplastic left heart syndrome. The importance of the initial palliative procedure cannot be overemphasized. A poorly performed aortopulmonary shunt that destroys a pulmonary artery may prohibit the child from having a completion Fontan correction. Hence, although these are older and seemingly less important procedures, they must be performed well to ensure a smooth eventual corrective procedure.

AORTOPULMONARY SHUNTS

Classic Blalock-Taussig Shunt

The Blalock-Taussig shunt (Table 75.2) was the first aortopulmonary shunt; it was first performed in 1944 by Alfred Blalock of the Johns Hopkins University Medical Center. The classic Blalock-Taussig shunt is a direct end-to-side anastomosis of the transected subclavian artery to the pulmonary artery. Legend has it that Helen Taussig, the pediatric cardiologist at Johns Hopkins University, observed that the condition of infants and children with severe forms of tetralogy of Fallot worsened after their patent ductus arteriosus closed. She traveled to Boston and asked Robert Gross if he could create an artificial duc tus in these children. He supposedly told her that he was in the business of closing the ductus, not creating new ones. She then met with Blalock, the chairman of the department of surgery at her institution. Blalock had successfully created a left subclavian artery-to-pulmonary artery anastomosis 6 years earlier while developing a canine model of pulmonary hypertension at Vanderbilt University. Taussig suggested to Blalock that he will apply his experimental procedure to the many patients that she saw in her clinic who had cyanosis from insufficient pulmonary blood flow. The first operation was performed on November 29, 1944, on a 15-month-old girl with the diagnosis of tetralogy of Fallot and severe pulmonary stenosis. After that first successful case, hundreds of cyanotic children went to Baltimore for "the operation." Within the next 2 years, more than 500 patients had undergone the Blalock-Taussig shunt. During this time, there was an early mortality of 16%, and 6% of the patients were considered inoperable. This procedure was very commonly used until the introduction of the modified Blalock-Taussig shunt, which uses an interposition graft of Gore-Tex, avoiding sacrifice of the subclavian artery. The Hopkins group recently reported a six decade experience with 2,000 Blalock-Taussig shunts.

The anastomosis for the classic Blalock-Taussig shunt is classically constructed on the side opposite the aortic arch. When there is a left aortic arch, there is typically a right innominate artery, and using the subclavian artery on this side provides a gentle curve down to the pulmonary artery. With a right aortic arch and mirror-image branching, the left innominate artery provides a similar gentle curve to the pulmonary artery. In contrast, the other subclavian artery for each arch would require an angulation of the artery of nearly 180 degrees to effect the anastomosis. Figure 75.1 illustrates the anatomy for exposure of the subclavian and pulmonary arteries through a right thoracotomy (see inset). The branches of the right subclavian artery are ligated and divided along with the distal subclavian artery, and the subclavian artery is pulled through the loop formed by the right recurrent laryngeal nerve. The carotid artery is freed to provide more mobility. The end of the subclavian artery is spatulated, so the anastomosis is 1.5 to 2.0 times larger than the subclavian artery per se. The anastomosis is constructed to the proximal pulmonary artery, with care taken to avoid the complication of performing the anastomosis to the right upper lobe branch. The subclavian artery will then be in a groove just posterior to the superior vena cava (SVC) and the phrenic nerve (Fig. 75.2).
Aortopulmonary Shunts

The classic Blalock-Taussig shunt does not require prosthetic material and provides a precise amount of pulmonary blood flow limited by the orifice of the subclavian artery. In addition, the shunt grows with the patient, providing more pulmonary blood flow as the child grows. However, the Blalock-Taussig shunt sacrifices the subclavian artery, which in a small number of cases can result in hand or arm ischemia. In addition, the affected arm is usually shorter than the contralateral arm, is always somewhat cool to the touch, and will not have a palpable pulse. Finally, even with mobilization of the carotid artery and division of the inferior pulmonary ligament, the subclavian artery may still be so short as to cause the pulmonary artery to be “pulled” up and kinked. Takedown of the classic Blalock-Taussig shunt at the time of complete correction through a median sternotomy involves dissection posterior to the SVC. The artery can then be encircled and double ligation performed (Fig. 75.3).

Modified Blalock-Taussig Shunt

The use of a polytetrafluoroethylene (PTFE) tube for an aortopulmonary shunt was first reported by Gazzaniga and associates in 1976. Three infants with pulmonary atresia underwent aorta-to-pulmonary artery shunt using an interposed 4-mm PTFE tube. DeLeval coined the term modified Blalock-Taussig shunt when he reported on 99 patients operated on between 1975 and 1979 having a prosthesis of Dacron (13) or PTFE (86) interposed between the subclavian and pulmonary arteries (Table 75.3). Shunt failure rate was 6%, and mortality was 8%. The advantages of the modified Blalock-Taussig shunt,

which has now become the shunt of choice at most congenital heart surgery centers, include (1) preservation of the circulation to the affected arm, (2) regulation of the shunt flow by the size of the systemic (subclavian or innominate) artery, (3) high early patency rate with minimal tissue ingrowth of even a small-diameter expanded PTFE arterial prosthesis (Gore-Tex; W.L. Gore & Associates, Inc., Flagstaff, AZ), and (4) guarantee of adequate shunt length. One disadvantage of the modified Blalock-Taussig shunt is the occasional excessive leaking of serous fluid through the interstices of the fabric of the PTFE. This may result in excessive and prolonged chest tube drainage, localized seroma formation around the graft, or both. This complication occurs in 3% to 5% of patients.

The modified Blalock-Taussig shunt can be performed through a right or left thoracotomy or a median sternotomy. In the last 10 years, we have exclusively used a median sternotomy approach. This facilitates the use of CPB support if the child has significant oxygen desaturation during the procedure. This, of course, is much easier with a median sternotomy approach. CPB should always be readily available for such an instance when a shunt is performed. There are several other advantages to the median sternotomy approach. A patent ductus arteriosus can be ligated as soon as the shunt is opened or when the patient is placed on CPB. The lungs are not compressed by the exposure through a thoracotomy (which can affect the $O_2$ saturations). If a thoracotomy approach is used, the side selected depends on the subclavian and pulmonary artery anatomy, the presence and location of a ductus arteriosus, and the great-vessel relationship. The disadvantages (relatively minor) of the median sternotomy are the adhesions with reoperation. With a thoracotomy approach the latissimus dorsi muscle is divided, the serratus anterior is mobilized and spared. The thorax is entered through the fourth interspace. The lung is retracted anteriorly and inferiorly (Fig. 75.4). The mediastinal pleura is opened posterior to the SVC and phrenic nerve. The azygos vein is doubly ligated and divided. The subclavian artery is encircled with a vessel loop, with care being taken to avoid the right recurrent laryngeal nerve, which passes around the distal innominate artery at the takeoff of the subclavian and common carotid arteries. The right pulmonary artery is dissected free, with care being taken to identify the right upper lobe branch and main pulmonary artery continuation to the right lower and middle lobes. The right upper lobe and the distal right pulmonary artery branches are encircled with vessel loops, which can then be occluded with small Rommel tourniquets. Alternatively, a small vascular clamp can be placed on the pulmonary artery. The patient is administered 1 mg/kg of heparin intravenously.

The size of the PTFE graft selected is based on the size of the patient. We currently
use only the heparin-bonded “stretch” PTFE. We use a 3.0-mm shunt for neonates <2.0 kg, a 3.5-mm shunt for neonates 2.0 to 4.0 kg, a 4.0-mm shunt for infants >4 kg, and only rarely a 5-mm shunt in an infant over 5 kg. Nearly all neonates having a shunt procedure will have a bidirectional cavopulmonary anastomosis or a complete repair by 6 months of age; so long-term patency is not an issue. The PTFE is cut to size before the clamps are placed; the clamps distort the relative distance between the subclavian and pulmonary arteries. The graft is usually cut to give it a gentle curve, which allows for some patient somatic growth. It should not kink or distort the pulmonary artery, which can easily happen if the length is not accurate. The vessel loop is used to pull the subclavian artery, and a segment of the vessel is then occluded with a small Castaneda clamp. The PTFE graft is beveled as illustrated in Fig. 75.4A, and an arteriotomy is created in the inferior aspect of the subclavian artery. The PTFE graft is anastomosed to the opening in the subclavian artery with 7-0 polypropylene suture and a parachute technique. The clamp on the subclavian artery is left in place until the pulmonary artery anastomosis is completed. Repositioning the clamp to the

PTFE graft may increase the risk of blood stasis and shunt thrombosis. The proximal pulmonary artery is controlled with another small Castaneda clamp. The Rommel tourniquets are snugged on the right upper and right distal pulmonary arteries. A longitudinal arteriotomy is created in the superior aspect of the right pulmonary artery. With a single 7-0 polypropylene suture, the PTFE graft is anastomosed to the pulmonary artery (Fig. 75.4B). The distal Rommel tourniquets are released first, then the clamps on the pulmonary and the subclavian arteries.

There should be a nearly instantaneous rise of approximately 10% to 15% in the patient’s oxygen saturation as monitored by pulse oximetry. A thrill should be palpable in the shunt and in the distal pulmonary artery. It is important to maintain adequate systemic arterial pressure before, during, and after the operation to prevent early shunt thrombosis. This may require the use of inotropic support (dopamine, dobutamine). Bleeding is controlled with absorbable gelatin sponge (Gelfoam) soaked with topical thrombin. The heparin is not routinely reversed with protamine unless there is excessive bleeding from the suture lines. The graft should lie in a groove posterior to the SVC, where it is accessible at the time of takedown for intracardiac repair through a median sternotomy approach. The chest is closed in layers with a single chest tube directed posteriorly and superiorly. We routinely sedate and ventilate the child for the first 24 hours postoperatively.

Williams and colleagues recently reviewed 2,000 shunt procedures performed at the Johns Hopkins hospital since Alfred Blalock’s first operation. Of these patients, 70% carried a diagnosis of tetralogy of Fallot as a result of the large number of cases done in the 1940s and 1950s before the advent of complete intracardiac repair. Operative mortality ranged from 15% in the first decade of use (1940s) to 8% to 10% in the modern era. Complications of stroke, bleeding, and infection are all <5% in the current era. Over the six decades, the review encompassed its use decreased, the operative mortality declined, and there was a shift in application to single ventricle patients.

Petrucci reviewed outcomes of all shunt procedures recorded in the Society of Thoracic Surgeons Congenital Heart surgery database during the modern era (2002 to 2009). This study included 1,273 patients. The overall mortality rate was 7.2% and the complication rate (need for mechanical circulatory support or unplanned reoperation) was 13%. Low weight (<3 kg), functionally univentricular hearts, or a diagnosis of pulmonary atresia with intact ventricular septum were all risk factors for death. Notably, one-third of deaths occurred within the first 24 hours of operation.

The takedown at the time of intracardiac repair through a median sternotomy is quite easily performed, particularly if the shunt was placed on the right side (Fig. 75.5). The shunt can be identified by dissecting the medial aspect of the SVC posteriorly. Locating a shunt on the left side is more difficult, but it can be identified either by dissecting along the left pulmonary artery, along the aorta to the shunt, or by entering the pleural space and approaching the shunt laterally. The dissection will first encounter a thick fibrous “peel,” which typically forms around the PTFE graft. After the plane between the “peel” and the PTFE graft is entered, the dissection proceeds relatively quickly and easily and enough graft length can be achieved for double hemoclip application proximally and single hemoclip distally. The graft should be divided between the hemoclips to prevent distortion of either the subclavian artery or the pulmonary artery as the patient grows and the distance between these two vessels naturally increases. No attempt is made to remove the proximal portion of the graft. In some patients, the distal graft will require removal to facilitate performing a bidirectional Glenn anastomosis. However, if the operation involves repair at the site of the main pulmonary artery, the distal graft can be left in place and typically does not cause a residual peripheral pulmonary artery stenosis.

As mentioned earlier, our preference is to perform the modified Blalock–Taussig shunt through a median sternotomy approach. This is particularly useful for the child who is having uncontrollable episodes of oxygen desaturation despite sedation, paralysis and full ventilation, and administration of phenylephrine (Neo-Synephrine). CPB with a single atrial cannula and cooling to 32°C will allow the Blalock–Taussig shunt to be performed in a safe and unhurried...
fashion, with the heart beating in normal sinus rhythm throughout the procedure. We and others have adopted the median sternotomy as the standard approach for a modified Blalock-Taussig shunt, believing that the safety factors outweigh the adhesions at reoperation.

One other consideration at the time of Blalock-Taussig shunt construction is the question of whether or not to ligate the patent ductus arteriosus. Our practice until recently has been to ligate the patent ductus arteriosus either when CPB is started or when the clamps for the shunt are released (no CPB). A recent review by Zahorec and colleagues noted a higher early hospital mortality (9.7% vs. 0%) when the arterial duct was surgically closed versus being left open (n = 62).

One other trend in the management strategy of neonates requiring a source of pulmonary blood flow is the use of transcatheter ductal stenting. McMullan and colleagues recently reported 11 neonates who underwent percutaneous transcatheter placement of an endovascular stent to maintain patency of the arterial duct as an alternative to modified Blalock-Taussig shunt. When compared with 43 patients who had a modified Blalock-Taussig shunt during the same time period, they found that percutaneous stenting had greater freedom from reintervention and fewer procedural complications. These promising results merit consideration as worldwide experience with this new technique expands. Continued work with this alternative is necessary prior to widespread adoption of this new transcatheter approach.

**Waterston/Cooley Shunt**

In 1962, Waterston (Table 75.4) first reported an aortopulmonary shunt that was an anastomosis between the posterior ascending aorta and the anterior right pulmonary artery. This procedure was performed through a right thoracotomy with the anastomosis posterior to the SVC. Denton Cooley reported the same technical shunt but it was performed anterior to the SVC. After mobilizing the proximal and distal right pulmonary artery, the distal pulmonary artery branches can be controlled with small Rommel tourniquets. Proximally, a Castaneda clamp is used to occlude both a portion of the ascending aorta and the right pulmonary artery. The aorta is rotated slightly anteriorly with a forceps so that a posterior rather than a lateral portion of its wall is exteriorized by the clamp for the anastomosis. As illustrated in Figure 75.6, matching incisions are made in the posterior aorta and anterior pulmonary artery. These incisions are between 3 and 4 mm in length, depending on the size of the patient. An anastomosis is then created with running polypropylene suture as illustrated in Figure 75.7. The tourniquets are released and the clamp is removed, and the oxygen saturation should increase appropriately.

A major problem with the Waterston shunt is that it is not as controlled a shunt as either the classic or the modified Blalock-Taussig shunts. If the incisions in the aorta and pulmonary artery are too long and the anastomosis is too large, there will be excessive pulmonary blood flow with a risk of pulmonary vascular disease. If the incisions are too short and the opening is too small, there will be inadequate pulmonary blood flow. A second problem with the Waterston anastomosis is that as the patient grows and the aorta rotates, the anastomosis tends to put traction on the right pulmonary artery and actually to kink and distort the right pulmonary artery. This may cause preferential flow to one lung. For this reason, almost all patients who have takedown of a Waterston shunt will require a major reconstruction of the right pulmonary artery.

The Waterston shunt (Fig. 75.8) is taken down at the time of intracardiac repair.

of the primary cardiac lesion through a median sternotomy. It is important to dissect out the shunt area and pulmonary arteries before CPB to occlude the shunt on initiation of CPB to prevent pulmonary runoff with inadequate systemic perfusion. Alternatively, the right and left pulmonary arteries can be snared or clamped. The repair is done with the patient on CPB with the aorta cross-clamped distal to the shunt. After cardioplegic solution has been administered (occluding the shunt or pulmonary arteries to prevent cardioplegic solution runoff), the aorta is separated from the right pulmonary artery with an incision made along the original anastomotic line. Typically, the aorta in these patients is large, and the opening in the aorta can be closed primarily with running suture. The cross-clamp can then be temporarily removed and a PTFE or pericardial patch used to patch open the area of the right pulmonary artery where focal stenosis is usually created by the shunt. Another approach to the Waterston shunt at the time of takedown (originally described by Cooley) is to open the aorta anteriorly after the cross-clamp has been applied and inspect the opening from within the aorta itself. The aorta can also be completely divided to provide better exposure of the right pulmonary artery. The Waterston shunt has fallen out of favor because of the previously mentioned disadvantages and has been replaced in most centers by the modified Blalock–Taussig shunt. However, there are still a number of patients (now constantly declining) who have had this shunt who will require eventual takedown as described.

Potts Shunt

The Potts shunt is described here for almost solely historical purposes. The Potts shunt (Table 75.5) is an anastomosis between the descending thoracic aorta and the left pulmonary artery performed through a left lateral thoracotomy incision; it was first reported by Willis J. Potts from Children’s Memorial Hospital in Chicago. The first operation was performed on September 13, 1946. The child was 21 months of age and weighed 8.3 kg. She had been cyanotic since 3 months after birth and had multiple hypercyanotic spells. She was intensely cyanotic and clubbed. She had eventual intracardiac repair and lived to be 64 years old. The Potts anastomosis was performed using a special clamp developed by Potts that only partially occluded the descending thoracic aorta. The proximal and distal left pulmonary artery was occluded. The anastomosis was performed between parallel 4-mm incisions made in the descending thoracic aorta and the posterior left branch pulmonary artery. The completed shunt is shown in Figure 75.9.

The Potts anastomosis was widely used at Children’s Memorial Hospital in the late 1940s and 1950s. Between 1946 and 1967, 659 such shunts were performed. However,

</table>

there were several serious complications that developed from the Potts shunt. Many children developed large aneurysms of the left pulmonary artery. Another complication was that the Potts shunt was frequently either too small and the patient remained cyanotic, or it was too big and caused congestive heart failure. The final and most significant problem with the Potts shunt was the difficulty in taking down the shunt at the time of complete correction of the intracardiac lesion. Initial attempts at simply ligating the shunt resulted in uncontrollable hemorrhage in the operating room or in the immediate postoperative period. The preferred technique now is to use deep hypothermia and circulatory arrest, with adequate precautions taken to avoid air embolism to the cerebral circulation with the descending aorta opened. After CPB is initiated through a median sternotomy with aortic or femoral arterial cannulation, the aortopulmonary anastomosis is digitally occluded with a finger from outside the pulmonary artery to limit the left-to-right shunt and improve the efficiency of cooling (Fig. 75.10). The head vessels are encircled with vessel loops. The aorta is cross-clamped, and the heart is arrested with cardioplegic perfusion. The head vessels are snared, and the patient is placed on circulatory arrest. Only then can the left pulmonary artery be safely opened anteriorly (Fig. 75.11). Under circulatory arrest, the communication between the pulmonary artery and the aorta can be visualized and closed with a PTFE patch. The circulation can then be resumed, taking standard precautions to prevent air embolus to the cerebral circulation, venting air out of the patch occluding the Potts shunt before the knot is tied.

Other complications during Potts shunt takedown can occur because of the potential for aneurysm formation of the left pulmonary artery and the difficulty with gaining access to a very posterior anastomosis from the anterior mediastinum. Because of the complications of left pulmonary artery aneurysm, excessive pulmonary blood flow and resultant pulmonary hypertension, and the difficulties in taking down the Potts shunt, this procedure is essentially no longer performed at congenital heart surgery centers. This has been true for many years, and there are very few patients alive with a Potts shunt intact.

PULMONARY ARTERY BANDING

Pulmonary artery banding (Table 75.6) was first suggested by Muller and Dammann in 1952 for children with a large left-to-right shunt or single ventricle. For many years, pulmonary artery banding was the preferred initial palliation for any small child with a large left-to-right shunt and increased pulmonary blood flow, that is, ventricular septal defect, atrioventricular
Section III: Congenital Cardiac Surgery

canal, or common arterial trunk. However, as improvements in neonatal CPB and surgical techniques have taken place, pulmonary artery banding has fallen out of favor for almost all lesions with the exception of a very few precise defects, which include (1) Swiss-cheese muscular ventricular septal defects, (2) multiple ventricular septal defects with coarctation, and (3) single ventricle (i.e., tricuspid atresia type Ilc) with increased pulmonary blood flow in anticipation of an eventual Fontan procedure; (4) to prepare the left ventricle of a patient with transposition of the great arteries for the arterial switch procedure either (a) after presentation after 6 to 8 weeks of age or (b) after prior atrial repair; and (5) to prepare the left ventricle of a patient with congenitally corrected transposition of the great arteries in preparation for a “double switch.”

There has recently been a resurgence of interest in the use of pulmonary artery banding for infants with hypoplastic left heart syndrome. There are two strategies that have incorporated the use of pulmonary artery banding. One new approach is the “hybrid Norwood” using bilateral pulmonary artery banding and a catheter-delivered stent in the ductus as the first stage of the classic three-stage approach. The other use for pulmonary artery bands is as part of a strategy for patients slated for orthotopic cardiac transplantation. Bilateral pulmonary artery bands are placed with a stent in the ductus to avoid prostaglandin E1 administration while awaiting a donor heart. Another “twist” for pulmonary artery banding that I will review is the modification using an “intraluminal” pulmonary artery band.

Pulmonary artery banding in a child with normally related great vessels can be performed either through a left lateral thoracotomy or a median sternotomy incision. We prefer the median sternotomy approach. Many of the same advantages noted for a modified Blalock–Taussig shunt apply to use of a median sternotomy for pulmonary artery banding. The left thoracotomy is used with simultaneous coarctation repair. The bands we use are either Teflon-impregnated Dacron or a strip of PTFE. The pericardium is opened anterior to the phrenic nerve through a left lateral thoracotomy incision (Fig. 75.12). Stay sutures are placed to hold the pericardium open. The left atrial appendage generally sits just at the site where the band is to be applied and can be retracted with a stay suture. Encircling a dilated, thin-walled pulmonary artery can possibly lead to inadvertent entering of the pulmonary artery and thus needs to be done with great care. The safest way to encircle the pulmonary artery is by the subtrusion technique. This is illustrated in Figure 75.12A. The band is first placed around both the aorta and the main pulmonary artery proximally (Fig. 75.12B). This initial maneuver also avoids the complication of encircling only the left pulmonary artery. A plane is then developed between the aorta and the pulmonary artery with a combination of sharp dissection and electrocautery. A right-angled clamp is then passed around the aorta

A modification that may be useful in complex patients is the adjustable pulmonary artery band. There are many different types of adjustable pulmonary artery bands reported. Some are constructed with standard suture materials, others have reported mechanical devices capable of precise transcutaneous calibration.

Pulmonary artery band takedown is performed at the time of intracardiac repair through a median sternotomy. The patient is placed on CPB. Generally, the intracardiac repair is performed first, and the pulmonary artery reconstruction can be done while the patient is being warmed. All portions of the band should be removed because even a small portion of Dacron band left posteriorly can create scarring, which can cause late pulmonary artery stenosis. Removing the band completely, however, is not always adequate for providing pulmonary blood flow without pulmonary stenosis because the pulmonary artery wall does not necessarily rebound open. The area of banding usually must be either patched anteriorly or excised. The patch technique is illustrated in Figure 75.14. A patch of either pericardium or PTFE is used to provide an opening for the pulmonary blood to flow over the posterior scarred area and into the right and left pulmonary arteries without hemodynamic obstruction to flow. This sometimes requires the use of a “pantaloon” 1-mm/kg body weight. A narrower band is required for infants with a functionally univentricular heart. We have based final band tightness on the distal pulmonary artery pressure and \( O_2 \) saturation.

Placement and tightening of the band in general result in an elevation of the aortic systolic blood pressure by 10 to 20 mmHg. The distal main pulmonary artery systolic pressure should be reduced to \(<50\%\) of the measured aortic systolic blood pressure for the patient who is to undergo a two-ventricle repair. For a patient who is going to eventually undergo a Fontan procedure, the lowest possible distal main pulmonary artery pressure that can be achieved with acceptable oxygen saturations is desired. Oxygen saturations for a patient who is going to undergo biventricular repair can be left at 95%. For the patient who eventually is going to undergo a Fontan operation, the oxygen saturation should preferably drop to between 80% and 85%. It should be kept in mind that as the child grows, the band will automatically become “tighter” and further reduce the distal pulmonary artery pressure. After the band has been tightened to the desired degree, it is fixed to the proximal pulmonary artery with several interrupted polypropylene sutures to prevent distal migration of the band and encroachment on the right pulmonary artery. A possible complication of band placement is the aforementioned encroachment, which tends to pinch off the right pulmonary artery while allowing excessive blood flow to the left pulmonary artery. This results in severe proximal right pulmonary artery stenosis and left pulmonary artery hypertension. After the band has been secured in place, the pericardium is irrigated with saline, so there is less chance of intrapericardial adhesions at the time of intracardiac repair. The pericardium is approximated with several interrupted polypropylene sutures, with care being taken to avoid injury to the phrenic nerve. The chest is closed in the usual fashion with a single pleural drainage tube.

![Fig. 75.13. Details of sequential tightening of the pulmonary artery band.](image)

![Fig. 75.14. Takedown of a pulmonary artery band with anterior polytetrafluoroethylene patch placement. LPA, left pulmonary artery; RPA, right pulmonary artery.](image)
Another method of pulmonary artery band takedown is the "intraluminal" technique (Fig. 75.15). This involves resecting the area where the band was positioned and then doing an end-to-end anastomosis between the two remaining pulmonary arterial segments with interrupted, absorbable, fine monofilament suture. The distal right and left pulmonary arteries must be completely mobilized and the ligamentum arteriosum ligated and divided to provide a tension-free anastomosis. Although most surgeons have used a patch anteriorly, this usually still results in a mild main pulmonary artery stenosis and residual murmur. The use of transection of the site of the band and direct end-to-end anastomosis in most cases results in no gradient and no residual murmur. If the band is only in place for a few weeks, pulmonary artery reconstruction may not be necessary.

Another method of pulmonary artery band placement is the "intraluminal" technique (Fig. 75.16). This technique is used only in patients who require CPB for other, simultaneous procedures. The technique utilizes a Gore-Tex patch with a calibrated precut hole in the center that is sutured as a patch in the main pulmonary artery. It results in a consistent and significant reduction in pulmonary artery pressure and flow. It essentially eliminates the problem of band "slipping" with resultant pinching of the right pulmonary artery. One of the advantages of this "band" is that it can be dilated with transcatheter techniques if the patient should become progressively cyanotic with growth. Pulmonary artery band takedown is performed by incising the pulmonary artery and resecting the Gore-Tex patch and then performing an end-to-end anastomosis. Many of the patients, however, who have the intraluminal band go on to a bidirectional Glenn (Fontan strategy), in which case the pulmonary artery is transected at the site of the patch.

### MISCELLANEOUS PALLIATIVE PROCEDURES

Miscellaneous palliative procedures include atrial septectomy (Table 75.7), either the surgical Blalock–Hanlon atrial septectomy or the transcatheter Rashkind balloon septostomy, and palliative Glenn and Mustard operations. The Blalock–Hanlon atrial septectomy was first performed in 1950 and was done through a right thoracotomy. A portion of the right and left atria is occluded with a single clamp. The atria are then opened within the confines dictated by the clamp with two parallel incisions, one on either side of the septum, and a portion of intratrial septum is grasped, pulled up, and excised from within the clamp. The clamp is then repositioned so that the atrial septum falls back into the atrial cavity and the clamp is only holding the cut edges of the atrium, and the atrial suture line is closed. This procedure is generally no longer performed, and most patients now who require an atrial septal defect undergo Rashkind balloon septostomy. The Rashkind septostomy is typically performed in an infant with transposition of the great arteries and intact ventricular septum. A balloon-tipped catheter is passed up the femoral vein across the patent foramen ovale and into the left atrium. The balloon is initially inflated in the left atrium and then rapidly pulled across the septum into the right atrium, tearing the atrial septum. For patients with a thick atrial septum that is recalcitrant to Rashkind balloon septostomy, open atrial septectomy with CPB is the safest procedure. The atrial septectomy can be performed either during a short period of aortic cross-clamping or with induced electrical fibrillation of the heart. The entire atrial septum within the fossa ovalis can be excised, with the surgeon taking care to avoid injury to the atrioventricular node or cutting outside the heart. Rashkind balloon septostomy in the cardiac catheterization laboratory now is the preferred approach for most cases.

Some patients with complex cyanotic congenital heart disease and suboptimal anatomy for complete correction undergo a Glenn operation or a Mustard procedure for palliation of their cyanotic heart disease. These patients will have an elevation in their oxygen saturations after these palliative procedures, but are not completely corrected.

### CONCLUSION

In summary, the primary palliative operations for congenital heart disease are aortopulmonary shunts and the pulmonary artery band. We prefer a median sternotomy approach for both techniques. The aortopulmonary shunt of choice is the modified Blalock–Taussig shunt. Transcatheter ductal stenting may decrease the number of patients having a modified Blalock–Taussig shunt. Pulmonary artery banding is selected for very few patients now, but is still indicated for patients with Swiss-cheese muscular ventricular septal defects and infants with single ventricle and increased pulmonary blood flow, who are candidates for the Fontan procedure. There has been a
resurgence in the use of pulmonary artery banding for infants with hypoplastic left heart syndrome either as a replacement for the Norwood procedure or as part of a heart transplant strategy. Surgeons need to be aware of the techniques used to create a Waterston or Potts anastomosis and the possible complications of these shunts to care for those patients who have had these procedures in the past.

As the authors have noted, palliative procedures have become less important for patients with congenital heart disease because early primary repair has become the standard approach to treatment. A small number of patients, however, still require palliative shunts or pulmonary artery banding. Most typically, shunting is required as a component of more complex reconstructions, such as the Norwood operation for hypoplastic left heart syndrome. Isolated shunting is still required for certain patients with single-ventricle physiology with limited pulmonary artery blood flow, who require immediate intervention in infancy as staged palliation to later Fontan procedures. Similarly, pulmonary artery banding may be required in certain patients with excessive pulmonary artery flow in infancy, who are also candidates for later single-ventricle repairs. Early limitation of pulmonary blood flow to prevent elevation of pulmonary vascular resistance is very important.

The standard Blalock-Taussig shunt takes advantage of growth of the subclavian artery, which may improve the pulmonary artery blood flow into early infancy and childhood. However, the sacrifice of a subclavian artery, with limitation of use of that artery for monitoring purposes and reduction in limb growth, has limited the usefulness of the standard Blalock anastomosis. In most centers, PTFE-modified Blalock-Taussig shunts, which do not require the sacrifice of a subclavian vessel, are preferentially used. We have generally used smaller PTFE grafts of 3.5 to 4.0 mm in most neonates and infants because in most cases additional surgical intervention, either for complete repair or additional palliation, will occur before the child is 6 months of age, and therefore long-term patency is not necessary.

We have chosen sternotomy as the primary approach for almost all palliative operations, including the systemic-to-pulmonary shunt and pulmonary artery banding. For shunting procedures, the side of the aortic arch is not of concern if a median sternotomy approach is used, and, in addition, the shunt can be placed to the main pulmonary artery if necessary in very small infants with this technique. Access to the patent ductus for ligation to remove competitive flow is always possible through the sternotomy approach. As noted by the authors of this chapter, it is controversial whether ligation of patent ductus arteriosus should be routinely performed at the time of placement of an aortopulmonary shunt. There are conflicting data in the literature regarding this practice. In most centers, ductus arteriosus ligation is performed after placement of any aortopulmonary shunt primarily to insure that shunt flow is adequate; however, it is not uncommon with ligation of the ductus arteriosus for oxygen saturation to dramatically drop and yet over time the saturations tend to recover. The ductus arteriosus tends to be quite large in most of these patients, who are often on prostaglandin therapy, and therefore the aortopulmonary shunt flow, while adequate, can be relatively less than the flow through an open patent ductus arteriosus. Thus, there may be transient changes in pulmonary blood flow that affect pulmonary resistance and oxygen saturation which subsequently resolve. Maintenance of a patent ductus arteriosus after aortopulmonary shunting can create a situation where competitive flow occurs in the pulmonary arteries and could lead to higher incidence of shunt thrombosis. Computer modeling techniques have suggested that leaving the patent ductus arteriosus is suboptimal while other clinical studies as suggested by the authors have indicated that leaving the ductus open can lower early postoperative mortality. The question remains an open one. An additional advantage of a sternotomy for aortopulmonary shunting is the possibility of creating a more central shunt from the main aorta to the pulmonary artery if the innominate vessel is small or there is an aberrant right subclavian artery making the first branch from the ascending aorta the right carotid artery. The use of the carotid artery for the proximal anastomosis of the modified Blalock-Taussig
EDITOR’S COMMENTS (continued)

...in all cases, and we therefore reserve the left thoracotomy approach for pulmonary artery banding to selected patients where additional surgery on the ductus arteriosus or coarctation is necessary.

The authors described the use of the Blalock–Hanlon atrial septectomy, which is a closed technique for removing the atrial septum. As they stated, the Rashkind balloon septostomy or atrial septal stenting has virtually replaced the Blalock–Hanlon operation. In patients in whom the atrial septum is particularly thick or in cases in which the capacity is lacking to perform a Rashkind balloon septostomy or atrial septal defect stenting in the catheterization laboratory or when restrictive atrial septal flow remains and operative intervention is necessary, it is preferable to use open techniques to widely excise the atrial septum. In patients with bilateral superior venae cavae and restrictive atrial septal defect, it may be necessary to cut back the roof of the coronary sinus into the left atrium to achieve a wide opening of the atrial septal wall and avoid recurrent obstruction even after open septectomy.

Although palliative operations for congenital heart disease are relatively uncommonly performed, there may be a resurgence of interest in these techniques, as noted by the authors, for certain kinds of neonatal conditions, including hypoplastic left heart syndrome. The recognition that neonates are particularly sensitive to neurologic injury has led to interest in avoiding neonatal operations requiring cardiopulmonary bypass if possible. Delaying intervention into early infancy (6 to 8 weeks) may potentially decrease the risk of neurologic injury, although data have not yet been accumulated to define whether the additional risks of abnormal physiology may outweigh the potential benefits in neurologic outcome. Early primary repair has become the standard approach for lesions where it can be accomplished in the newborn or infant period, and therefore this “hybrid” approach represents a relatively radical change in the approach to newborns with congenital heart disease. However, if data continue to accumulate suggesting that there is a specific neurodevelopmental advantage in avoiding early operation, then palliative procedures, either operative or in the catheterization laboratory, may take on a greater role.

There has been much interest in ductal stenting as an alternative to surgical aortopulmonary shunt creation. Ductal stenting provides a stable source of pulmonary blood flow; however, there continue to be issues with the ability to create a stable shunt size with the use of ductal stenting techniques and the potential for stent migration and for stent ingrowth and obstruction if the stent does not completely extend across the entire length of ductal tissue. Hybrid approaches using intraoperative pulmonary banding and ductal stenting for hypoplastic left heart syndrome are gaining increasing interest, although the results are not superior to standard surgical approaches. In the past, banding of the pulmonary arteries had been used for patients with truncus arteriosus; however, the difficulties in placing bands on small pulmonary arteries accurately and the potential for occlusion of the artery or significant distortion, making repair more difficult, have led to abandonment of this technique. It is, therefore, interesting that it is being resurrected for patients with hypoplastic left heart syndrome as a potential way to avoid early surgical morbidities. There have even been attempts to create endovascular pulmonary artery bands with calibrated openings in a endovascular plug that can be delivered in the catheterization laboratory. As these techniques evolve, the relative risks and benefits of these more modern palliative approaches and hybrid approaches remain to be evaluated.

Although the authors describe pulmonary artery banding as being useful for patients with Swiss-cheese muscular ventricular septal defects and complex ventricular septal defect (VSD) with coarctation, in most cases primary repair of multiple VSDs has been accomplished with good results. Therefore, pulmonary artery banding is reserved for patients with multiple ventricular septal defects in whom direct operative intervention is not considered possible, such as true “Swiss-cheese” defects or isolated ventricular “noncompaction” in which little true septum is present. The problem with pulmonary artery banding in these patients is the development of significant right ventricular hypertrophy, which may obscure...
the margins of the VSDs at the time of operative intervention. In addition, after banding, angiography may suggest that most muscular ventricular septal defects have become small or closed, whereas when ventricular hypertrophy regresses after pulmonary artery debanding, residual VSD lesions may be significant. We believe that generally it is best to address these VSDs early and that in most cases, direct closure can be accomplished. With the advent of transcatheter interventions, small residual or moderate residual defects can be addressed in the catheterization laboratory, and, on occasion, device delivery in the operating room via a transventricular puncture may aid in complete closure of VSDs that are difficult to access via the right atrium.

Complex VSDs with coarctation can often be addressed by primary coarctation repair and VSD closure at a single operation. Although results with coarctation repair and pulmonary artery banding for significant ventricular septal defects are excellent with later repair of the defect and debanding, the progression of techniques of infant repair allows one-stage repair of both defects in most circumstances.

Pulmonary artery banding is now used most commonly in patients with single ventricle with increased pulmonary blood flow to prepare the patient for an eventual Fontan procedure and as a secondary procedure to prepare the left ventricle in patients with late presentation of transposition of the great arteries or for right ventricular failure after the Mustard operation in anticipation of a takedown and an arterial switch procedure. Remotely adjustable banding devices are being developed for this purpose. The authors stated that simple removal of pulmonary artery banding is rarely sufficient to allow relief of pulmonary outflow obstruction. We and others have noted that if second operations are undertaken early, then pulmonary artery debanding can often be accomplished with complete relief of residual obstruction. As the trend toward early intervention for complete repair continues, it may be possible to use very short terms of pulmonary artery banding in most patients with single-ventricle physiology with takedown of the band and performance of a hemi-Fontan or bidirectional Glenn procedure by 3 to 6 months of age. A similar scenario can be used for most patients with multiple VSDs, as noted by the authors. We have not elected to use pulmonary artery banding for atioventricular canal defects because the use of a band results in significant right ventricular hypertrophy, which may complicate the actual repair of the intracardiac defect. Even in very small patients, primary repair of atioventricular canal defects has been associated with excellent results; therefore, banding is very rarely indicated.

Knowledge of palliative approaches to congenital heart disease is still essential for congenital heart surgeons to permit the appropriate staging of patients to complete repair. In addition, as noted by the authors, knowledge of the range of palliative operations is particularly important so that successful takedown can be accomplished at time of complete repair.

TLS
INTRODUCTION
This chapter discusses the abnormalities of position and connection of the major systemic venous channels that drain into the heart. Although an understanding of the morphogenesis of the venous system is important, a classification of venous anomalies that is helpful to the surgeon is most appropriately based on anatomic considerations. Thus, this chapter is organized on an anatomic basis, and the anomalies of the venous system within each anatomic segment are addressed. Few of these venous anomalies are intrinsically pathologic to the circulation. However, many, if not most, present important surgical considerations during the palliation or correction of congenital cardiac conditions. Diagnosis of these abnormal systemic venous connections can usually be made echocardiographically, although angiography, computed tomography, and magnetic resonance imaging serve as adjunctive and very useful modalities.

Where appropriate, the relative frequency of presentation and incidence of the major venous anomalies is provided. This incidence is based on the Cardiology Patient Database at Children’s Hospital of Pittsburgh (CHP), which numbers >34,200 patients entered from 1955 to 1979. The information is based on a diligent coding of all cardiovascular anomalies in this patient database. Further information from the Children’s Hospital of Pittsburgh Heart Museum database is also used when appropriate to illustrate certain relationships between classes of congenital heart defects and anomalies of the systemic venous circulation.

ANOMALIES OF THE SUPERIOR CAVAL VEINS

Bilateral Superior Caval Veins Draining to the Systemic Venous Atrium
The superior caval drainage embryologically begins by means of paired cardinal veins (Fig. 76.1). After development of the left brachiocephalic (innominate) vein at week 7 of gestation, the left superior vena cava (SVC) usually involutes and becomes the ligament of Marshall. The most common anomaly of the superior caval circulation is persistence of the left SVC. This is readily recognized during cardiac catheterization or echocardiography and is frequently seen with the absence of the left innominate vein. Small bridging veins between the right and left SVCs may be present, thus joining the superior cavae. The presence of a left SVC may cause the right SVC to be somewhat smaller than usual, but the relative size of either the right or left vein is variable. In the usual circumstance, with rare exception, if there are no lateralization abnormalities, the left SVC drains into the coronary sinus and thus into the systemic or morphologic right atrium. It produces no physiologic abnormalities in its isolated condition and only becomes important when it is associated with other cardiac anomalies that require surgical correction or during cardiac transplantation.

The presence of bilateral SVCs, with the left caval vein entering the coronary sinus, is by far the most common major venous anomaly in the CHP database. It was found in 0.8% of all the patients and in >4% of the specimens in the heart museum. Seventeen percent of these patients had ventricular septal defects, and 10% to 15% had coarctation of the aorta, tetralogy of Fallot, or atrioventricular septal defects. A slightly smaller percentage had atrial septal defects, double-outlet right ventricle, transposition of the great vessels, and various forms of single-ventricle anatomy.

The left SVC originates at the junction of the left jugular and left subclavian veins. It is located anterior to the aortic arch and left pulmonary artery. Before entering the pericardial space, it accepts the hemiazygos vein, then runs inferiorly and medially into the posterior atrioventricular groove and joins the coronary sinus passing between the left pulmonary veins and the left atrial appendage (Fig. 76.2).

When the right atrium must be opened during open cardiac surgical procedures, provision must be made for management of both right and left SVC drainage. Short periods of occlusion of one, either the right or the left SVC, are tolerated nicely, but long procedures usually require cannulation of not only the right superior vein but also the left. It is believed that venous pressures proximally in the left SVC system that are <30 mmHg when the left SVC is occluded are well tolerated during most surgical procedures.

There are several options for managing drainage of the left SVC. This may be managed by cannulation through the coronary sinus from within the right atrium or directly with surgical cannulation of the left SVC using techniques similar to those on the right side. In very small infants, the use of circulatory arrest is another potential option. Bilateral SVCs, when joined by a bridging vein reminiscent of the left innominate vein, allow for the usual right SVC cannulation and simple (temporary) occlusion of the left SVC. The presence or absence of a left innominate vein is readily determined early during the operation when a midternal approach is taken.

The augmented blood flow through the coronary sinus enlarges the coronary sinus, and this becomes an important echocardiographic manifestation of the presence of a left SVC that drains via the coronary sinus. Knowledge that a left SVC is present in the face of a coronary sinus orifice that appears normal is a tip that the left SVC may drain directly into the left atrium or that the coronary sinus may be “unroofed.” An enlarged or dilated coronary sinus is an important consideration during the surgical repair of specific heart defects, the most important one perhaps being the repair of an atrioventricular septal defect. In this abnormality, which was present in 15% of our patients with a left SVC draining into the coronary sinus, the large and dilated coronary sinus changes somewhat the anatomic relationships during the surgical repair. In some centers, the placement of the septal
ACV. anterior cardinal vein; AV. azygos vein; CS, coronary sinus; HAV, hemiazygos vein; IVC, inferior vena cava; LSVC, left superior vena cava; RSVC, right superior vena cava; SV, sinus venosus; UV, umbilical vein.

Another rare problem can then be encountered with a left SVC entering the coronary sinus in patients who have elevations of right atrial pressure and pulmonary hypertension in the presence of a dilated coronary sinus, which can impinge on the wall of the left atrium and create what appears echocardiographically and functionally to be a cor triatriatum with limitation of free flow from the pulmonary venous confluence across the mitral valve. The coronary sinus, when decompressed on bypass with the heart under cardioplegic arrest, eliminates the ridge seen on echocardiography, and the defect can be quite obscure.

Although persistence of the left SVC, which drains through an intact coronary sinus into the right atrium, is not intrinsically a pathologic state, a defect in the common wall between the coronary sinus and the left atrium will produce a variable degree of interatrial communication and often must be surgically repaired. These defects in the partition may be small and relatively minor and become of greater significance only in association with complex disease. However, almost complete absence of this partition causes mixing and bidirectional shunting at the atrial level with the resultant systemic desaturation. It is difficult to diagnose various forms of unroofing of the coronary sinus when in association with a persistent left SVC. However, during the surgical repair of interatrial septal defects and other lesions in association with the persistence of the left SVC, the integrity of the coronary sinus with its drainage into the right atrium should be ascertained. Surgical options may include ligation of the SVC if a left innominate vein is present, and then a repair of the coronary sinus interatrial communication in the usual way, or simply a patching of the coronary sinus/left atrial defect to maintain left superior caval drainage into the right atrium through the coronary sinus. This condition is discussed in detail in a later chapter.

**Isolated Left Superior Caval Vein**

The presence of a left SVC may rarely be associated with the absence of the right SVC. When this occurs, there is a right brachiocephalic (innominate) vein that joins the left SVC. We found 15 cases (0.05%) in the CHP database and 5 additional cases in the Heart Museum. The most commonly associated anomalies were ventricular...
There are open and closed techniques for veins may be left alone. If a large portion of venous return into the abnormally located both atria. ANOMALIES OF THE INFERIOR CAVAL VEIN
Anomalies of the inferior vena cava (IVC) are less common than anomalies of the SVC. The Cardiology Patient Database at CHP indicates an incidence of 0.3%. Slightly >1% of the hearts in the museum collection were associated with IVC anomalies. Other than lateralization abnormalities, atrioven­tricular septal defect was the only cardiac malformation with an apparent association with abnormalities of the IVC. Fully 15% of the patients with interruption of the IVC in our database have this anomaly.

Retroaortic Innominate Vein
Occasionally, the surgeon will encounter what appears to be an absence of the left innominate vein. However, on opening the pericardium, a large vein may be found passing across the upper pericardial space, connecting the left internal jugular and subclavian veins to the right SVC. This vein passes dorsal to the ascending aorta, and its course parallels the right pulmonary artery. It is not thought to be associated with any specific cardiac abnormality; however, most patients with a retroaortic innominate vein have a congenital cardiac malformation. It has been noted with a left SVC, but this association is uncommon. There are no specific surgical connotations associated with this interesting finding other than an awareness of its occurrence so that it may be protected during dissection and not be confused with other structures.

Anomalies of the inferior vena cava (IVC) are less common than anomalies of the SVC. The Cardiology Patient Database at CHP indicates an incidence of 0.3%. Slightly >1% of the hearts in the museum collection were associated with IVC anomalies. Other than lateralization abnormalities, atrioven­tricular septal defect was the only cardiac malformation with an apparent association with abnormalities of the IVC. Fully 15% of the patients with interruption of the IVC in our database have this anomaly.

Absence of the Hepatic Segment of the Inferior Caval Vein
Clearly, the most noteworthy form of IVC anomaly is the absence of the hepatic seg­

Azygos Continuation to the Right Superior Cava Vein
In the absence of lateralization abnor­malities, IVC blood return to the heart is through an azygos vein continuation to the right SVC from the infrahepatically interrupted IVC (Fig. 76.5). Rarely, the continuation is via the left (hemi) azygos system to a left SVC, even without lateralization abnormalities. It is the most common infe­rior caval anomaly, and, aside from surgical consideration during the repair of other cardiac anomalies, it is of no major conse­quence. The hepatic veins usually connect singly through a short suprahepatic conflu­ence resembling a normal IVC to the right atrium. On rare occasions, there may be several separate hepatic vein connections to the atrium, and in the absence of hetero­taxy they connect to the right atrium.
from the pulmonary circuit. Additionally, the development of arteriovenous pulmonary connections (fistulae) is much more common when the pulmonary circuit is deprived of hepatic venous blood flow. Most patients with a bidirectional SVC-to-pulmonary artery connection in the presence of azygos continuation of an interrupted IVC will eventually require baffling of some or all of the hepatic veins to the pulmonary artery—a completion of the modified Fontan operation.

### Interruption of the Inferior Caval Vein in Visceral Heterotaxy

Fifty percent (37 patients) of the CHP database patients with IVC interruption had lateralization abnormalities. All but one were left isomerism with the IVC continued into a left SVC by means of the hemiazygos vein. The surgical considerations are the same as those that apply to the right-side continuation with the azygos vein. Exceptions depend on how the left SVC connects with the atrial mass, either directly or by means of the coronary sinus.

In patients with right isomerism, interruption of the IVC is extremely rare, and the azygos vein anatomy is of much less concern. However, there is a tendency for the hepatic veins to connect directly to the atrial mass, either on the right or the left side. This direct connection of the hepatic veins is very common, of course, in left isomerism because of the higher frequency of IVC interruption in this cardiac defect. The hepatic vein anatomy is much more variable in right isomerism and must be delineated carefully in anticipation of procedures designed to separate the pulmonary and systemic venous drainage and during cardiac transplantation.

### Other Abnormalities of the Inferior Caval Vein

Duplication of the IVC below the renal veins is not infrequent, but it has no relation to congenital abnormalities of the heart. Its presence or the presence of a left infrarenal IVC that crosses sharply to the right at a subhepatic level may cause the cardiologist some problems during catheterization. The surgeon may experience difficulty during the usual circumstance of passing large cardiopulmonary bypass venous canulae from the femoral approach in circumstances when bypass is necessary before the chest is opened or when transthoracic IVC cannulation is not feasible.

Congenital membranous obstruction of the IVC as it enters the right atrium has also been described, and similar to Budd-Chiari syndrome, may present with liver dysfunction. Resection of such membranes can be performed using cardiopulmonary bypass.

Rarely, the IVC may be completely absent, and the venous return from the lower body is through small paravertebral venous channels that communicate through the azygos systems.

### Pulmonary Vein Connection to the Systemic Veins

Anomalous connection of a portion or all of the pulmonary veins to either the superior or inferior caval systems may occur. Other than enlargement from increased flow, the systemic vein anatomy and connections are usually normal in this circumstance. The subject is addressed in a later chapter.

### Total Anomalous Systemic Venous Connection

There are reports of patients with absence of both the right superior and infrahepatic caval veins with azygos continuation to a left SVC and then to the left atrium. Surgical considerations pertain to separation of the pulmonary venous and systemic venous drainage.

---

**Fig. 76.5.** Absence of the hepatic segment of the inferior vena cava (inferior vena cava interruption with azygos continuation). AV, azygos vein; HV, hepatic veins; RA, right atrium; SVC, superior vena cava.
It is postulated that most of these patients have some form of lateralization abnormality.

ANOMALIES OF THE CORONARY SINUS

The coronary sinus receives venous blood from the cardiac veins and is usually the major venous pathway of the coronary circulation. A minor group of cardiac veins (venae cordis minimae) provides a variable degree of additional drainage directly into the cardiac chambers, predominantly the right atrium. The anterior cardiac vein drains directly into the right atrium, and the recognizable thebesian foramina provide outlets for either the minor cardiac veins or the sinusoidal systems of the heart with their drainage into the right atrium and, to some extent, into the right ventricle. Because of these alternative pathways, long-standing (slow onset) obstruction of the coronary sinus or absence of the coronary sinus, most frequently seen in right isomerism, is well tolerated without impairment of the coronary circulation.

Whereas the phenomenon of “unroofing” (partial or complete absence of the common wall between the left atrium and the coronary sinus) of the coronary sinus is found more commonly in patients with a left SVC draining via the coronary sinus, it may also occur in situations of a solitary (normal) right SVC and, in either circumstance, provides an interatrial communication by means of the coronary sinus (coronary sinus atrial septal defect).

The coronary sinus may be entirely absent in an otherwise normal heart, although this is quite unusual. More commonly, the coronary sinus is absent in the lateralization abnormalities, most frequently with right isomerism. In addition, the coronary sinus may be small and underdeveloped with the predominance of the venous drainage of the coronary system through the minor venous channels directly into the right atrium and right ventricle.

Although stenosis or hypoplasia and agenesis of the coronary sinus are well tolerated as a developmental anomaly, acute closure or narrowing of the structure with a sudden rise in cardiac venous pressure is associated with myocardial edema and may be implicated in myocardial dysfunction. It has, however, been difficult to document whether the lateral tunnel approach to the Fontan procedure, which leaves the coronary sinus draining into the lower pressure atrium, carries any functional benefit. Narrowing or obstruction of the coronary sinus should be guarded against, and preferably one should avoid leaving the coronary sinus in an acutely increased venous pressure situation such as the classic right atrium-to-pulmonary artery connection with the Fontan procedure.

Coronary sinus diverticula and aneurysms have also been described. They are often associated with accessory atrioventricular pathways and consequently with arrhythmias.

The most important anomaly of the coronary sinus is related to its enlargement because of flow increases caused by a left SVC connection or by an anomalous pulmonary venous connection. The latter is addressed in a later chapter as one form of anomalous pulmonary venous return. The dilated coronary sinus should alert the surgeon to these possibilities.

ANOMALIES OF THE VALVES OF THE VENOUS SINUS

A consideration of the morphogenesis of the valves of the sinus venosus is fundamental to the understanding of atrial anatomy and the systemic and pulmonary venous connections to the atrial mass. Involution of the right venous valve leaves remnants we recognize as the thebesian and eustachian valves, guarding the coronary sinus and the IVC, respectively. Failure of various degrees of the involution process may leave harmless remnants we recognize as a Chiari network in the right atrium or may produce a fully developed membrane that

![Fig. 76.6. Persistence of the right atrial venous valve (cor triatriatum dexter). ASD, atrial septal defect; LA, left atrium; MF, membrane fenestration; MV, mitral valve; PFO, patent foramen ovale; RA, right atrium; RAP, right atrial partition (persistent venous valve); TV, tricuspid valve.]
right side of the heart, or a pedunculated right atrial tumor. We have resected three of these interesting lesions, each of which occurred without associated cardiac abnormalities other than patent foramen ovale. They provide interesting echocardiographic findings for the cardiologist and may produce long-term problems with trauma to the tricuspid or pulmonary valves. It has been speculated that they may cause arrhythmias because of their movement throughout the right heart system in addition to progressive interference with systemic venous return and may be associated with thrombus formation. These structures should be removed when identified.

**EDITOR’S COMMENTS**

Anomalies of systemic venous return to the heart are often ignored in texts on congenital heart abnormalities. Although the majority of systemic venous return abnormalities are of no particular physiologic consequence, an understanding of venous anatomy and development and the variations of venous connections to the heart is critically important for congenital cardiovascular surgery in which cavopulmonary anastomoses and separation of pulmonary and systemic venous return are required, as in the Fontan operation.

As noted in the chapter, the most common venous anomaly is a left SVC that drains into the coronary sinus into the systemic venous atrium. This venous anomaly, although physiologically unimportant, can have significant consequences if unrecognized at the time of cardiac operation. It is possible to snare the left SVC temporarily, especially with the use of vacuum-arrested venous drainage, simplifying cannulation during cardiac repair. In complex anomalies, we have used circulatory arrest to avoid having to separately cannulate the LSVC. Although the presence of a left SVC entering the coronary sinus was thought to complicate cardiac transplantation, in fact, the vein can be left in situ and cardiac transplantation performed in the usual manner with only minor modification, as described in Chapter 99 on Pediatric Cardiac Transplantation. One problem we have seen on occasion with a left SVC entering the coronary sinus in patients who have elevations of right atrial pressure and pulmonary hypertension is the presence of a dilated coronary sinus, which can impinge on the wall of the left atrium and create what appears echocardiographically and functionally to be a cor triatriatum with limitation of free flow from the pulmonary venous confluence across the mitral valve. The mitral valve may also be relatively small in these patients. This abnormality has on occasion resulted in exploration of the left atrium at the time of cardiac repair without finding any abnormality of the left atrium. The coronary sinus, when decompressed on bypass with the heart under cardiopulmonary arrest, eliminates the ridge seen on echocardiography, and the defect can be quite obscure.

As is apparent from the summary presented in this chapter, knowledge of the possible venous connections to the heart and recognition that the venous drainage must be identified at the time of atrial repairs and cavopulmonary connections are important for the management of children with congenital heart disease. Minor unrecognized systemic venous connections after cavopulmonary anastomoses can create decompression of the SVC and result in significant arterial desaturation. Thus, in patients with cavopulmonary anastomoses in whom significant desaturation is noted postoperatively, a search in the catheterization laboratory for other systemic venous pathways to the atrium should be undertaken and coil embolization performed to eliminate these decompressing channels. In spite of the theoretical need to ligate the azygos vein in patients who undergo SVC-PA anastomosis or a hemi-Fontan procedure for single ventricle, we have found in many patients that the azygos vein can be left open without producing significant desaturation despite relative elevation of superior vena caval pressures. Thus, it would appear that development of significant systemic venous collaterals to the left or right atrium in patients with cavopulmonary anastomoses is likely related to elevated resistance to pulmonary blood flow.

The authors noted that there are often abnormalities of coronary sinus drainage in patients with lateralization abnormalities. On occasion, the absence of the coronary sinus can be associated with direct drainage of the major cardiac veins into the right atrium from the epicardial surface. In these situations, care must be taken not to divide these veins when performing a right atriotomy for access to the intracardiac lesions. Often these patients have associated left juxtaposition of the atrial appendages, which makes the right atrial wall smaller than normal and limits access to the right side of the heart.

Perhaps the major surgical issue with anomalies of systemic venous return is the situation of a left superior vena cava that enters the left atrium directly. In these cases, it may be difficult to reconnect the left superior vena cava to the right atrial chamber. As outlined in the chapter, various techniques have been described including detachment of the left superior vena cava and anastomosis to the right superior vena cava, recreating

(continued)
an innominate vein. Often, however, the size of the great arteries and space limitations in the superior mediastinum prevent there being enough length for this reconstruction to be accomplished without tension. Other approaches have involved detaching the left superior vena cava and reattaching it to the dome of the right atrium or right atrial appendage if there is no compression in the pulmonary artery or aorta. In some cases, it may be possible to create an intra-atrial baffle that redirects the flow from the superior vena cava as it enters the roof of the left atrium over to the right side of the heart either with the use of prosthetic patch material or by imbricating left atrial tissue to create a conduit. In situations where there is left juxtaposition of the atrial appendages, we have found it useful to divide the left superior vena cava and then anastomose it to the appendage of the right atrium, which is now on the left side, adjacent to the left superior vena cava. In situations where the left superior vena cava cannot reach the right-sided structures adequately, there have been reports of ligation of the left superior vena cava without serious sequelae, although at least transient left facial and arm edema is often present and chylothorax may be a problem. In situations of single ventricle or if the pulmonary artery pressure is expected to be low, another alternative is to perform a left bidirectional Glenn shunt, which allows the left superior vena caval flow to go directly to the pulmonary arteries.

It is particularly important to understand the systemic venous anomalies when dealing with patients with lateralization abnormalities (heterotaxy syndromes). In patients with interrupted inferior vena cava and azygos or hemi-azygos continuation, creation of the Kawashima-type connection between the vena cava and pulmonary artery can result in maldistribution of hepatic blood flow such that arteriovenous malformations in the lung can be prevalent. The hepatic veins generally have to be redirected into the pulmonary vascular bed; however, if directed on the side opposite the Kawashima connection, most of the hepatic flow may be pushed to the ipsilateral lung. In this situation, patients may return with progressive cyanosis despite an otherwise good functional Fontan result. There has been increasing interest in the use of computational fluid dynamic modeling with MRI to redesign the Fontan pathways to maximize flow distribution in these patients. In some cases, it may be advisable to connect the hepatic veins to the retrocardiac inferior vena cava or azygos vein such that the large return to the pulmonary arteries is distributed equally to both lungs. In other cases, use of a Y-graft may distribute hepatic flow into the right and left pulmonary arteries to optimize flow distribution.

While the modification of the Fontan operation with the use of an extracardiac conduit leaves the coronary sinus in a low-pressure system and therefore should not result in significant elevation of coronary sinus pressure, there have been situations where lateral tunnel connections have left the coronary sinus in the systemic venous aspect of the repair. This has resulted in some cases in progressive dilation of the coronary sinus with potential decompression into epicardial coronary veins, which ultimately can find their way back to the left-sided atrium and result in cyanosis. Thus, in most cases the coronary sinus should be carefully left in the low-pressure side of the Fontan circulation to avoid these potential problems.

TLS
DEFINITION
The ductus arteriosus is a vascular communication between the systemic and pulmonary vasculature, usually between the isthmus of the aortic arch and the origin of the left pulmonary artery, which forms a vital part of the fetal vascular anatomy. Normally, the ductus arteriosus arises from persistence of the distal portion of the embryonic sixth aortic arch.

FETAL CIRCULATION
In the fetus, the lungs are not ventilated and pulmonary resistance is high. The majority of relatively desaturated venous blood from the superior vena cava returning to the right ventricle passes through the ductus arteriosus into the descending aorta, whence some of it exits the fetal body through the umbilical artery to be oxygenated by the placenta. The ductus arteriosus is normally strategically positioned so that this desaturated blood does not travel to organs with the greatest oxygen metabolism (the brain and myocardium). After birth, pulmonary gas exchange commences and the circulation is “in series.” With the ductus arteriosus no longer essential, spontaneous closure normally occurs in hours to a few days after birth.

MECHANISMS OF SPONTANEOUS DUCTAL CLOSURE
Ductal closure occurs in two stages. The first is functional closure, occurring within the first 6 to 15 hours after birth. This stage results from medial smooth muscle constriction, promoted by four principal factors: (1) increase in arterial oxygen tension, (2) decrease in circulating prostaglandin E2 (PGE2), (3) decrease in mean ductal blood pressure, and (4) decline in the density of PGE2 receptors in the ductal wall. Part of the oxygen dependence is intrinsic to the specialized smooth muscle cells. The second stage (anatomic closure) is usually completed in a few days to weeks after birth and results from (1) subendothelial deposition of extracellular matrix, (2) resorption of the internal elastic lamina and elastin fibers in the media, and (3) migration of undifferentiated smooth muscle cells into the subendothelial space. The ductus closes from the pulmonary end toward the aortic end, often leaving a “ductal ampulla” seen on echocardiography. The resulting non-patent ductus is then called the ligamentum arteriosum. The patent ductus arteriosus (PDA) is defined as persistent patency of the fetal ductus arteriosus beyond its normal time of spontaneous closure.

RISK FACTORS FOR PATENT DUCTUS ARTERIOSUS
Any pathology that alters the molecular mechanisms of normal ductal closure may result in PDA. By far, the most frequently encountered risk factor for PDA is prematurity. The incidence of PDA increases with lower birth weight and estimated gestational age (EGA), reaching 77% at EGA 28 weeks. Circulating PGE2 activity is greater in the preterm infant than in the full-term infant, promoting persistent ductal patency, presumably because PGE2 is completely metabolized with first pass through the mature lung but incompletely in the premature lung. The risk for PDA is further increased with infant respiratory distress syndrome (RDS). Ninety percent of babies with RDS and <32 weeks EGA have PDA.

PATHOPHYSIOLOGY, CLINICAL MANIFESTATIONS, AND DIAGNOSIS

Premature Neonates
In premature neonates, the normal decrease in pulmonary vascular resistance with time leads to a left-to-right shunt, which results in pulmonary vascular overcirculation and an excess volume load on the left ventricle. If the shunt is large, clinically significant congestive heart failure can develop, leading to compromised pulmonary function and systemic cardiac output. Findings include pulmonary congestion, tachypnea, ventilator dependence, peripheral edema, and poor organ and tissue perfusion.

Lung immaturity confounds the relationship between PDA and these clinical manifestations. Pulmonary dysfunction may be due to RDS and bronchopulmonary dysfunction (BPD) and difficult to separate from the clinical effects of pulmonary overcirculation. Necrotizing enterocolitis may be related to microbial effects rather than to PDA. Discriminating the underlying causes has proven to be very difficult. Until an evidence-based guide to clinical impact is developed, McNamara and Sehgal have proposed a combined clinical and echocardiographic staging system for determining the “importance” of the hemodynamically significant PDA in the premature neonate, described in Table 77.1.

Full-Term Infants and Children
As in premature newborns, the principal pathophysiology of PDA is a left-to-right shunt leading to congestive heart failure. With large shunt, infants manifest failure to thrive, upper respiratory infections, and fatigue with exertion (including feeding). Physical examination shows a continuous “machinery murmur” in the left second intercostal space, bounding pulses, an overactive precordium, wide pulse pressure, and enlarged liver. Chest film shows increased vascular markings, interstitial edema, and enlarged cardiac silhouette. Echocardiography demonstrates the ducatal and aortic arch anatomy, direction of flow, and evidence of chamber dilatation.

With a large shunt present for a sufficiently long time (but as little as 6 months), pulmonary vasculopathy may develop. Patients will have symptoms consistent with pulmonary hypertension (PAH). They may exhibit differential cyanosis due to
flow reversal in the PDA. Echocardiography will confirm bidirectional or right-to-left flow in the PDA. With progressive vascular injury, PAH becomes irreversible, leading to Eisenmenger’s syndrome. Cardiac catheterization is indicated for any patient with PDA with clinical or echocardiographic suspicion of PAH.

PDA with a small left-to-right shunt may be asymptomatic and produce no chamber enlargement. Even smaller PDAs may lack an audible murmur (so-called “silent ductus”) and are found incidentally on echocardiography or contrast studies.

In Adults

Adults with small, restrictive PDA may be asymptomatic and show no other pathological findings. Adults with anatomically large PDA may show signs of congestive heart failure or they may present with symptoms and signs of PAH or Eisenmenger’s syndrome, as described above. Rarely, an adult may present with infective endocarditis, ductal aneurysm, aortic or pulmonary aneurysm, or aortic dissection. Chest film and echocardiography may demonstrate calcification of the ductus.

**Table 77.1** Representative “Staging System” for Determining the Magnitude of the Hemodynamically Significant Ductus Arteriosus Based on Clinical and Echocardiographic Criteria

**Children and Adults**

The spontaneous closure rate in children >1-year old is about 0.6% per year. Among patients with significant sized PDA, the overall mortality in older patients with PDA at 0.49% per year (for age 2 to 19 years) and 1.8% per year (for age >20 years), 30% are dying from congestive heart failure. Patients with large, untreated PDAs that progress to severe PAH have survival curve typical for that of Eisenmenger’s syndrome. The risk of bacterial endocarditis is very low in the antibiotic era but not zero, even with a “silent ductus.”

**TREATMENT**

**Historical Notes**

The first successful PDA ligation was performed on a 7-year-old girl by Robert...
Edward Gross (1905 to 1988) on August 26, 1938. The history, along with some legend, is detailed by Alexi-Meskishvili and Böttcher. In 1966, Werner Porstmann (1921 to 1982) was the first to close a PDA by catheter technique. In 1976, Heymann, Rudolph, and Silverman first reported the use of indomethacin to close PDA in premature infants.

**Indications for Treatment**

**Premature Neonates**

The staging system proposed by McNamara and Sehgal (Table 77.1) is a reasonable guide to therapy—a “C3E4” patient would certainly be recommended for PDA closure in most neonatal centers. Most commonly, such a baby has (1) a large PDA with a large shunt, (2) refractory or worsening ventilator dependence and/or poor tissue perfusion in the absence of some other dominating and reversible cause, and (3) has failed a trial of COX inhibitors. Babies with stage C4 are a very high-risk group and the decision to undergo surgical ligation should be based on careful discussions with the neonatologists and parents. PDA management in babies with stage less severe than C3E3 is subject to the most debate.

The surgeon should understand the basis for uncertainty in the indications for PDA closure in this population. The primary reason is that, despite at least 75 randomized-controlled trials of interventions to close PDA in premature infants, there is scant evidence that either prophylactic or therapeutic PDA closure, either by medical or by surgical means, improves any clinical outcome measure. Taken individually, each of these randomized-controlled studies had weaknesses—most were small studies (<100 subjects), many had “rate of ductal closure” as their primary outcome measure and cross-over rates were frequently high. Only 17 of the 75 trials were conducted after the advent, in 1989, of exogenous surfactant therapy. Benitz, in 2010, attempted a meta-analytic study of these trials. Such an approach mathematically narrows the confidence intervals of odds ratios for the chosen outcomes, but it widens the underlying variability of the covariates. The Cochrane Reviews apply more stringent criteria to selection of studies for meta-analysis, eliminating studies with significant methodological deficiencies. The reviewers found only one eligible study pertaining to prophylactic surgical ligation of PDA, which showed that ligation decreased the incidence of NEC but had no long-term effect on mortality or BPD incidence. Furthermore, the reviewers found only one eligible study pertaining to surgical ligation for the treatment of PDA, concluding that this study contained insufficient data to evaluate the effectiveness of the intervention. Thus, as of year 2011, there are no studies, properly designed and containing sufficient data that evaluate surgical ligation for the treatment of PDA in premature infants.

**Full-term infants:** In full-term infants >6 to 12 months old, occlusion of an audible PDA with left-to-right flow is reasonable. PDA occlusion is also indicated at any age when the PDA is moderate to large and produces congestive heart failure. Infants and children with PDA undergoing other cardiac or thoracic operations should undergo simultaneous PDA ligation.

**Children and Adults**

Beyond infancy, probably the spontaneous ducetal closure is low. Audible PDA with left-to-right flow should be occluded. Recommendations for PDA closure in adults are further described in the American College of Cardiology/American Heart Association 2008 Guidelines for Adults with Congenital Heart Disease (ACC/AHA).

**Contraindications to Treatment**

PDA should not be occluded in patients with PAH associated with significant pulmonary vascular obstructive disease (PVOD). At cardiac catheterization, if pulmonary vascular resistance index is greater than eight Woods units per meter squared and does not decrease with oxygen, nitric oxide, or other pulmonary vasodilators, then PDA closure is contraindicated. Indications for PDA closure in the presence of some reactivity of PAH are controversial.

In premature neonates, bidirectional flow in a PDA is not a contraindication to ligation. PDA should not be ligated as an isolated procedure in the presence of “ductal dependent circulation.” The treatment of an inaudible PDA is not contraindicated but is controversial.

**Medical Treatment**

COX inhibitors close PDA in premature neonates in about 70% of cases, a significantly lower success rate than the closure rate of surgical ligation. Complications are reported for all COX inhibitors, including ibuprofen, in this population. COX inhibitors are not effective in closing PDA beyond a few weeks of age.

**Catheter-Based Treatment**

Catheter-based occlusion of PDA is an acceptable method of treatment in some cases. The choice of device is often made on the basis of the classification of Krichenko et al. Gianturco or Flipper coils are generally deployed by the femoral artery approach and used for types D and E, or ductus <2 mm diameter. The Amplatz vascular plug IV is deployed usually via the femoral vein and is applicable for types C, D, and E. Finally, the Amplatz II occluder device (ADO) is usually deployed via the femoral vein and applicable for type A. In patients <10 kg, this device may obstruct the aorta. In large diameter or short PDA, the incidence of residual flow has been shown to be less with the ADO than with coils.

Complications of catheter-based PDA occlusion include femoral artery pseudoaneurysm, limb ischemia, device embolization, left pulmonary artery stenosis, endarteritis, radiation exposure risks, dye-induced renal dysfunction, residual ductal flow, device-related hemolysis, descending aortic obstruction, hemorrhage, need for transfusion, and failure to complete the procedure (Fig. 77.1). The precise incidences of these complications are not well known due to the paucity of published data from catheterization registries, multi-institutional studies, or Cochrane reviews. The incidence of device embolization is approximately 2% and that of residual flow is 1.4% to 7%. Hemolysis typically occurs with incomplete ductal closure, though it can also occur with complete occlusion. The incidence of complications during and after catheter interventions of all types has been estimated to be nearly 20%.

Experience with catheter-based PDA occlusion has extended to smaller infants and even premature neonates. Long-term outcomes were not determined in these series.

**Fig. 77.1.** Gianturco coils occluding the descending aorta after attempted coil occlusion of patent ductus arteriosus. The Doppler gradient was 40 mmHg. Through a lateral thoracotomy, proximal and distal aortic control was achieved, a short aortotomy made, and the coils removed. The PDA was doubly ligated.
Catheter-based closure of PDA is effective in adults and preferred in adults with calcified PDA or with significant other medical problems. Relative contraindications include the presence of ductal aneurysm or active ductal/pulmonary arterial endarteritis. Case reports of the use of covered aortic stents have recently appeared. This approach may be appropriate for the large or aneurismic ductus.

In infants and children, catheter-based PDA occlusion has been compared with open surgical ligation. Total complication rates are similar, but coil occlusion is less costly than open surgical ligation. In a single-institution matched cohort study by Dutta et al. comparing video-assisted thoracoscopic ligation (VATS) and coil occlusion, however, the total costs were not significantly different. The mean length of stay was 1.6 ± 0.2 days for VATS. With “same day discharge” following VATS PDA ligation, the cost difference has shifted in favor of VATS ligation. In 2011, Chen et al. published a study of 294 patients undergoing either Amplatzer device closure or VATS ligation. The complication rate was 1.5% in the VATS group and 10.2% in the catheter-based device closure group. The cost of VATS therapy was only one-third that of catheter-based closure. Thus, the current evidence shows that, for many patients with PDA, the catheter-based and VATS approaches are comparable in safety, effectiveness, and expediency, and VATS appears to be less costly.

**Surgical Treatment**

**Open Technique**

*Premature neonates:* Open ligation is the standard technique for premature neonates and can be performed in neonates as small as 350 g. These babies are often unstable. The risks of transport can be obviated by performing the procedure in the neonatal intensive care unit. Intraoperative and postoperative systolic ventricular dysfunction, hypotension, and decreased cerebral blood flow have been reported. These effects underscore the importance of expediency, minimal retraction on the lungs, avoidance of visceral pleural air leak, and meticulous hemostasis during the operation, and compulsive care postoperatively.

The situs of the ductus should be ascertained from the echocardiogram report. The patient is placed in the lateral decubitus position, prepped, and draped (Fig. 77.2). Adherent drapes should be avoided. A lateral thoracotomy incision, with minimal curvature, is made. Ideally, one can spare both the latissimus dorsi and serratus anterior muscles. The pleural cavity is entered through the fourth interspace, which is frequently identified as the first somewhat wider interspace just under the scapula. Even a slight injury to the lung surface during pleural opening may result in pneumothorax. A rib retractor is placed. Small rubberized malleable retractors, controlled by the first assistant, are used to retract the lung lobes.

Using low-power “needle point” cautery, a short pleural flap is mobilized, then planes just cephalad and just caudad to the ductus are developed with a Jacobson clamp, not cautery (Fig. 77.3A and 77.3B). Small cotton swabs can be used to facilitate dissection or blot minor bleeding should it be present. The clip applicator should be tested on the drape, as scissoring can tear the duct. Depending on ductal size, one “medium” or “medium-large” hemoclip is applied to the aortic end of the ductus (Fig. 77.3B). If the ductus is sufficiently long, a second clip can be applied, being careful not to overlap the first clip, by mild retraction of the descending aorta.

If the ductus tears during mobilization or ligation, one should use a cotton swab to apply direct pressure to the site, maintaining flow to the pulmonary artery and aorta, until blood is available. After sufficient time, removal of the cotton swab usually does not result in immediate bleeding. At that point, hemoclips can generally be applied to achieve hemostasis and ductal closure. Alternatively, one can obtain proximal and distal control of the aorta with clamps or tourniquets before ligating the duct with prolene suture or clips.

If hemostasis is good, the lung retractors are immediately released to allow full ventilation. The blood pressure may
transiently decrease after ligation due to the acute increase in left ventricular afterload, but it usually recovers within minutes. With large PDA, the diastolic blood pressure should rise after this transient effect. Often, with moderate-sized PDA, one does not see a significant change in blood pressure acutely. A pleural drain should be avoided if (1) the lung surface was not violated during the procedure and (2) there is no residual bleeding or evidence of lymphatic leak. If necessary, a 5-F pigtail catheter is sufficient for a drain. Any hemodynamic or respiratory instability immediately following the procedure should prompt immediate auscultation and transillumination of the chest by a neonatologist, as pneumothorax is the most common cause. This complication can be treated with needle aspiration or percutaneous placement of a drain. A postprocedure chest film is always obtained. 

**Full-term infants and children:** The open surgical procedure is similar to that of premature neonates, with some modifications. After cephalad and caudad dissection, a right angle clamp is used to bluntly dissect under the ductus and is then used to pull through one or two silk or Tevdek ties. The ductus can then be doubly ligated with two ties, or one tie and a hemoclip (Fig. 77.4). If the ductus tears during dissection or ligation, bleeding should be immediately controlled with a cotton tip or sponge stick while blood is made available. Proximal and distal control of the ductus should be obtained with clamps, and the ductus divided and the ends securely oversewn, as described below. 

![Fig. 77.4. Open ligation of PDA. Note two ties that have been passed under the ductus. The first one is being tied with traction of the other.](image)

A very large and/or short ductus should be divided. After mobilization, a partially occluding clamp is placed across the ductal origin. Alternatively, proximal and distal clamps may be applied on the aorta. Then, a straight, toothed Potts clamp is applied across the pulmonary artery end of the ductus. The ductus is divided and each end oversewn with doubly run prolene suture (Fig. 77.5).

**Adults:** The ductus is frequently thin-walled and calcified, typically on its aortic end, in adults. Evidence of calcification should be sought by echocardiography or computerized tomography. If the ductus has some length and is not calcified, the standard approach described above can be taken. If the ductus is heavily calcified or is very short, the transpulmonary approach, using a median sternotomy and cardiopulmonary bypass, should be taken. Under moderate hypothermia and reduced flow, the pulmonary artery is opened and the ductal orifice is closed with a polytetrafluoroethylene patch. Fogarty balloon occlusion of the orifice may facilitate patch placement. Circulatory arrest should not be required.

**VATS Ligation With and Without Robotic Assistance**

The technique of VATS PDA ligation is described by Laborde, Burke, DeCampli, and Nezafati et al.

**Premature neonates:** Burke performed VATS PDA ligation in a series of premature neonates <800 g weight. He used a 2.7-mm 30-degree angle thoracoscope. Hines et al. performed VATS PDA ligation in 100 preterm infants with a weight range of 420 to 1,500 g.

**Full-term infants, children, and adults:** VATS PDA ligation can be performed in young infants as well as adults. This approach is suitable for small to moderate-sized ductus. “Giant ductus” or “AP window-type” ductuses are best repaired with an open technique.

The preoperative echocardiogram should be inspected to note the position of the ductus. This will minimize the need for dissection to search for the ductus. Selective lung ventilation is preferred. In infants, a cuffed single-lumen tube can be advanced into the right mainstem bronchus. In older children and adults, a double lumen tube, or a single-lumen tube with a left mainstem bronchial blocker can be used. Single-lung ventilation should be instituted well ahead of the incision time to allow time for lung collapse. Instruments should be available for full thoracotomy, in case conversion is necessary. A unit of blood should be available. The procedure is described in Figures 77.6 and 77.7. At the completion of the ligation, hemostasis is checked. A transesophageal echocardiogram is obtained prior to completion of the procedure so that residual flow can be secured with an additional clip if needed. The instruments are withdrawn and an 8-F pigtail catheter...
layers with absorbable suture. If there is no evidence of pneumothorax or air leak, the lung is re-expanded under camera guidance. The wounds are closed in layers with absorbable suture. If there is no evidence of pneumothorax or air leak, the drain is removed in the recovery room. The patient is discharged home a few hours later.

If bleeding is encountered during the VATS procedure, and especially if ductal tear is suspected, the procedure should be converted to open. Generally, three or four of the port incisions can be joined together and a thoracotomy performed. A sponge stick can be used through one port to control bleeding while this is done.

Robotic-assisted VATS: DeCampli, at The Children’s Hospital of Philadelphia, used AESOP (ComputerMotion, Inc., Santa Barbara, CA), a voice-controlled robot arm, to manipulate the thoracoscope, as described in Figures 77.6 and 77.7. Suematsu et al., at Boston Children’s Hospital, used the Da Vinci System (Intuitive Surgical, Sunnyvale, CA) to perform nine PDA clip ligation procedures. The grasper was controlled by the left robotic arm and the cautery tip by the right robotic arm. All patients did well. These cases comprised an intriguing proof of concept that with future improvements in technology may someday allow for superior surgical precision.

COMPLICATIONS OF SURGICAL THERAPY

Premature Neonates

Complications of surgical PDA ligation include pneumothorax, chylothorax, bleeding, aortic obstruction, pulmonary artery obstruction, residual flow, vocal cord dysfunction, wound infection. Treatments of some of these complications are discussed in the prior section. Perhaps the most common, and potentially serious complication is injury to the recurrent laryngeal nerve, resulting in unilateral vocal cord paralysis (VCP). In series published since 2008, the incidence in premature infants ranges from 4.8% to 67% (24% to 67% in infants <1,000 g at the time of closure). Clement et al. showed that, as compared with matched controls without VCP following PDA ligation, infants with VCP require longer duration of tube feeding (relative risk 9.0; P = 0.003), supplemental oxygen, ventilator support, and hospital stay. Benjamin et al. showed that infants with VCP are more likely to develop BPD (82% vs. 39%; P = 0.002), reactive airway disease (86% vs. 33%), and need for gastrostomy tube feeding (63% vs. 6%). Truong et al. examined the rate of recovery of VCP in patients undergoing cardiac surgery. They found that among 80 patients who were followed up for a minimum of 3 months after injury, 35% recovered function at median time of 6.6 months and 65% of patients had persistent VCP at median follow-up of 16.4 months. Forty-five percent of patients demonstrated evidence of aspiration and 27% of patients required intervention for feeding difficulties.

Clearly, VCP represents a frequent and serious complication of PDA ligation. The risk increases with lower weight. The risk does not seem to depend on method of ligation (clip vs. ligature). The complication may explain the observed increased incidence of BPD after surgical ligation and may be largely responsible for the failure of studies to show a clear benefit of PDA ligation in the overall outcomes of premature neonates.

Roclawski et al. showed that among 38 patients following PDA ligation, the incidence of scoliosis was 55%, compared with 16% in a matched control. In those with scoliosis, the curve was thoracic in 76% and left-curved in 57%. The magnitude ranged from 10 to 42 degrees.

Some authors have suggested an increased risk of retinopathy of prematurity and neurosensory impairment at 18 months of age in premature infants undergoing PDA ligation. The principal study, however, was observational, the control group was not matched, and covariates were not accounted for in the analyses.

Full-Term Infants and Children

In older infants and children after PDA ligation, reported incidences of residual flow range from 0% to 8%, chylothorax range from 0.2% to 4%, and VCP of 0% to 12%. Aortic obstruction or left pulmonary artery obstruction, presumably due to impingement or misplacement of the ligature or clip, has been reported but occurs rarely.

Adults

Jatene et al. reported on 34 adult patients (aged 18 to 53 years) undergoing open PDA ligation between 1997 and 2008. Only one patient required cardiopulmonary bypass. Eight patients had ductal calcification, and 12 patients had a prior attempt at catheter device closure. Twenty-five patients had ligation and division, eight patients had ligation alone, and one required an aortic patch. Complications included dysphonia (14.7%), hemorrhage (8.8%), residual flow (5.9%), and pneumothorax (5.9%). Three of the patients with dysphonia had documented VCP (one permanent). The authors felt that a risk factor for VCP was a ductus diameter >10 mm.

CONCLUSIONS

Moderate-to-large PDA can cause congestive heart failure and, later, PVOD. Any PDA presents a persistent risk of endocarditis or, rarely, aneurysm. The vast majority of PDAs should, therefore, be closed.

In children, options for closure include catheter-based device placement and surgical ligation. Catheter-based and VATS approaches are comparable in safety, effectiveness, and expediency, but VATS may be less costly.

Fig. 77.6. Videoscopic (VATS) PDA ligation, here with robot assistance. Port incisions are made at the third interspace at the anterior axillary line (#1), fourth interspace at the mid-axillary line (#2), fifth interspace just anterior to the scapular tip (#3), and sixth interspace posterior to the scapula (#4). In this procedure, the lung retractor, grasper, camera (here robot manipulated using voice control), and cautery are placed through ports #1, 2, 3, and 4, respectively. The surgeon should be flexible and may move the relative port locations of the instruments during the procedure. With the lung retractor fixed on a bar, the procedure can be performed by a single surgeon.

Chapter 77: Patent Ductus Arteriosus

793
The effect of PDA ligation, and its comparison with COX inhibitor therapy, on outcomes of very premature infants has not been studied adequately. In infants with signs attributable to congestive heart failure, surgical ligation is a reasonable therapeutic measure as it will completely eliminate the cause of congestive heart failure due to the left to right shunt. VCP is a serious complication of surgical PDA ligation in premature infants, and its avoidance should be compulsively addressed by every surgeon performing the procedure.

PDA closure in adults should generally be performed with catheter-based devices, especially in the presence of calcification. Large, short, calcified or infected ducts that cannot be closed with a device should be closed with a patch through the pulmonary artery using cardiopulmonary bypass.

**SUGGESTED READINGS**

Caplin JL, Dymond DS, Barrett DS, et al. Pulmonary mycotic aneurysms secondary to...

Because the ductus arteriosus is a normal fetal structure representing the left sixth aortic arch, persistent patency of the ductus arteriosus is one of the most common congenital heart defects. Ductal patency seems to be more common in girls, and persistent ductal patency occurs in approximately 1 in 2,000 term births. In premature infants, ductal patency is common. By 1 year of age, only about 1% of ducts remain open, and after 1 year of age, <1% per year spontaneously close. Thus, persistent patency of the ductus arteriosus at 6 months to 1 year of age is generally considered an indication for ductal closure. Certainly, ducts that are large, producing significant left-to-right shunts with congestive heart failure symptoms should be closed promptly.

As discussed in this chapter, the approach to ductal closure remains controversial. Although the incidence of endarteritis associated with ductus arteriosus is low, the occurrence of this problem even in clinically silent ducts (Balzer D, Spray TL, Cantor CE, Strauss AW. Endarteritis associated with a clinically silent patent ductus arteriosus. Am Heart J 1993;125:1192.) suggests that ductal closure should be effected in all patients including those with a clinically silent duct.

Coil occlusion techniques are being used increasingly for ductal closure and have the advantage of avoiding chest incisions and direct dissection of the ductus with attendant risks of recurrent nerve injury or bleeding; however, these techniques are limited somewhat by vascular access in very small children, and in very large ducts, coils may embolize or be difficult to place without protruding into the pulmonary artery or aorta. In addition, an inadequately closed ductus with a metallic foreign body and the attendant potential risk of late endarteritis remains a concern with this technique. If, however, complete ductal closure can be effected with coil occlusion, there appears to be no disadvantage to this approach. Certainly, adults with calcified ducts have a significant enough risk from operative intervention that transcatheter occlusion should be considered, especially in younger patients if at all possible. In older patients, the incidence of vocal cord paralysis is relatively large and the morbidity higher, and therefore, transcatheter closure should be considered.

Surgical closure of the ductus arteriosus with clips or simple ligatures has been associated with recanalization rates as high as 20% to 25% in some series (Sorenson KE, Kristensen BO, Hansen OK. Frequency of occurrence of residual ductal flow after surgical ligation by color flow mapping. J Am Coll Cardiol 1991;67:653.). Therefore, despite documented complete closure after thorascopic ductal ligation with clips, recanalization must be considered a relative risk. Certainly, the gold standard for ductal occlusion with the lowest incidence of recanalization is ductal division, although the technical aspects of ductal division require larger incisions and more complete control of the vessel before division. Longer follow-up on the use of transcatheter occluder devices and clip ligation with the thorascopic technique should address the issue of late recanalization and residual patency before these techniques completely supplant open division, especially for the significant-sized ductus arteriosus. Ligation of the ductus arteriosus through a median sternotomy incision is relatively simple, although it is very important to identify the origin of the duct just beyond the take-off of the right pulmonary artery and to adequately dissect the groove between the ductus and the left pulmonary artery before the duct is mobilized for ligation.

As nicely described by Dr. DeCampili, there has been increasing recognition that studies have not clearly identified a benefit of ductal ligation in premature infants with respiratory insufficiency. The limitations of these studies have been well described; however, there has been a relative decrease in the referral of premature infants for duct ligation based on this accumulating body of data. It is interesting, however, that some studies have suggested a lower incidence of necrotizing enterocolitis after duct ligation, which maybe of particular benefit to these infants. It is unclear why the incidence of vocal cord paralysis is so high in patients after PDA ligation. Sweeping the recurrent laryngeal nerve away from the ductus is relatively straight forward in these patients, although clip ligation often leaves the tip of the clip obscure as it is being applied, and it potentially could impinge upon the recurrent laryngeal nerve as it passes behind the ductus and out of the visual field. Surgeons have been increasingly cognizant of this concern and I suspect that the incidence of vocal cord paralysis is somewhat diminished in more recent experience, especially with better visualization techniques as described in this chapter.

The issue of ductal recanalization is a significant one. The use of metallic clips, especially double clip ligation, seems to decrease the risk of this complication, but simple ligation and even simple clip application have been associated with recanalization rates that are not insignificant. In addition, residual or recurrent ductal patency has been shown in catheter-based techniques in a frequency that is not dissimilar to that recorded in surgical series.
**Vascular Rings, Slings, and Other Arch Anomalies**

Christopher E. Mascio and Erle H. Austin

### HISTORICAL ASPECTS

Recognition of anomalies of the aortic arch and pulmonary artery began in 1737 when Hommel first described a double aortic arch. Fifty-seven years later, Bayford discovered an aberrant retroesophageal subclavian artery in a patient with a history of dysphagia. He called the anomaly a “lusus naturae,” or “prank of nature,” and coined the term “dysphagia lusoria” to describe the symptoms. The first surgical correction of a double aortic arch was performed by Gross in 1945 on a 1-year-old boy with chronic wheezing. The pulmonary arterial sling anomaly was described by Glaevecke and Doehele in 1897 and was first repaired by arterial division with reimplantation by Potts in 1954.

### EMBRYOLOGY

By 5 weeks of fetal development, the primordial heart tubes have fused and six aortic (branchial) arches have formed between the ventral roots and dorsal aortae (Fig. 78.1). Migration and involution of the arches result in the complex system of the higher mammal. During normal development, persistence of the left fourth aortic arch forms the arch of the aorta between the left common carotid and left subclavian arteries. The right fourth aortic arch forms the proximal right subclavian artery. Involution of the distal right aorta results in an unpaired single aortic arch. Table 78.1 shows the fate of the remaining arches.

Failure of involution or migration of specific segments of the aortic arches results in anomalies that may form partial or complete vascular rings about the trachea and esophagus. The most common of these are diagrammed in Fig. 78.2.

Pulmonary artery development arises from two separate vascular sources: (1) the lung buds deriving their blood supply from the splanchnic plexus and (2) the proximal left and right sixth aortic arches (Fig. 78.3). Figure 78.4 demonstrates how abnormal migration of the separate blood supplies can result in dislocation of the left pulmonary artery posterior to the trachea, resulting in the pulmonary artery sling anomaly with its associated tracheal compression.

### CLASSIFICATION AND INCIDENCE

Aortic arch anomalies producing tracheoesophageal constriction account for 1% to 2% of all congenital heart defects. A simple and commonly used system of classifying these vascular anomalies is given in Table 78.2. The relative prevalence of these lesions in surgical series is also indicated.

**Group I: Complete Vascular Rings**

**Anatomy**

A double aortic arch (type IA) occurs when the right dorsal aorta fails to involute (Fig. 78.2), resulting in persistence of the right and left fourth aortic arches. The right aortic arch is most commonly dominant. The descending aorta is usually in its normal position on the left, as is the ligamentum arteriosum (or patent ductus arteriosus). Generally, each subclavian and common carotid artery arises independently from its respective aortic arch. The innominate vessels do not develop. Twenty percent of cases have other cardiac anomalies, with ventricular septal defect and tetalogy of Fallot being most common.

Type IB vascular rings (right aortic arch with retroesophageal ligamentum arteriosum) account for 45% of complete vascular rings. The majority of these defects have left descending aortas. A right aortic arch with retroesophageal left subclavian artery and ligamentum results from abnormal involution of the left fourth arch. A remnant or stump of the left fourth arch (Kommerell’s diverticulum) may persist. The left subclavian artery arises abnormally behind the esophagus from the right-sided arch or from Kommerell’s diverticulum.

Near this point, the left-sided ligamentum emanates and joins the left pulmonary artery to create a complete ring about the trachea and esophagus. Another variant of right aortic arch with left descending aorta is called the circumflex aorta. This variant is characterized as having a hypoplastic retroesophageal arch and a coarctation (Fig. 78.9A and 78.9B).

A right aortic arch may occur with mirror image branching with the left innominate artery arising anteriorly and dividing into the left carotid and subclavian arteries. If the ligamentum arteriosum occurs between the left innominate artery and the left pulmonary artery, as is commonly seen in association with tetalogy of Fallot, there is no vascular ring. Therefore, these patients are usually asymptomatic. However, when the ligamentum arises from the aorta behind the esophagus and connects with the left pulmonary artery, a compressive vascular ring is formed.

A rare variant among vascular rings is the cervical aortic arch, in which case the arch exists in the neck above the clavicle, sometimes as high as the C2 vertebral body. There are two main subtypes. The first and the larger group are type IB anomalies with a right-sided arch, an anomalous left subclavian artery, and a retroesophageal ligamentum arteriosum. The second group has a left-sided arch with a normal branching pattern and thus does not form a complete ring. These anomalies are thought to result from a failure of the normal descent of the aortic arch from its cephalic location at 3 weeks to its intrathoracic location at 7 weeks of gestation.

**Clinical Presentation**

The clinical presentation of vascular rings can vary from mild dyspnea or dysphagia to respiratory distress and apnea. Signs and symptoms often depend on the type of anomaly.

A double aortic arch produces the earliest and most severe symptoms as a result of the presence of a tight ring around
Fig. 78.1. Normal aortic arch development. The normal aortic arch arises from the persistence of the left fourth embryologic arch. Note that the recurrent laryngeal nerve recurs about the derivative of the sixth embryologic arch on the left, that is, the ductus arteriosus, and the derivative of the fourth embryologic arch on the right, that is, the right subclavian artery. This occurs because of the normal involution of the right sixth embryologic arch. a., artery; Ao, aorta; car., carotid; com., common; Duct. art., ductus arteriosus; Esoph., esophagus; ext., external; int., internal; L., left; LPA, left pulmonary artery; n., nerve; PA, pulmonary artery; R., right; Rec. laryn. nn., recurrent laryngeal nerves; RPA, right pulmonary artery; subcl., subclavian.

the trachea and esophagus. Seventy-five percent of affected patients develop symptoms by 1 year of age, often within the first month of life and rarely after 6 months of age. Stridor, a nonproductive cough, or a hoarse cry may be noted soon after birth. The stridor generally worsens with feedings, especially solid foods. The cough is characterized as a “seal bark” or “brassy cough.” Respiratory distress can lead to choking, cyanosis, and apnea. Vomiting may precede or follow choking. Despite the esophageal compression, most infants with double aortic arch tolerate liquids well and appear well fed.

When tracheoesophageal compression results from a right aortic arch and a retroesophageal ligament, symptoms are similar in nature but are usually less severe and present later in infancy or in early childhood. These rings are generally less stenotic and become notable as the aorta grows.

Those with a right arch and left descending aorta (circumflex aorta) may present with murmur, upper extremity blood pressure differential, exertional dyspnea, and/or chest pain.

Patients with cervical arches are usually asymptomatic but may present with a pulsatile mass in the neck or the

### Fig. 78.2. Vascular rings most frequently requiring surgical intervention and their embryologic development. Kommerell's diverticulum is a remnant of the involuted left fourth aortic arch, which may be the origin of the ductus (ligamentum), the left subclavian artery, or both. a., artery; Ao, aorta; L. ext. car. a., left external carotid artery; L. int. carotid a., left internal carotid artery; LCCA, left common carotid artery; Lig. art., ligamentum arteriosum; LSA, LSCA, left subclavian artery; PA, pulmonary artery; PDA, patent ductus arteriosus; RCCA, right common carotid artery; RSA, RSCA, right subclavian artery; roman numerals refer to embryologic aortic arches.
supraclavicular fossa. Infants with the type IB anomaly may also exhibit the compressive symptoms of dyspnea and stridor. Adults more commonly present with dysphagia. Some adults have presented with central nervous system symptoms and the subclavian steal syndrome as a result of stenoses of the left subclavian artery and origin of the vertebral artery.

**Diagnosis**

A vascular ring may be suggested on chest radiography by the presence of a pulmonary infiltrate, atelectasis, or unilateral or bilateral hyperinflation. The presence of a right aortic arch should raise suspicion.

Barium esophagogram remains a useful diagnostic measure. In cases of double aortic arch, the lateral view will reveal a posterior indentation in the esophagus. In the anterior projection, there are dual indentations, higher on the right and lower on the left. An aberrant right subclavian artery from a left aortic arch will also produce posterior esophageal indentation on the lateral view. On the anterior view, however, the aberrant right subclavian artery takes an oblique course descending left to right. The aberrant retroesophageal left subclavian artery from a right aortic arch will show a similar posterior indentation on the lateral view, but the oblique course on the anterior view runs in the opposite direction: from right to left. A circumflex aorta (right arch and left descending aorta) will have an impression on the right side of the esophagus on the anterior view and a deep, posterior indentation on the lateral view.

Historically, the clinical presentation and barium esophagogram have provided sufficient information to proceed to surgical treatment. The increasing availability and sophistication of magnetic resonance imaging (MRI) and computed tomography (CT), however, have elevated these noninvasive imaging techniques to the preferred diagnostic modality at most institutions. Both modalities provide detailed and complete depiction of the anatomy and compressive effects of a vascular ring. MRI, however, is expensive and requires sedation in the younger patients who are at the greatest risk from airway compression. Without sedation, motion artifacts frequently result in poor image quality. Traditional CT scanning with three-dimensional reconstruction can also provide excellent images.
but is limited by the need for intravenous contrast and exposure to radiation and may also require sedation for adequate imaging. Rapid, multislice, helical CT scanning (if available) permits rapid scanning with significantly decreased radiation exposure. These scans can be done in <2 seconds in infants, obviating the need for sedation. Aortography is the most invasive technique and is rarely used. It can establish the completeness of a double aortic arch and identify areas of luminal irregularity. It cannot, however, distinguish between a double aortic arch with an atretic segment and a right aortic arch with a retroesophageal ligament. Trans-thoracic echocardiography is used to detect associated cardiac anomalies and is reasonably sensitive in evaluating vascular rings but appears deficient in determining atretic and nonluminal segments. Echocardiography is important in defining any other associated cardiac anomalies. As mentioned above, these are present in up to 20% of patients and are more common in association with right aortic arch (compared with double aortic arch).

Cervical arches may be suspected by the presence of a wide mediastinum, the absence of the aortic knob, and anterior tracheal deviation on chest radiography. Although angiography has been the standard for diagnosis, CT scanning and MRI now provide a noninvasive technique to confirm the diagnosis.

**Indications for Surgery**

Surgical correction of complete vascular rings is indicated when symptoms are present. There is no evidence that surgery has any benefit in the absence of symptoms, thus asymptomatic patients (children or adults) should not be exposed to the operative risk. Adults with minimal symptoms should be followed for significant progression prior to operative repair. Anomalies identified shortly after birth or within the first 6 months of life require surgical correction much more frequently than those discovered after the age of 6 months. Very mild symptoms presenting in the older infant or young child may resolve as the child grows. A watchful approach is appropriate in such cases.

**Surgical Technique**

Ninety percent of vascular ring cases can be corrected through a left posterolateral thoracotomy. Single-lumen general endotracheal anesthesia is applied.

**Double aortic arch:** In cases of double aortic arch, where flow is present in both arches, the dominant arch is preserved. Division is performed at the location on the ring that preserves the greatest brachial and cephalic flow. When an atretic segment of the vascular ring is present, division is performed at the atretic segment. Before vascular division, the carotid and radial pulses are monitored by the anesthesiologist to confirm flow after clamps have been placed.

After induction of general orotracheal anesthesia, the infant is placed in a full lateral position with the left side up (Fig. 78.5). Through a posterior lateral muscle-preserving incision, the left chest is entered through the third or fourth intercostal space. The lung is retracted anteriorly and inferiorly, exposing the posterior mediastinum. This position is retained with malleable retractors secured to the chest retractor with nonpenetrating towel clamps.
Section III: Congenital Cardiac Surgery

3-mm embryo
No bud develops on the left side
Bud from left lung primordium migrates to right side

Fig. 78.4. Anomalous development of the left pulmonary artery and formation of the pulmonary artery sling. When the splanchnic bud of the left pulmonary artery fails to fuse with the left sixth aortic arch, it migrates posteriorly between the trachea and esophagus to fuse with the right pulmonary artery. This results in a compressive “sling” about the trachea. Anom., anomalous; LPA, left pulmonary artery; RPA, right pulmonary artery.

The descending aorta, anterior (left) aortic arch, left subclavian artery, and the vagus and phrenic nerves are identified before the pleura is opened (Fig. 78.5). The vagus nerve descends anterior to the left subclavian artery, crossing the left aortic arch, giving off the recurrent laryngeal nerve as it penetrates into the mediastinum medially around the ligamentum arteriosum. The posterior (right) aortic arch may or may not be visualized initially depending on the extent of mediastinal fat.

The pleura is incised from the descending aorta inferiorly to the left subclavian artery, and then elevated from the mediastinum anteriorly and posteriorly with stay sutures. The vagus nerve is elevated off the mediastinum with the anterior pleural flap exposing the branching of the recurrent laryngeal nerve. If necessary, the vagus and recurrent laryngeal nerves may be mobilized with the posterior pleural flap to achieve better exposure of the proximal anterior arch and prevent nerve injury. This is similar to the exposure of a patent ductus arteriosus. The ligamentum arteriosum (or ductus arteriosus) is identified between the distal anterior (left) aortic arch and the left pulmonary artery. The ligamentum is sharply dissected out in its entirety in preparation for ligation and division in standard manner. The posterior pleural flap is gently elevated off the mediastinum. With this, the posterior (right) aortic arch becomes visible as it penetrates the mediastinum posterior to the esophagus and joins the left (anterior) aortic arch to form the descending aorta. Opening the pleura extensively in this manner will provide wide exposure to the mediastinal structures. The anterior arch is dissected to the level of the left common carotid artery. The left subclavian artery is mobilized distally toward the thoracic outlet. The posterior arch is fully isolated from its mediastinal attachments, and all adhesive bands are sharply divided. At this point, the narrowest portion of the vascular ring is identified. In most cases, the narrowest segment will involve the anterior (left) arch either between the left carotid and left subclavian arteries (Figs. 78.6 and 78.7) or between the left subclavian artery and the posterior (right) arch. In 20% of cases, the posterior arch is smaller and can be divided via left thoracotomy at its junction with the anterior arch. If both arches are of equal size, division is planned for the most accessible point in the ring; usually between the left subclavian artery and the posterior arch.

The ligamentum arteriosum (ductus arteriosus) is divided in standard manner. Once the appropriate site for ring division is identified, vascular clamps are applied and all radial and carotid pulses confirmed. Intraoperative neuromonitoring, especially transcranial Doppler, provides immediate feedback about cerebral blood flow after clamping and prior to vascular division. The vessel is then divided and each end is closed with a running 4-0 polypropylene suture. Clamps are slowly removed to assure hemostasis. Dissection of the posterior arch in its course through the posterior aspect of the mediastinum is performed to allow retraction of the posterior arch away from the posterior wall of the esophagus. Final inspection for hemostasis is performed and the pleura is closed. A single chest tube is then placed posteriorly along the mediastinum into the apex of the left chest.

When MRI or CT scan clearly shows that the right (posterior) arch is smaller than the left, a right thoracotomy is the
preferred approach. The smaller posterior arch is easily accessed through the right chest. The divided posterior segment of the arch does not retract behind the spine (as it does through a left thoracotomy) but remains readily controllable should significant bleeding occur.

**Right aortic arch with retroesophageal ligament:** In cases of right aortic arch with a retroesophageal ligament, the surgical approach is through a left thoracotomy. Division of the ring is achieved by division of the ligament. Through a posterolateral muscle-sparing thoracotomy, the vagus nerve is identified in the pleura overlying the mediastinum. The pleura is opened from the proximal descending aorta to the left subclavian artery posterior to the vagus nerve. The anterior flap of pleura is elevated to expose the left pulmonary artery, at which point the ligamentum arteriosum is identified. Several different potential origins of the ligament exist: (1) from a Kommerell’s diverticulum off the posterior (right) arch, (2) directly from the right posterior arch, and (3) from the retroesophageal left subclavian artery. Dissection of the ligamentum is performed to the point of its origin while the recurrent laryngeal nerve is protected. The ligamentum arteriosum is divided in standard manner. All adhesive bands are released. In most cases, it is not necessary to excise the diverticulum as pexy to the prevertebral fascia usually prevents recurrent symptoms. Routine excision of Kommerell’s diverticulum is advocated by some groups as it has been known to cause both independent tracheoesophageal compression and recurrent symptoms (Fig. 78.8A and 78.8B). With adequate mobilization, the structures will retract, releasing impingement on the trachea and esophagus. When Kommerell’s diverticulum appears large or dilated, it should be resected to prevent subsequent independent compression of the trachea and esophagus. In these cases, transfer of the left subclavian artery to the left carotid artery or aorta is performed to relieve any sling-like effect of the posterior arch and left subclavian artery on the trachea (Fig. 78.8C).

**Vascular rings requiring right thoracotomy:** A right thoracotomy is indicated in correction of vascular rings in 10% to 20% of cases. As discussed, the most common of these indications is the double aortic arch with dominant left arch. Rarer cases include (1) left aortic arch with a right descending aorta and right ligamentum arteriosum between the right descending aorta to the right pulmonary artery and (2) left aortic arch with aberrant right subclavian artery and right ligamentum arteriosum. The surgeon should be alerted to these rare cases by a distinctive esophagogram demonstrating significant indentation high in the upper left posterior aspect of the esophagus. MRI and CT will also identify these cases. Similar principles apply to correct these anomalies. The recurrent laryngeal nerve recurs around the right-sided ligamentum arteriosum. Division of the ring is achieved by division of the ligamentum arteriosum. Isolation of the ligamentum arteriosum and caution with dissection of the recurrent laryngeal nerve are applied. Dissection of the arch of the aorta through the mediastinum posterior to the esophagus is performed to divide adhesive bands to the posterior wall of the esophagus.

**Vascular rings requiring median sternotomy:** Median sternotomy accounts for approximately 5% of surgical approaches to vascular rings. This approach is used when the vascular ring is associated with correction of another cardiac defect such as tetralogy of Fallot, in which 20% to 25% of cases have an associated right-sided arch. In most cases of tetralogy with right aortic arch, however, there is mirror image branching with the ligamentum arteriosum between the left innominate artery and left pulmonary artery and thus no vascular ring.

Surgical repair for cervical arches is rarely indicated but may be required for complications such as compressive symptoms, arch hypoplasia, and aneurysm of the arch. The surgical approach in these cases is dictated by the anatomy of the complicating feature and may range from division of the ligamentum arteriosum to aneurysm resection with graft interposition.

For a right arch with left descending aorta and associated arch hypoplasia and coarctation (the circumflex aorta), the approach is via median sternotomy and includes wide mobilization of the ascending aorta, retroesophageal arch (and all associated branches), and proximal descending aorta. The entire circumflex retroesophageal arch (and coarctation site if present) is excised and an anastomosis is performed between the distal ascending aorta and the descending aorta (Fig. 78.9A and 78.9B). The anastomosis is anterior to the trachea and esophagus. Although this technique can be performed off-pump, we recommend support with cardiopulmonary bypass. An alternative repair more suitable for an adult is an extra-anatomic bypass between the ascending and descending aorta via sternotomy.

**Group II: Partial Vascular Rings**

Partial vascular rings include (1) left aortic arch with retroesophageal right subclavian artery and left ligamentum arteriosum and (2) leftward origin of the innominate artery resulting in anterior tracheal compression.

Section III: Congenital Cardiac Surgery

Fig. 78.5. Surgical approach, exposure, and anatomy of a complete vascular ring. (A) The patient is placed in the right lateral decubitus position with an axillary roll. The right leg is bent at the hip and knee. Legs are separated by pillows, and the left leg is straight. The incision is a gentle S-curve, at the tip of the scapula. With a muscle-sparing technique, the chest is entered through the fourth interspace. (B) The chest retractor is placed with the crossbar anteriorly. The lung is retracted anteriorly and inferiorly and is held into position with a moistened sponge secured with malleable retractors that are fixed to the retractor crossbar. (C) Before the pleura is incised, note the position of the vagus nerve, aorta, left pulmonary artery, and, if possible, the posterior (right) arch and ligamentum arteriosum. LCCA, left common carotid artery; LPA, left pulmonary artery; LSCA, left subclavian artery; n, nerve; PDA, patent ductus arteriosus.

Left Aortic Arch with Aberrant Right Subclavian Artery

The anomaly of left aortic arch with aberrant right subclavian artery is the most common anomaly of the aortic arch, found in 0.5% to 1.8% of the population. Most patients are asymptomatic. It forms as a result of involution of the entire right dorsal aorta. The right subclavian artery migrates posteriorly behind the esophagus as the left subclavian artery migrates cranially. Coarctation is often associated with this lesion. When symptoms do occur they are most commonly related to difficulty in swallowing. A barium esophagogram is usually sufficient for diagnosis. Surgery is rarely indicated for this anomaly. When symptoms persist, correction consists of left thoracotomy and mobilization and division of the retroesophageal right subclavian artery. An alternative approach favored by some surgeons is a right thoracotomy with division of the right subclavian artery and reimplantation into the right carotid artery or aorta.

Anomalous Innominate Artery with Tracheal Compression

Anatomy

This entity is described in patients with a normal left aortic arch and left-sided ligamentum arteriosum. In these patients, the innominate artery arises either partially or completely to the left of the trachea and in its course from left to right produces anterior compression on the distal trachea. The degree of tracheal compression varies considerably, with only a small proportion of patients developing symptoms of airway obstruction.

Clinical Presentation

Innominate artery compression occurs most commonly in children younger than 2 years of age. Primary symptoms are respiratory and include repeated bronchopulmonary infections, stridor, and apnea.
Chapter 78: Vascular Rings, Slings, and Other Arch Anomalies

805

Diagnosis
Diagnosis of innominate artery compression is best obtained with bronchoscopy, during which an anterior pulsatile indentation is noted compressing the trachea 1 to 2 cm above the carina. The trachea should be narrowed at least 50% to 75% for the symptoms to be attributed to this anomaly. The diagnosis can also be made with MRI or CT angiography.

Indications for Surgery
Surgical therapy is dictated by the severity of symptoms. Patients with mild symptoms are managed conservatively and allowed to improve with growth. Patients with a history of apnea, severe stridor, or respiratory distress or two or more episodes of bronchopneumonia or tracheobronchitis are candidates for surgery if significant tracheal compression is demonstrated.

Surgical technique: Several techniques for correction of innominate artery compression have been described. Mustard’s technique requires division of the artery overlying the trachea. Langlois’s technique involves division of the artery and reimplantation on the ascending aorta. We prefer Gross’s technique of innominate artery suspension.

Although Gross used a left anterior thoracotomy, we prefer a right anterior thoracotomy through the second intercostal space (Fig. 78.10). The right lobe of the thymus is excised, and the innominate vein is mobilized to expose the innominate artery. The innominate artery should not be dissected from the trachea so that suspension of the artery exerts traction on the compressed segment of trachea restoring the lumen of the airway. Video-assisted rigid bronchoscopy is extremely valuable in assessing the effect of suture placement and tension on the tracheal lumen. Several 3-0 braided sutures are placed in the adventitia of the innominate artery at the level of the pericardium at a point directly beneath the sternum (Fig. 78.11). These sutures are then placed deeply into the periosteum of the posterior surface of the sternum. Alternatively, the ends of the sutures may be passed through holes bored in the sternum, tying the sutures over the anterior surface of the sternum. It is important to achieve a secure suspension to the sternum in either case. Two to four additional 3-0 sutures are placed more distally in the innominate...
Fig. 78.7. Division of the anterior (left) aortic arch. The patent ductus arteriosus has been divided and oversewn. Vascular clamps are applied, with care being taken to make sure that the recurrent laryngeal nerve is not trapped in the clamp on the posterior surface of the left arch. The anterior (left) arch is divided and oversewn in two layers. The distal stump may be rotated and attached to the prevertebral fascia. Adhesive bands about the trachea and esophagus are divided sharply, relieving esophageal and tracheal compression. Ant., anterior; LCCA, left common carotid artery; LSCA, left subclavian artery; n, nerve; PDA, patent ductus arteriosus; Rec., recurrent.

artery and secured to the periosteum of the adjacent ribs such that the entire extent of the innominate artery producing compression on the anterior wall of the trachea is suspended (Fig. 78.12). Emphasis is placed on bronchoscopic guidance to assure relief of the tracheal obstruction. In the rare case in which innominate artery suspension fails to significantly improve the tracheal compression, reimplantation of the innominate artery via a median sternotomy should be considered. Reimplantation is advisable as the primary procedure when present with a chest wall deformity.

**Group III: Pulmonary Artery Sling**

**Anatomy**

In cases of pulmonary arterial sling, the left pulmonary artery originates from the posterior aspect of the right pulmonary artery, proceeds over the right mainstem bronchus, between the trachea and the esophagus, and reaches the hilus of the left lung at a level lower than normal (Fig. 78.13). This lesion does not form a ring but forms a sling around the distal trachea and right mainstem bronchus, producing compression of these structures. The esophagus is not obstructed, but indentation on the anterior wall of the esophagus can be noted on esophagoscopy or barium esophagogram, a pathognomonic feature of this lesion.

Pulmonary artery sling anomalies are associated with tracheal stenosis in 33% to 64% of cases. In these cases, tracheal stenosis results from the absence of the normal posterior membranous portion of the trachea and proximal primary bronchi, replaced by complete tracheal rings. This ring deformity can occur in an isolated segment of the distal trachea or can be much more debilitating when it involves the entire length of the trachea. Predominately, this defect is limited to the area impinged on by the pulmonary arterial sling.

**Clinical Presentation**

Pulmonary artery slings produce symptoms of tracheal compression due to posterior impingement of the trachea. Infants generally present soon after birth with stridor that is episodic. They are often treated as asthmatics and may have a history of chronic respiratory infections. On examination, stridor, tachypnea, nasal flaring, inspiratory and expiratory wheezing, and intercostal retraction may be noted.
Fig. 78.8. (A) Anatomy of right aortic arch with retroesophageal left subclavian artery and associated Kommerell’s diverticulum. (B) Patch closure or primary closure after resection of Kommerell’s diverticulum. (C) Reimplantation of left subclavian artery into left carotid artery. Asc ao, ascending aorta; Esoph, esophagus; LCCA, left common carotid artery; LSCA, left subclavian artery; MPA, main pulmonary artery; RCCA, right common carotid artery; RSCA, right subclavian artery.
Diagnosis
In cases of pulmonary artery sling, chest radiography may demonstrate anterior bowing of the right mainstem bronchus, deviation of the lower trachea and carina to the left and unequal aeration of the lung. As with vascular rings, barium esophagography may be diagnostic. The position of the anomalous left pulmonary artery between the trachea and esophagus creates an anterior indentation in the esophagus when viewed in the lateral projection. MRI, however, provides more complete three-dimensional information and is the preferred diagnostic modality for this lesion.

Indications for Surgery
Patients with pulmonary artery sling and signs and symptoms of significant respiratory obstruction are candidates for operative repair. All patients should undergo preoperative bronchoscopic evaluation to assess the position, degree, and extent of any tracheal or bronchial constriction.

When workup demonstrates extrinsic tracheal compression without fixed stenosis, surgical repair entails relocation of the left pulmonary artery anterior to the trachea. This is achieved by reimplantation of the left pulmonary artery in its anatomically correct location on the main pulmonary artery (Fig. 78.13). Resection of redundant left pulmonary artery is usually necessary to prevent kinking after reimplantation. An alternative approach involves transection of the trachea with reanastomosis posterior to the undivided left pulmonary artery. When a fixed tracheal stenosis is noted, a sliding tracheoplasty is performed in addition to reimplanting the left pulmonary artery (Fig. 78.14A and 78.4B).

Surgical Technique
Patients are approached through a median sternotomy. Although cardiopulmonary bypass is not essential for reimplantation of the anomalous left pulmonary artery, its use does replace respiratory function and allows a wide anastomosis on empty and open vessels. The use of cardiopulmonary bypass also provides the option of dividing the trachea without dividing the left pulmonary artery. For this reason, we prefer a median sternotomy with cardiopulmonary bypass for all patients with pulmonary artery sling with or without fixed tracheal stenosis.
Fig. 78.9. (A) Anatomy of circumflex aortic arch including resection of the hypoplastic retroesophageal arch, PDA ligation and division, and reimplantation of the left subclavian artery. Section III: Congenital Cardiac Surgery

Fig. 78.10. Positioning and approach for relief of innominate artery compression. A right anterior thoracotomy through the second interspace is used. A ventilating fiber optic rigid bronchoscope with video attachment is placed before the incision is made. IA, innominate artery; LCC, left common carotid artery; LSCA, left subclavian artery.

Fig. 78.11. Arteriopexy for innominate artery compression. The surgical exposure demonstrates the leftward origin of the innominate artery. Braided 3-0 sutures are placed in the adventitia of the vessel. The cross-sectional view reveals the mechanism of anterior tracheal compression. The adventitial tissue between the vessel and the trachea must not be dissected if satisfactory retraction of the anterior tracheal wall is to be achieved. a., artery; Ao, aorta; SVC, superior vena cava.

After standard median sternotomy, the pericardium and left pleura are opened. After appropriate heparinization, the patient is cannulated via the aorta and right atrium. Cardiopulmonary bypass is instituted, and the patient is cooled to 32°C. The proximal right and left pulmonary arteries are dissected free and the trachea is identified. The ligamentum arteriosum (ductus arteriosus) is divided and oversewn. At this point, options include division of the left pulmonary artery at its origin with reimplantation anterior to the trachea or simple transection of the trachea with anterior relocation of the undivided left pulmonary artery.

Whether or not tracheal compromise exists, we prefer to divide the left pulmonary artery and anastomose it to the left lateral aspect of the main pulmonary artery at a site approximating the take-off of a normal LPA. It is usually necessary to excise redundant LPA prior to completing the anastomosis (Fig. 78.13).

In patients with fixed tracheal stenosis (Fig. 78.14A), the trachea is transected at the midpoint of the stenosis. The superior portion of the stenotic trachea is then incised posteriorly and the inferior portion of the stenotic trachea is incised anteriorly. A sliding tracheoplasty is then performed using interrupted 5-0 polydioxanone suture (Fig. 78.14B). The tracheal repair is then tested under 40 cm H₂O to rule out air leaks.

Once the integrity of the tracheal anastomosis is ensured, ventilation is re instituted and cardiopulmonary bypass is discontinued. After heparin reversal and satisfactory hemostasis, the sternotomy is closed in the standard manner.

**POSTOPERATIVE CARE**

Particular care must be given to respiratory management in all cases. In most vascular ring and pulmonary sling cases, extubation can occur immediately or within 24 hours of surgery. Occasionally, if postobstruction collapse or pneumonia was present preoperatively, prolonged intubation is necessary for tracheal suctionsion, positive-pressure breathing, and oxygen administration. Humidified oxygen with bronchodilator therapy should be initiated. After extubation, continued administration of humidified air and bronchodilator therapy are required, as well as aggressive pulmonary toilet. Bronchoscopy is frequently necessary to assist with management of secretions and granulation tissue after slide tracheoplasty.
Fig. 78.12. Reduction of innominate artery compression. Retraction on the adventitial sutures elevates the innominate artery and the anterior wall of the trachea. The use of video-assisted bronchoscopy assures ideal suture placement for maximal tracheal decompression. Fixation to the sternum is demonstrated in the 30-degree view.
Section III: Congenital Cardiac Surgery

Fig. 78.13. Surgical anatomy of the pulmonary artery sling. Exposure via median sternotomy is shown. Localized tracheal stenosis is present in this case. Esoph, esophagus; LPA, left pulmonary artery; MPA, main pulmonary artery; RPA, right pulmonary artery.
Fig. 78.14. (A) Location of tracheal incisions for sliding tracheoplasty. The trachea is divided at the midpoint of the stenosis and incisions are made anteriorly (inferior trachea) and posteriorly (superior trachea). (B) The superior and inferior portions are then slid over one another and anastomosed with interrupted absorbable suture. MPA, main pulmonary artery; n., nerve; PDA, patent ductus arteriosus.
Symptoms frequently are not resolved immediately, and it may take days to weeks for edema to resolve. Infrequently, recurring upper respiratory infections and chronic brassy cough may persist for as long as 1 to 2 years. Such prolonged postoperative symptoms are especially prominent in children who had onset of symptoms at age <6 months but were operated on late in their disease process.

VIDEO-ASSISTED THORACOSCOPIC SURGERY

Video-assisted thoracoscopic surgery (VATS) has been successfully applied to some patients with complete vascular rings. Safe use of this technique requires a significant VATS experience on the part of the operator as well as appropriate patient selection. The most suitable patients are those with a right aortic arch with aberrant left subclavian artery and left ligamentum arteriosum (type IB) and the occasional patient with a double aortic arch with an atretic left arch. In these patients, a nonvascular segment of the ring can be approached endoscopically and safely divided. Endoscopic vascular clamps are not reliable enough to recommend this technique for division of a patent vascular segment. MRI can accurately detect segmental patency or atresia and thereby identify those vascular ring patients suitable for the VATS approach.

RESULTS

In cases of true vascular rings, mortality rate ranges from 0.5% to 6.0%. Most deaths are due to postoperative complications secondary to upper respiratory infections, pneumonia, and pulmonary failure in children undergoing delayed operation. Morbidity approximates 30% in children with complete vascular rings and 25% in cases of innominate artery compression. This morbidity most frequently includes chronic wheezing and upper respiratory infections. Infrequent complications include recurrent laryngeal nerve injuries and chylothorax.

Pulmonary artery sling repair performed with division and reimplantation of the artery demonstrates patency rates exceeding 75% and mortality rates under 5%.

SUGGESTED READINGS

As noted in the chapter on imaging modalities, MRI scanning has become perhaps the most useful imaging technique for the evaluation of vascular rings and slings. Although barium swallow studies can give a fairly accurate assessment of arch anatomy, the relative size of the anterior and posterior arch in double aortic arch is not readily determined by this type of study.

Rapid multislice helical CT scanning has been very useful for the assessment of arch anomalies. The advantage of CT reconstruction is the ability to gain images in a very brief time, which may obviate the need for sedation or intubation with general anesthesia as for MRI scanning. Images are usually quite good and comparable to MRI images. However, the increased amount of radiation and the need for contrast are disadvantages to this technique.

In patients with aberrant left subclavian artery with right aortic arch and Kommerell's diverticulum, it is sometimes valuable to perform a pexy of the diverticulum or the base of the left subclavian artery to the prevertebral fascia to maintain complete opening of the ring and to mobilize the trachea and the esophagus in the middle portion to ensure that there is no adventitial tissue that may result in residual compression. As noted by the authors, resection of Kommerell's diverticulum is rarely necessary, although some centers have routinely done this, believing that greater relief of potential reobstruction or aneurysmal formation is possible with this approach. If a resection of Kommerell's diverticulum is performed, we prefer to reimplant the left subclavian artery to the left carotid or the aorta to maintain flow to the left arm as suggested by the authors. Diverticulum resection in small infants can be associated with late stenosis of the reimplanted subclavian vessels; therefore, we prefer not to resect these diverticula unless aneurysmal formation has occurred.

The situation with innominate artery compressive syndromes is a complex

(continued)
one. In most cases, the innominate artery compresses the trachea because of abnormal location more to the left on the aortic arch than normal. Often this is associated with abnormalities of chest wall symmetry with either pectus excavatum or a decreased anteroposterior diameter. We believe that these abnormalities often predispose patients to innominate artery compression, and simple innominate arteriopexy to the chest wall through a thoracotomy may not completely relieve the compression. In these cases, we believe that it is valuable to relocate the innominate artery on the ascending aorta more to the right, which completely relieves the obstruction even in an abnormal chest geometry. This procedure can easily be undertaken through a sternotomy incision, although a supracavicular approach has also been described.

Although retroesophageal aberrant right subclavian artery is rarely associated with significant symptoms, we have seen patients who have had true dysphagia or chronic cough from this anatomy. Whereas ligation and division of the subclavian can relieve obstructive symptoms, we prefer to relocate the subclavian vessel from behind the esophagus over to the right side, either to the carotid or directly to the arch of the aorta. This maintains the patency of the subclavian vessel and prevents subclavian steal syndrome. This can generally be done through a right thoracotomy incision.

The anatomy of pulmonary artery sling is complex, and the results with repair of this defect are suboptimal. As noted by the authors, patients with pulmonary artery sling have had a very high mortality and a high occlusion rate of the left pulmonary artery when it has been divided and relocated anterior to the trachea. The causes for this are multifactorial; however, often these are small infants, and the pulmonary artery flow may not be adequate to maintain growth of the Anastomosed vessel. If reimplantation of the left pulmonary artery to the main pulmonary artery is performed in pulmonary artery sling, it is often advisable to shorten the posterior aspect of the pulmonary artery slightly to prevent kinking and to patch augment the anterior aspect with pericardium or homograft material to decrease the risk of stenosis. In our experience, relocation of the pulmonary artery anterior to the trachea, because of the abnormal origin of the left pulmonary artery, can lead to kinking and stenosis of the origin of the left pulmonary vessel due to the elongated nature of the left pulmonary artery, which now sits anterior to the trachea. In some cases, even with simple translocation of the left pulmonary artery anterior to the trachea, it may be necessary to patch augment the origin of the vessel to prevent development of kinking or stenosis.

Much of the mortality in patients with pulmonary artery sling is related to airway complications, and, as noted in this chapter, direct attention to the airway is the primary component of surgical repair for this condition. We have seen several patients who have a tracheal origin of the right upper lobe bronchus with complete tracheal rings of the distal trachea to the bifurcation. Because of the early take-off of the upper lobe bronchus, the distal trachea is quite small and the bifurcation into the mainstem bronchi is also relatively small. In these patients, either extensive resection of the complete rings with slide tracheoplasty or rib cartilage patch tracheoplasty is necessary in addition to division of the trachea and relocation of the pulmonary artery anteriorly. These complex operations can be done with good results, and we prefer to use rib cartilage grafts rather than pericardial patches if sliding tracheoplasty is not feasible in most of these patients because of the rigidity of the tissue and the maintenance of a patent airway without anterior malacia from a pericardial patch. In more typical forms of pulmonary artery sling, simple resection of involved tracheal segments can completely relieve the obstruction. Mobilization of the trachea with hilar releases is often fully sufficient to prevent tension on the anastomosis, even with extensive slide tracheoplasty for long segment tracheal obstruction.

These patients must be diligently managed postoperatively to prevent secretions from pooling in the airway, and repeated bronchoscopic examinations are also necessary to examine the airway to clear secretions and to avoid the development of obstructive granulation tissue at the tracheal anastomosis. Associated cardiac defects such as ventricular septal defect or tetralogy of Fallot may also be present with a pulmonary artery sling complex and can be addressed at the time of the tracheal repair.
Substantial changes have occurred in the management of atrial septal defects (ASDs) since the approval of the Amplatzer ASD occluder device by the Food and Drug Administration in 2002. Today, the vast majority of isolated ASDs are closed in the cardiac catheterization laboratory. However, secundum-type ASDs are frequently a component of more complex congenital heart defects and need to be closed surgically as part of the procedure. Also, other forms of ASD would appear to remain in the surgical domain for at least the foreseeable future. Therefore, it is still imperative that surgeons performing pediatric heart operations understand the physiology of these defects, the indications for intervention, and the surgical techniques used for their repair.

Secundum-type ASDs account for approximately 80% to 85% of all ASDs. Sinus venous defects (both the superior and the inferior type) and incomplete atrioventricular (AV) canal defects each constitute between 5% and 10% of all ASDs. Coronary sinus defects are a relatively uncommon form of ASD. The topic of incomplete AV canal—type ASDs is addressed in Chapter 82.

Secundum-type ASDs are three times more frequent in female than male patients. In addition, there is also a significant incidence of familial inheritance. These observations indicate that genetic factors play an important role in the formation of secundum ASDs; however, the exact gene locus responsible for this phenomenon has not been identified.

Most ASDs result in a left-to-right shunt ($Q_L/Q_S$) of about 2 or 3:1. The amount of flow across an ASD is determined by the relative ratio of diastolic compliance between the right and left ventricles because antegrade flow of the systemic and pulmonary venous return within the heart require the AV valves to be open. The amount of shunt is also influenced by the size of the interatrial communication, the presence or absence of pulmonary valve stenosis, and the pulmonary vascular resistance. Despite the increase in pulmonary blood flow seen with ASDs, most patients will have normal pulmonary artery (PA) pressures.

The chronic volume overload associated with an ASD has several adverse effects. The increase in flow through the left atrium (LA), right atrium (RA), and right ventricle (RV) results in enlargement of these structures. It is clear that cardiac enlargement, regardless of its etiology, will eventually translate into decreased quality of life as well as decreased life expectancy. With ASDs, the heart enlargement may take many decades before it leads to ventricular dysfunction or the onset of atrial arrhythmias. Similarly, the increase in pulmonary blood flow is initially well tolerated, but on a long-term basis may result in increased pulmonary vascular resistance.

The natural history of an ASD has been well documented. Studies indicate that patients with unrepaired ASDs and a $Q_L/Q_S$ of >1.5:1 will have a diminished life expectancy, averaging about 45 years. There is a great deal of variability in the natural history of these patients. Most infants and young children with ASDs are asymptomatic, demonstrating normal growth and absence of cyanosis. Some school-age children will tire a bit more easily than their peers or siblings and occasionally demonstrate peri-or periorbital cyanosis following exertion. As patients with untreated ASDs enter into their teens and 20s, they may have a gradual decline in their exercise capacity. Also during this time, women enter into their childbearing years. Women with an untreated ASD who become pregnant have a significant incidence of fetal (20% to 30%) and maternal (2%) mortality. As patients enter into their 30s and 40s, most experience a progressive decline in their exercise tolerance coincident with the deterioration in right ventricular function. Atrial arrhythmias are usually a late occurrence and may be the cause of palpitations. The development of arrhythmias may tip a previously well-compensated patient into congestive heart failure because of the loss of atrial contraction. Cyanosis is usually a very late and ominous sign of irreversible pulmonary vascular disease. Patients with a right-to-left shunt or a minimal left-to-right shunt are at risk for paradoxical embolus, although the actual risk is difficult to quantify. The combination of right heart failure, arrhythmias, and cyanosis generally progresses and eventually leads to the eventual demise of the patient.

**DIAGNOSIS**

The diagnosis of ASD is usually suspected based on the physical examination. The history may not be particularly helpful in children but is an important part of the assessment in adults. Echocardiography is used to confirm the diagnosis and to delineate the pulmonary venous drainage (Fig. 79.1). Echocardiographic diagnosis is sufficient in most cases because the vast majority of patients identified with ASDs are infants and children. Diagnostic cardiac catheterization is indicated in two specific circumstances. In children, the need for catheterization arises when there remains doubt as to the complete diagnosis (Fig. 79.2). This can occur with abnormalities of systemic or pulmonary venous drainage or to exclude other associated congenital heart defects. Diagnostic catheterization is indicated in adult patients to assess pulmonary vascular resistance and to exclude the presence of acquired heart disease.

**RECOMMENDATION FOR CLOSURE OF ATRIAL SEPTAL DEFECTS**

The recommendation for closure of ASDs is based on the premise that the risk of the intervention is substantially lower than the risk incurred by following the natural history. ASD repair prevents the progression of cardiac and pulmonary changes and in younger patients restores a normal life expectancy. When the diagnosis of ASD is
made in infancy or early childhood, closure is generally recommended between 2 and 4 years of age. Regardless of the technique selected (surgery vs. interventional catheterization), these procedures are usually well tolerated and are typically associated with a rapid recovery. The psychosocial aspects of the hospitalization may also be better handled at this age.

Patients with an ASD detected in adulthood will usually benefit from closure of the defect and remain good candidates for whichever technique is selected. Assessment of the adult patient is based on a combination of clinical history, physical findings, echocardiographic information, and cardiac catheterization data. Patients who are fully saturated (i.e., have a left-to-right shunt by echo) and have RV enlargement consistent with a volume load from the shunt will almost certainly derive considerable benefit from closure. Conversely, most patients who have developed cyanosis should not be considered for closure because they rarely benefit from this intervention. Cardiac catheterization may better define those patients in the gray zone. Pulmonary vascular resistance approaching systemic or a shunt ratio barely exceeding 1 suggests that the patient is not a candidate for closure (approximately 10% of patients by the fourth decade will have reached this stage). The conventional teaching has been that surgical intervention is warranted in patients with a $Q_L:Q_S$ of >1.5:1, but this criterion can probably be lowered to a $Q_L:Q_S$ of 1.2 or 1.3:1 with the less invasive septal occluder devices. Closure should also be strongly considered in patients with a history of stroke even if the defect is very small, in order to preclude subsequent events.

Women who are discovered to have an ASD during pregnancy represent a unique clinical situation. During pregnancy, the circulating blood volume expands by about 50%, allowing even more blood to shunt through the ASD. Women who were previously well compensated may develop signs and symptoms of heart failure during the third trimester of their pregnancy. Every attempt should be made to avoid cardiac surgery in this circumstance because the risk to both mother and fetus is quite high. Most pregnant women can be successfully
managed using a combination of medical therapy and bed rest. However, on occasion a patient cannot be stabilized and must undergo urgent intervention. This mode of presentation was more common years ago than it is today, presumably because of improved methods of diagnosis.

**SURGICAL TECHNIQUE**

ASDs are usually closed through a sternotomy approach. In boys, this can be performed through a relatively short, low-lying midline incision. Our preference in girls has been to use a curvilinear, transverse (inframammary) skin incision as shown in Figure 79.3. This technique, once it has been learned, provides a superior cosmetic result without compromising in any way the exposure or versatility. Independent of the orientation of the skin incision, the sternum is divided vertically through the midline. The sternal retractor is then positioned for exposure. The retractor does not need to be opened widely for this operation because visualization of the ASD is relatively straightforward. Excessive retraction can result in sternal fracture.

The thymus is a relatively large structure in younger children and can present an obstacle to cannulation of the aorta. A portion of the thymus can be excised to improve exposure. This maneuver is not necessary in adult patients. The pericardium is then opened according to the intended operation. For the repair of a secundum-type ASD, we prefer to open the pericardium slightly to the left of midline with the anticipation that the patch will be cut to the appropriate size and shape once the defect has been visualized. For the repair of a sinus venosus-type defect, the anterior pericardium can be harvested and preserved. Some surgeons prefer to treat the pericardium with glutaraldehyde because this both strengthens the patch and makes handling it a bit more straightforward. The remaining pericardial edges are sutured to the drapes to form a pericardial well. Inspection of the anatomy is then conducted with several specific considerations:

1. The heart is inspected with regard to its size and configuration. Often the degree of cardiac enlargement will seem disproportionate to that seen on chest X-ray film.
2. The great vessels are inspected and palpated. The PA is usually enlarged consistent with increased flow through this vessel. A thrill at the level of the pulmonary annulus may signify the presence of pulmonary stenosis.
3. The systemic veins are inspected to ensure that there are no abnormalities. A small or absent innominate vein suggests the presence of a left superior vena cava (LSVC). In the case of a superior sinus venosus defect, the SVC is isolated, and the presence or absence of anomalous pulmonary veins is confirmed. The position of the azygos vein should also be identified.
4. The pulmonary veins on the right are visualized, with the intent to inspect the left pulmonary veins once on bypass. As indicated, in the case of a sinus venosus defect the anomalous pulmonary veins should be identified at this point.

Fig. 79.3. (A) Landmarks for the transverse skin incision used in female patients with an atrial septal defect. (B) Exposure through a transverse skin incision is nearly identical to that of the standard vertical incision once the flaps have been adequately developed. (C) Closure of the transverse skin incision with a mediastinal and right pleural chest tube as well as two subcutaneous drains beneath the upper flap.
Cannulation is commenced by placing purse strings in the superior and inferior venae cavae as well as the aorta. If there are anomalous pulmonary veins in association with a sinus venosus defect, the superior vena caval cannulation site should be at the junction of the SVC and innominate vein in order to be well above the entrance of the anomalous veins. The patient is cannulated and cardiopulmonary bypass instituted. Normothermia is used in most cases of simple ASD. Mild levels of hypothermia (32 to 34°C) may be used when a longer cross-clamp time is anticipated (e.g., sinus venosus ASD with partial veins). Inspection of the heart is then completed. Specifically, the position of the left pulmonary veins and the presence of a LSVC can be ascertained by tilting the heart to the right. After inspection, caval tapes are placed around the superior and inferior venae cavae and a cardioplegia needle is inserted into the aortic root. The aortic cross-clamp is applied, and cardioplegia is delivered to achieve electromechanical silence. During this time, the caval tapes are tightened and the RA opened to collect the coronary venous effluent.

Surgical Repair of Secundum-Type Atrial Septal Defects

Secundum-type ASDs are approached through a standard right atriotomy (Fig. 79.4). Traction sutures can be placed at the edges of the atriotomy to facilitate exposure. The ASD is identified at its position just beneath the superior limbus. A few moments should be taken to identify the position of the coronary sinus and its relationship to the tricuspid valve. These two structures along with the tendon of Todaro form the triangle of Koch. The AV node should lie at the superior apex of this triangle and may not be too far from the medial border of the ASD. A right-angled clamp can be passed through the ASD into the pulmonary veins to confirm their position. Finally, the position of the inferior vena cava (IVC) cannula should be inspected along with its relationship to the inferior border of the ASD and the Eustachian valve. Misinterpretation of this anatomy can result in inadvertent baffling of the inferior vena caval flow across the ASD into the LA.

After this checklist of anatomic landmarks is completed, repair of the defect is undertaken. The majority of secundum ASDs in young children can be closed primarily, whereas in teenagers and adults the defects are usually large and the tissues less compliant, so that a patch repair is almost always indicated. Our preference has been to use autologous pericardium, although synthetic patches can also be used. Pericardial patch repair of an ASD is straightforward, and the technique described here is one of the several possible variations. Two separate sutures of 5-0 or 6-0 nonabsorbable vascular suture are placed at the superior and inferior ends of the defect. Each of these sutures is passed through the pericardium at a distance slightly exceeding the length of the ASD (Fig. 79.5). The pericardial patch is cut and lowered into position with the smooth side toward the LA. Each of the sutures is tied, and then each arm of the double-armed suture is run 90 degrees to meet its opposite suture. Just before completing this process, the left side of the heart is filled with blood by ventilating the patient to increase pulmonary venous return and thereby expressing any air remaining in the LA (Fig. 79.6). The patient is then positioned in a steeply head-down position and

Fig. 79.4. View of the right atrium and superior and inferior venae cavae from the surgeon's perspective. Right-angled cannulas have been placed in each vena cava. The dashed line demonstrates the placement of the atrial incision for repair of a secundum atrial septal defect.

the cross-clamp removed with the aortic root on suction. Rewarming is performed while the right atriotomy is closed with a double running 5-0 or 6-0 nonabsorbable vascular suture. The patient is weaned from cardiopulmonary bypass once rewarming is completed.

**Amplatzer Repair of Secundum-Type Atrial Septal Defects**

As we have previously stated, the majority of secundum-type ASDs are now closed in the catheterization laboratory. The original ASD devices were developed more than 30 years ago and were prone to late structural failures. The current design has proven to be both effective and durable (Fig. 79.7). The advantages of device closure are that it is less invasive than surgery and the recovery from the procedure is shorter. The limitations of the device include the fact that it requires a 7F or 8F sheath in the femoral vein, so that patients need to be at least 10 to 12 kg to accommodate the vascular access. Amplatzer device closure may not be feasible from a technical standpoint in patients with a deficient rim of tissue surrounding the ASD, particularly along the inferior aspect of the defect. For these reasons, there is still an occasional secundum defect that is best treated with surgical closure.

There are a number of early and late complications that have been reported following Amplatzer insertion. Systemic thromboembolism has been observed following implantation of an Amplatzer. Patients who experience this problem should undergo evaluation for hypercoagulable state (e.g., anti-thrombin 3 deficiency, protein C or S deficiency) and be anticoagulated. Repeat thromboembolism is a reasonably strong mandate for the removal of the device and conventional surgical closure of the ASD. Onset of new arrhythmia or heart block has also been described following deployment of the Amplatzer device. This finding may indicate that the Amplatzer is not seated properly. Dysrhythmias in this setting may potentially resolve over time but have also been associated with subsequent erosion of the device into adjacent structures. Thus, the presence of new arrhythmias should be investigated thoroughly with a high index of suspicion.

Complications following Amplatzer deployment may precipitate the need for urgent or emergent surgical intervention. The Amplatzer device may be malpositioned resulting in a residual ASD. In this setting, the patient can be taken to the operating room in the next 24 to 48 hours with the removal of the device and closure of the ASD. However, malposition of the Amplatzer with subsequent embolization of the device (typically to the aortic valve or ascending aorta) may result in hemodynamic compromise and require emergency surgery for extraction of the device and closure of the ASD. We have seen one patient who sustained a severe neurologic deficit following this scenario, possibly from thrombus forming on the malposed device.

Amplatzer devices can also erode into the LA, RA, base of the aorta, or into the free pericardial space. These complications may occur early (more frequent) but have also been reported years after device deployment (less frequent). The presentation of a patient with hemopericardium after an Amplatzer device should alert the surgeons to the possibility of erosion. This should be treated as a surgical emergency with cardiopulmonary bypass available prior to sternotomy. If erosion into the pericardial space is confirmed at surgery, the device should be removed and the ASD and atrial erosion site repaired. Erosions into the base of the aorta may manifest...
itself in one of two ways; at times a patient will present with a new murmur and echocardiography detects the presence of an aorto-left atrial fistula. An aorto-left atrial fistula may also be unmasked when a malposed Amplatzer is removed. A fistula is then detected by the intraoperative TEE. In this circumstance, the device itself is acting as a “bottle stopper,” and when it is removed, the fistula becomes apparent. To address the situation, the heart should be arrested (or rearrested), an aortotomy performed and the fistulous tract repaired with a small patch.

The widespread use of the Amplatzer device has created an interesting ethical dilemma. The use of this device represents a “self-referral” for cardiologists and thus has the potential for misapplication. In addition, the reporting of complications, while recommended, has not been mandated by the US Food and Drug Administration Manufacturer and User Facility Device Experience database. It is likely that complications are somewhat underreported. At various surgical meetings, informal surveys would suggest that catastrophes after Amplatzer implantation are far more frequent than the literature would indicate. Mandatory reporting of device complications would clarify the issue and facilitate safe use of these devices. So far, the call for mandatory reporting of Amplatzer complications has not been heeded. In summary, while Amplatzer device closure is an effective therapy for most secundum ASDs, cardiac surgeons should stay well versed in the field of urgent and emergent Amplatzer-device removal techniques.

Repair of the Superior-Type Sinus Venosus Atrial Septal Defect

The superior type of sinus venosus ASD is far more common than the inferior type. The hallmark of this diagnosis is the position of the ASD high in the RA above the superior limbus. The majority of the time the right upper and right middle pulmonary veins drain anomalously into the lateral aspect of the SVC. The distance between the entrance of the pulmonary veins into the cava and the entrance of the cava into the roof of the RA can usually be assessed from the outside by dissecting these structures in advance. The azygos vein is also identified in advance so that it is not confused with a pulmonary vein when these structures are inspected from the internal aspect of the cava. When the pulmonary vein entrance is near the cavoatrial junction, a simple patch repair can be performed to channel the pulmonary vein blood flow across the ASD into the LA. However, it is not infrequent that the pulmonary vein entrance is a considerable distance from the cavoatrial junction. In this circumstance, the “double-patch” technique is the preferred option. A lateral atriotomy is performed and extended cephalad across the cavoatrial junction onto the SVC (Fig. 79.8). Traction sutures may be helpful to facilitate exposure. A portion of previously harvested pericardium is used to baffle the anomalous veins to the LA. The patch is sutured in position with 5-0 or 6-0 nonabsorbable suture, beginning at the superior apex just above the entrance of the superiormost anomalous pulmonary vein (Fig. 79.9). Suturing is continued along the lateral border of the cava and then around the lateral and inferior border of the ASD. Deairing is performed before final completion of the suture line. The repair can be inspected for leaks by having the anesthesiologist ventilate the lungs (Valsalva maneuver). Because the pericardial baffle takes up a portion of the superior vena caval cross-sectional area, primary closure of the cava might result in compromise of the lumen. Therefore, a second pericardial patch is used to augment the cava along its anterior surface (Fig. 79.10).

Fig. 79.8. A lateral atriotomy is performed extending onto the superior vena cava. The orifice of the anomalous right superior pulmonary vein is seen entering into the cava.

Fig. 79.9. A pericardial patch is sutured above the orifice of the anomalous vein and continued inferiorly to encompass the orifice of the sinus venosus atrial septal defect.
Section III: Congenital Cardiac Surgery

An alternative approach to the repair of a superior-type sinus venosus defect, particularly when the entrance of the anomalous pulmonary veins is high on the SVC, is the Warden procedure. Popularized by Warden and colleagues in the 1980s and 1990s, it was first described in an animal model by Gerbode in 1949. The first clinical experience was reported simultaneously by Lewis and Ehrenhaft in 1958. The technique involves division of the SVC just above the entrance of the uppermost pulmonary vein and reanastomosis of it to the atrial appendage. The proximal end of the divided SVC is closed and a patch is placed on the inside of the atrium effectively closing the SVC and baffling the pulmonary vein blood flow across the ASD into the left side of the heart.

The potential advantage of the Warden procedure is the avoidance of any manipulation of the SA node or disruption of its blood supply, thereby reducing the risk of postoperative arrhythmias. In those patients with sinus venosus ASD where the pulmonary veins enter high on the SVC, baffling the veins with a single patch is not a feasible option. Placement of such a patch would lead to an unacceptably high incidence of SVC obstruction. In those patients, the "double-patch" technique is the only suitable alternative. However, the course of the SA node artery is highly variable and an incision across the lateral aspect of the SVC–right atrial junction necessary for the placement of the second patch may result in disruption of the blood supply to the SA node. Warden et al., in their series of 40 patients, identified the location of the sinus node artery in 27 individuals, observing that in 10 of these patients (37%), an incision across the cavoatrial junction would result in injury to the SA node artery.

The decreased risk of injury to the blood supply of the SA node with the Warden procedure makes it our procedure of choice for the repair of the superior-type sinus venosus ASD, particularly if the pulmonary veins enter high on the SVC. Although not unanimous, evidence in the literature tends to support this approach.

Our standard exposure is via a median sternotomy. Thymectomy is routinely performed and the right pleural space is opened widely in order to fully visualize all of the anomalous pulmonary veins and assess their relationship to the azygous vein. The SVC is dissected completely and the azygous vein is ligated and divided. Standard cardiopulmonary bypass and mild hypothermia are utilized. In Warden’s original description of the procedure, the SVC is cannulated with a straight venous cannula placed through the RA and the right atrial appendage. Alternative approach, and our preferred technique, is to cannulate the SVC directly, high at the SVC–innominate vein junction. Once the cardiopulmonary bypass is established, the SVC is divided just above the uppermost pulmonary vein. The proximal end of the SVC is then closed either primarily or with a patch (Fig. 79.11).

The RA is opened and the location as well as the size of the ASD is established. In some patients, the ASD may not be sufficient in size and may need to be enlarged, while in up to 18% of patients, the atrial septum is completely intact and an ASD needs to be created. A patch is then placed in the roof

Fig. 79.10. The superior vena cava and right atrial junction are augmented with a second pericardial patch to prevent narrowing of the superior vena caval orifice at this point.

Fig. 79.11. The Warden procedure. The superior vena cava (SVC) cannula is placed high, at the SVC–innominate vein junction. The SVC is divided just above the uppermost pulmonary vein. The proximal end of the SVC is closed either primarily or with a patch (pictured).
Fig. 79.12. After a standard atriotomy is performed, the superior vena cava (SVC) is closed from the inside with a patch incorporating the atrial septal defect (ASD), baffling the pulmonary vein blood flow across the defect to the left side of the heart. The atrial appendage is amputated and the muscle bundles in the area are carefully and thoroughly divided and resected.

Repair of the Inferior-Type Sinus Venosus Atrial Septal Defect

The inferior type of sinus venosus ASD is relatively rare and is often a surprising finding at operation. The hallmark of this defect is the absence of a rim of tissue from the IVC to the LA. This defect is positioned just above the inferior cavoatrial junction with the right lower pulmonary vein orifice quite visible through the ASD (Fig. 79.14). Thus, inferior sinus venosus defects are inferior and lateral in position as compared with secundum-type ASDs. It should also be noted that the Eustachian valve is often quite prominent in these patients, and care must be taken to create a suture line around the IVC that does not divert the IVC flow into the left by mistaking the Eustachian valve for the inferior rim of the defect.

Repair of the inferior-type sinus venosus ASD is accomplished by closing the atrial defect with a (pericardial) patch, leaving the inferior pulmonary vein on the left atrial side of the patch and the inferior cava on the systemic venous side of the patch. If it is known in advance (by echocardiography) that an ASD is an inferior sinus venosus type, the IVC cannulation can be performed a bit lower by incising the diaphragmatic pericardium...
Repair of Coronary Sinus Atrial Septal Defects

Coronary sinus ASDs are relatively rare and are usually associated with complex congenital heart disease or anomalies of systemic venous return. Conceptually, these defects can be divided into those with and those without an LSVC. In the absence of an LSVC, a coronary sinus ASD exists when the coronary sinus is unroofed into the LA. The distal coronary sinus acts as a passageway for blood to shunt from the LA to the RA. When an LSVC is present, it can be the cause of abnormal shunting either when it enters directly or is unroofed into the LA. Coronary sinus ASDs may be associated with a secundum ASD or a common atrium but may also be seen with an intact atrial septum.

The goal in repairing coronary sinus ASDs is to separate systemic and pulmonary return and eliminate shunting at the atrial level. Because these defects are adjacent to the conduction system and the pulmonary veins, care must be taken in planning and performing these repairs in order to minimize morbidity.

Repair of a coronary sinus ASD without an LSVC is accomplished by what is referred to as a “roofing” procedure. The operation is performed using bicaval venous cannulation and a standard right atriotomy. If the atrial septum is intact, the fossa ovalis is incised for exposure. The unroofed coronary sinus is identified medial to the pulmonary veins. A pericardial patch is used to cover the defect (Fig. 79.15). The atrial septum is repaired either primarily or with a second pericardial patch.

Repair of a coronary sinus ASD with an LSVC may be accomplished through one of two principal methods. Selection of the

overlying the cava. However, this differentiation between secundum and inferior sinus venosus defects is difficult to make by echocardiography, and statistically the secundum type is far more common. If the IVC is cannulated in a standard position, it may be discovered after the right atriotomy that the cannula overlies the defect. Repair can still be accomplished by clamping and removing the inferior cannula, placing a cardiotomy sucker through the cannulation site, and completing the inferior aspect of the suture line in this manner. The cannula can be replaced once the inferior corner has been completed. The pericardial patch is brought above the entrance of the right inferior pulmonary vein to maintain proper pulmonary venous drainage.

Fig. 79.14. (A) The position of an inferior type of sinus venosus atrial septal defect (ASD, being inferior and lateral to the fossa ovalis). Through the ASD, one can see the orifice of the anomalously draining right lower lobe pulmonary vein. (B) A pericardial patch is used to perform the repair.

Fig. 79.15. The fossa ovalis has been incised to view the left atrial anatomy. The “unroofed” coronary sinus is shown in its position medial to the four pulmonary veins. A pericardial patch is used to repair the defect.
method depends on the anatomy of each particular case. When the LSVC is small, and particularly when there is a bridging vein, the simplest option is usually to ligate the LSVC and perform a roofing procedure as described previously. However, if the LSVC is large, an intra-atrial baffle technique can be considered. The fossa ovalis is incised to allow adequate inspection of the left and right atrial anatomy. A portion of the septum primum is excised under direct visualization to allow placement of the intra-atrial baffle. Autologous pericardium works quite well for this purpose. The suture line begins between the two AV valves along the rim of the ASD. Anteriorly, the suture line dips below the left atrial appendage and the orifice of the LSVC. Laterally, the suture line extends around the right pulmonary veins. Along the inferior border, the suture line follows the rim of the ASD; superficial bites are taken adjacent to the orifice of the coronary sinus (Fig. 79.16). If there is a common atrium, the orifice of the coronary sinus in the RA may be absent and thus the landmarks for the conduction system less certain. In this case, the baffle is sutured along the annulus of the tricuspid valve and then is carried out onto the right atrial wall to include the area of the conduction system on the left atrial side (Fig. 79.17).

Raghib syndrome refers to an LSVC to the LA with the absence of a coronary sinus and a low-lying ASD (near the position of an inferior sinus venosus ASD). This rare condition is physiologically analogous to a coronary sinus ASD with LSVC and a common atrium (Fig. 79.17). Anatomically, the two are quite distinct because in Raghib syndrome one cannot see the pulmonary veins or left atrial appendage from the RA. Simple closure of the ASD results in persistent desaturation because of the LSVC to the LA. Raghib syndrome should be suspected whenever there is a low-lying ASD with an LSVC. Correction can be accomplished through ASD repair and ligation of the LSVC (relatively simple) or excision of the septum primum and placement of an intra-atrial baffle (complex).

**Repair of Scimitar Syndrome**

Scimitar syndrome is a relatively rare group of findings that may be associated with an ASD. This condition is associated with anomalous venous drainage of the right lung to the IVC at the level of the diaphragm. This anomalous vein creates a curvilinear density adjacent to the right heart border and was likened to the shape of a Turkish sword (or scimitar). In its full-blown manifestation, scimitar syndrome also includes hypoplasia of the right lung, hypoplasia of the right mainstem bronchus, shift of the mediastinum to the right (dextroposition of the heart), pulmonary sequestration to the right lower lobe, and a secundum-type ASD. Not all of the patients have the complete spectrum of abnormalities, thus accounting for the considerable variability among patients with this syndrome.

Operative techniques for the repair of scimitar syndrome have traditionally been (1) baffling of the right pulmonary vein flow through the RA across a secundum ASD to the LA, (2) reimplantation of the anomalous pulmonary veins higher into the RA with baffling across the ASD, and (3) reimplantation of the anomalous pulmonary veins into the LA with closure of the ASD. These techniques have all been associated with failures due to kinking and obstruction of the pulmonary veins. A fourth alternative that may be used when it is apparent that the anatomy is not amenable to any of these techniques is to incise the walls of the RA and the right common pulmonary vein as they travel in parallel and then sew the edges together in a side-to-side anastomosis. This brings the right pulmonary vein confluence more superiorly in the RA and can then be baffled to the LA through the ASD without creating any point at which the baffle becomes narrowed or has an acute change in direction.
Atrial Septal Defect with Failure to Thrive

There is the occasional patient who will present in infancy with a secundum-type ASD and failure to thrive. These patients demonstrate poor eating and poor weight gain, and have the clinical appearance that one would normally associate with infants who have a large ventricular septal defect. It is also of note that these patients invariably have significant pulmonary hypertension, with PA pressures typically one-half to three-fourths systemic. The pulmonary vascular resistance tends to be quite elevated, so that the $Q_p/Q_s$ is usually on the low side (1.5:2.0) for patients with ASDs. The RV is usually noted to be thick due to the increased PA pressures. Some of these patients will have Down syndrome, and others will have a dysmorphic appearance that may be part of an unnamed syndrome. It has been speculated that the primary abnormality in this setting is the pulmonary hypertension and that the ASD is almost an incidental finding.

Surgical closure of a secundum ASD in this setting is usually prompted by the poor weight gain in association with a congenital heart defect. The patients are quite frail due to their poor nutritional status and pulmonary hypertension. Thus, they should be approached with caution much like one would approach an infant with failure to thrive associated with a VSD. The operative technique is identical to the standard approach outlined previously. However, we recommend the additional placement of a PA catheter to measure PA pressures postoperatively. This measure at first may seem unwarranted but will serve as an early warning system for the first time the CO$_2$ levels increase and the PA pressures rise to systemic or suprasystemic levels. It has been our experience with this entity that many of these patients will continue to demonstrate poor growth after surgical repair of the ASD, but at least the congenital heart defect is removed from the potential list of causes.

CONCLUSION

ASDs are among the more common forms of congenital heart defect. Repair of an ASD is a curative procedure that restores a normal life expectancy. With modern techniques, these procedures can be performed with an extraordinarily low rate of morbidity and mortality.

SUGGESTED READINGS

Although ASD (usually of the secundum type) is one of the most common congenital heart defects seen in any clinical practice, it is not a completely benign lesion. Even small ASDs can be associated with paradoxical emboli or volume overload of the RV with the consequent arrhythmias. As noted by the authors, when an ASD presents in adulthood with only a small shunt, the occurrence of significant pulmonary vascular disease must be suspected and closure might not be indicated if there is any bidirectional or right-to-left shunting.

ASD closure is now commonly being performed for secundum defects with occluder devices such as the Amplatzer device. As noted, there are still complications with these devices, which fortunately are rare, but include erosion into the aorta or through the atrial wall. In addition, as larger devices are being deployed for defects that were not previously amenable to device closure, the incidence of such complications may increase; therefore, continued longitudinal follow-up of patients with occluder devices is necessary. Certainly, a small proportion will eventually require removal and standard ASD closure.

The surgical techniques for the closure of ASDs are numerous. We prefer a vertical skin incision in both male and female patients, especially when the operation is performed in early childhood. These incisions are quite short and quite low to make them as cosmetic as possible. A partial sternotomy incision is generally used. We have avoided transverse incisions in young girls because it may be difficult to identify breast tissue, and if the incision cuts across any breast tissue, unsightly

(continued)
scars can occur. In addition, we have abandoned the thoracotomy incision for ASD closure in most cases because if the mammary pedicle is damaged, there may be asymmetric breast development. Thus, we believe that the most cosmetic incision may well be a very small low vertical incision in the midline over the xiphoid (2.5 cm in length), which avoids elevation of major skin flaps and usually heals with excellent cosmetic results.

The minimally invasive approach to secundum ASD repair through a small sub-xiphoid incision can be done with the use of electrical fibrillation and normothermic bypass, which avoids the need to cross-clamp the aorta. Even in larger secundum defects without a superior rim, where patch closure is necessary, the procedure can be performed through these small incisions without the need for cardioplegic arrest. Operations for atrial septal defects are generally done under normothermia at our institution because bypass and cross-clamp times are generally extremely short.

Many centers have used different approaches to close ASDs and other simple cardiac lesions with superior cosmetic results. A significant experience has been accumulated in making small axillary incisions for exposure of ASDs and VSDs and other centers have considered posterior thoracotomy approaches and minimally invasive and even robotic techniques through port access. All of these approaches have met with significant success and now, especially in females who require a surgical ASD closure, the selection of the incision for the optimal cosmetic result is generally the primary consideration.

Some comments are warranted on the multiple techniques for repair of sinus venosus-type ASDs of the superior and inferior types. The authors described a technique for the repair of the superior sinus venosus defect that also involves patching of the superior vena cava/right atrial junction. In the majority of cases, sinus venosus defects occur just at the superior vena cava/right atrial junction and the right pulmonary veins enter at that site. In these cases, approach through a right atrial incision as used for secundum defects with gentle retraction on the superior vena cava will expose the defects adequately so that direct patch closure can be performed without narrowing the vena cava as it enters the right atrium. Care must be taken, however, to tailor the patch appropriately so that it does not bulge into the superior vena cava or left atrium. The advantage of this approach is avoidance of an incision across the superior vena cava/right atrial junction, which might interrupt sinus node blood supply. In cases where the right pulmonary veins enter high in the superior vena cava well away from the right atrium we have preferred the use of the Warden-type repair as described in this chapter, in which the superior vena cava is divided and then reconnected to the right atrial appendage and the stump of the superior vena cava, to which the anomalous veins return, is baffled across the atrial septal defect to the left atrium. This approach avoids the need for an incision across the caval-atrial junction that may interfere with sinus node blood supply, and there have been many recent reports of excellent consistent results with this technique with a low incidence of late development of superior vena caval stenosis. If superior vena caval stenosis occurs at the suture line, and if the azygos vein is left open, decompression is often to the IVC, and the SVC can be dilated or stented in the catheterization lab if significant obstruction is present.

The authors described the techniques for repair of scimitar syndrome, which include reimplantation of the anomalous vein or baffling of the vein across an atrial septal defect to the left atrium. They presented a good summary of the various techniques that have been used. Recently, there has been a resurgence of interest in reimplantation of the right-sided pulmonary veins directly into the left atrium through a right thoracotomy incision without the use of cardiopulmonary bypass. An advantage of this technique is the fact that the geometry of the vein can be better assessed with the lung slightly inflated through a thoracotomy incision, which may prevent kinking of the vein as it enters the left atrium. This technique is most applicable when there is not a significant atrial septal defect present. Although it is possible to close the atrial septal defect through a right anterior thoracotomy incision and reimplant the anomalous vein, we believe that if bypass is necessary, a standard sternotomy incision is generally the simplest way to get to the areas of interest and avoids struggling with the division of the right pulmonary vein entrance at the level of the diaphragm. Although the few reports of direct reimplantation off bypass through a thoracotomy have suggested a very good patency rate, the development of stenosis or occlusion of the reimplanted vein over time needs to continue to be assessed before this technique can be adapted routinely.

The greatest complication after repair of scimitar syndrome is stenosis or kinking of the scimitar vein at the anastomosis to the right or left atrium. This can result in occlusion of the vein and late development of hemoptysis, which is extremely difficult to treat. In some cases, stenosis of the vein can be treated with stent implantation in older children. Because of the concerns of obstruction of the scimitar vein, I have most recently been interposing a short segment of PTFE graft between the scimitar vein and the anastomosis to the left atrium through a right thoracotomy approach to prevent stenosis of the suture lines. While follow-up remains short, at this point there appears to be some improvement in flow through the veins with the use of this technique. Essentially, the short segment of PTFE graft acts as a stent to prevent contraction of the suture lines.

It should also be noted that scimitar syndrome presenting in infancy with significant pulmonary hypertension has a very poor prognosis. Because of the high incidence of vein obstruction in scimitar syndrome in adulthood, some authors have recommended that these patients be followed without operative intervention. We still believe, however, that patients with a significant left-to-right shunt and no associated anomalies with no evidence of pulmonary vascular resistance should be considered for surgical therapy with attention to the technical details to prevent vein obstruction.
In patients who present with scimitar syndrome in infancy with pulmonary hypertension, often associated with other left-to-right shunts, assessment of the aortopulmonary collateral circulation to lower portion of the right lung is imperative. It may be possible to palliate many of these children with occlusion of these aortopulmonary collateral vessels to decrease the left-to-right shunt and improve pulmonary hypertension in the newborn and infant. The subsequent need for the repair of the scimitar syndrome is then based on the relative size of the right lung and the relative magnitude of the left-to-right shunt that is flowing through the generally hypoplastic right lung. In some cases, if the flow distribution is markedly to the left lung and away from the hypoplastic right side, repair of the scimitar vein may not be indicated.

The authors commented on the presence of ASDs with failure to thrive in infancy. Although it is certainly not predictable that closure of a secundum ASD will alter the growth patterns of very young children (because generally these shunts are not large), I have seen several patients over the years who have had marked improvement after a moderate-sized secundum defect was closed in infancy. Care must be taken, however, to ensure that these patients do not have additional left-sided cardiac lesions that exacerbate the left-to-right shunt from a relatively small ASD and that can be unmasked after ASD closure. Nevertheless, in patients with no other cause for failure to thrive and a significant ASD, I believe that the low risk of closing the defect is warranted.
VENTRICULAR SEPTAL DEFECTS

Ventricular septal defects (VSDs) are among the most common congenital heart anomalies. Isolated VSDs represent approximately 20% to 30% of all congenital cardiac malformations and have a prevalence of 1 to 2 per 1,000 live births. There is a slight female predominance.

Roger first described the clinical signs and symptoms of a VSD in 1879 as a small, flow-limiting VSD with associated normal pulmonary artery. At the other end of the clinical spectrum is a large VSD with severe pulmonary hypertension and fixed pulmonary vascular resistance resulting in cyanosis with right-to-left shunting through the VSD, first described by Eisenmenger in 1897.

VSDs may be associated with a wide variety of other cardiac defects, including mitral valve disease, atrioventricular (AV) discordance, conotruncal abnormalities such as transposition or double-outlet ventricle, and hypoplasia of either ventricle. They are the most common heart defect in many chromosomal anomalies, including patients with trisomies 13, 18, 21 and with Holt–Oram syndrome. Isolated VSDs and those associated with patent ductus arteriosus and coarctation of the aorta are described in this chapter.

CLASSIFICATION OF VENTRICULAR SEPTAL DEFECTS

The ventricular septum forms between 4 and 7 weeks of gestation and involves fusion of several tissues, including endocardial cushion-derived mesenchyme, primary atrial septum, and muscular components of the atrial and ventricular septum. The muscular intraventricular septum forms by infolding of the ventricular muscle within the primitive cardiac tube. It then aligns with the conal septum that is positioned between the two outflow tracts. The membranous septum closes adjacent to the anteroseptal commissure of the tricuspid valve. VSDs may occur anywhere in the septum.

VSDs are classified based upon their location within the ventricular septum. Spontaneous closure rate and the presence of associated defects depend upon the location of the defect and the type of VSD. Of the many classifications of VSDs, the most widely accepted today are those of Soto and van Praagh (Fig. 80.1). The ventricular septum has three main components: (1) an inlet portion beneath the septal leaflet of the tricuspid valve and extending from the tricuspid annulus to the papillary attachments of the tricuspid valve chordae, (2) a trabecular or muscular portion that extends from the chordal attachments of the tricuspid valve to the apex of the ventricles and cephalad to the conal septum, and (3) a smooth-walled conal or outlet septum, which comprises the infundibular septum clasped between the anterior and posterior limbs of the septal band (trabecular septomarginalis) and extends up to the pulmonary and aortic annuli. The inlet and trabecular portions are often referred to collectively as the ventricular septum, in contrast to the conal septum, which is also called the “outlet” or “infundibular” septum.

Conoventricular (Perimembranous) Defects

Conoventricular defects are the most common isolated VSDs, comprising about 70% to 80% in most series. They are situated in the junctional area between the conal or outlet and inlet portions of the septum and may extend into the inlet, outlet, or both parts of the septum. They extend up to the tricuspid valve annulus in the region of the anteroseptal commissure of the tricuspid valve. The aortic valve is easily visible through the defect when viewed through the tricuspid valve at operation. Alternatively, these defects may be partially occluded or rendered restrictive by overlapping tricuspid valve tissue. Occasionally, the noncoronary aortic leaflet may prolapse through the defect resulting in progressive aortic incompetence.

The conduction system is intimately associated with this VSD. The bundle of His penetrates the right trigone of the central fibrous body at the anteroseptal commissure of the tricuspid valve. From there, it is closely related to the lower half (posteroinferior edge) of the defect, giving off the left fascicles along its course to the medial papillary muscle (also called the muscle of Lancisi or the papillary muscle of the conus). As it passes just inferior to the latter, only the right bundle remains, and this continues into the trabecular septomarginalis away from the edge of the defect. Conoventricular septal defects are usually repaired through the right atrium.

Conal Septal Hypoplasia (Outlet) or Conotruncal Defects

Conotruncal defects are also called supracristal, subarterial, subpulmonary, juxtaparticular, or infundibular. They account for 5% to 10% of isolated defects, except in the Asian population in whom they are more common accounting for up to 30% of VSDs. Typically, the defects are oval in shape and extend up to the pulmonary and aortic annuli. Because the normal subpulmonary conus is deficient, the pulmonary and aortic valves are separated only by a very thin rim of fibrous tissue that maintains fibrous continuity between the aortic and pulmonary valves. This results in aortic leaflet prolapse, which occurs in 40% to 50% of conal defects. The right aortic leaflet most commonly is sucked into the defect, resulting in aortic insufficiency. The conduction tissue is remote from the borders of this type of VSD, which is most easily repaired through a short transverse incision in the right ventricular outflow tract, or through the main pulmonary artery (Fig. 80.1). These defects will not close spontaneously.
Muscular Defects (Trabecular Defects)

Muscular VSDs account for 10% to 20% of isolated VSDs, may be single or multiple, and may occur in any part of the muscular septum. They may be associated with other types of VSDs. They are generally classified depending upon their location in the septum and may be divided into midmuscular defects (most common), apical or posterior muscular, and anterior muscular defects (Fig. 80.1). Muscular defects may have numerous openings of variable size on the right ventricular side but only a single opening on the left ventricular side of the septum. This is referred to as a "Swiss cheese" defect. The conduction tissue is generally remote from the edges of a muscular defect, with two notable exceptions: (1) when associated with a conoventricular defect, the penetrating bundle usually runs in the muscle bridge separating the two defects and may easily be injured if each are closed individually and (2) if a muscular defect is present in the inlet septum (i.e., the defect is separated from the tricuspid valve by a thin rim of muscle), the conduction tissue runs along the defect superior and anterior (leftward) margin—the AV node penetrates the interventricular septum at the anteroseptal commissure of the tricuspid valve and takes the most direct route to the medial papillary muscle along the superior border of the defect. Muscular defects often close spontaneously. Surgical approach is variable based upon the location of the defect.

**PATIENT CHARACTERISTICS**

Both the relative pulmonary vascular resistance and the size of the defect determine the hemodynamic effect of the VSD. In the early newborn period, when pulmonary and systemic vascular resistances are relatively equal, there is little or no shunting of blood across the defect. As the pulmonary vascular resistance declines in the first weeks of life, the degree of shunting across the defect increases. Shunting occurs largely during systole and is directed to the lungs and the left side of the heart, causing left heart overload. In infants with a hemodynamically significant VSD, increased pulmonary blood flow from moderate-to-large defects leads to symptoms and signs of heart failure and to left atrial and left ventricular dilation.

Infants and children may not develop symptoms early in life unless the VSD is large. Patients with symptomatic VSDs present similar to those of heart failure, including tachypnea, tachycardia, increased work of breathing and, in some cases, repeated pulmonary infections. Those patients with large VSDs are often too tachypneic to feed orally, experience recurrent chest infections and aspiration of gastric contents, and may have pulmonary hyperinflation syndrome or cardiac asthma. The latter results from systemic pressure in the segmental pulmonary arteries compressing the small bronchi and resulting in chronic air trapping. Many of these infants fail maximal medical management aimed at decreasing the symptoms of heart failure.

**DIAGNOSIS**

The size, number, and location of VSDs can be accurately defined by echocardiography. Estimates of pulmonary artery pressure can be made using Doppler imaging of the velocity of a tricuspid regurgitant jet, if present. Defects are considered “large” if they approximate the size of the aortic annulus or result in systemic pulmonary artery pressures. Chronic elevation in...
pulmonary blood flow can alter the pulmonary vascular bed, leading to intimal proliferation and muscularization of the arterioles known as Eisenmenger syndrome, a condition where the increased pulmonary vascular resistance leads to pulmonary hypertension and right-to-left shunting across the VSD. Ultimately, this can result in cyanosis.

VSDs are also characterized by the degree of shunting by catheterization. A simple formula for calculating the $Q_p$/$Q_s$ ratio using oxygen saturations measured by cardiac catheterization is as follows:

$$Q_p/Q_s = \frac{(Ao%-RA%)/(PV%-PA%)}$$

"Medium"-sized defects result in a $Q_p/Q_s$ ratio of 2:1 to 3:1 and a systolic pulmonary artery pressure that is 40 to 50 mmHg or about one-half that of the aorta. "Small" defects have essentially normal pulmonary artery pressures and a $Q_p/Q_s$ ratio of <1.5:1.

**INDICATIONS FOR OPERATION**

More than 75% of small VSDs will close by fibrosis and muscular hypertrophy within the first 2 years of life. Closure of a VSD is recommended once a large VSD is detected or once a patient becomes symptomatic. Thus, infants with large VSDs presenting in the first few months of life with severe congestive heart failure should undergo prompt repair. Delaying surgery until the patient is "bigger" is not beneficial and often results in additional morbidity and mortality.

Historically, small infants with a large VSD were initially palliated by placing a constricting band around the main pulmonary artery, suturing this to the adventitia, and gradually narrowing the band circumference until the systolic pressure in the pulmonary artery distal to the band was reduced by 50%. This decreased the flow through the pulmonary artery, ameliorated congestive cardiac failure, and allowed the patient to grow to a large enough size for the band to be removed and the VSD to be safely repaired. However, as methods of myocardial protection advanced and the surgical skills and postoperative care of small infants improved, pulmonary artery banding was abandoned in favor of primary closure of the VSD except in rare cases.

When reviewing the indications for surgical closure of a VSD, there are four aspects to take into consideration: (1) characteristics of the defect, (2) the patient’s age and symptoms, (3) pulmonary vascular resistance, and (4) associated cardiac and noncardiac defects.

Any VSD associated with failure to thrive should be closed. If a VSD is associated with prolapse of the aortic valve leaflet resulting in even mild regurgitation, this should be repaired irrespective of the symptoms or size of the defect. In addition, surgical repair is recommended for inlet or outlet types as they are not likely to close spontaneously. The same is true for residual VSDs typically >3 mm in size.

The exception to early primary closure in a symptomatic infant is the presence of multiple muscular defects, which is still associated with significant mortality when repaired in infancy. This is one of the few remaining indications for pulmonary artery banding. Debanding of the pulmonary artery and repair of the VSDs are done when the patient is about 6 to 12 months of age. Some muscular defects may be suitable for percutaneous catheter device closure by our cardiology colleagues. This can be done either before operation, intraoperatively with a hybrid approach or postoperatively. Apical and anterior muscular defects are often difficult to adequately close in the operating room and may be closed percutaneously.

Infants with symptoms controlled with medical therapy and large defects that have not appreciably decreased in size should be electively repaired between 6 months and 1 year of life. Most of these infants experience poor weight gain and failure to thrive. Many will develop increased pulmonary vascular resistance. These infants are considered to have "reactive pulmonary hypertension" and are at increased risk for developing pulmonary hypertensive crises in the postoperative period, particularly if their surgery is delayed.

Beyond 12 to 18 months of age, patients with large VSDs should undergo cardiac catheterization and be repaired if their pulmonary vascular resistance is <8 to 10 U/m² while inspiring 100% oxygen or on nitric oxide thus demonstrating reversibility or the $Q_p/Q_s$ ratio exceeds 1.5:1 at rest. Pulmonary vascular resistance is seldom prohibitive during the first year of life in patients with an isolated VSD, except occasionally in patients with associated Down's syndrome. These patients tend to develop pulmonary vascular obstructive disease at an earlier age.

In a patient with high fixed resistance, the defect should not be closed. When small defects are discovered later in childhood, spontaneous closure is unlikely. These defects should be closed if any complications develop including endocarditis and psychological trauma including sports restriction.

**ASSOCIATED CARDIAC AND NONCARDIAC PATHOLOGIC CONDITIONS AFFECTING CLOSURE**

Infants with significant additional left-to-right shunts, such as an atrial septal defect or patient ductus arteriosus, usually have intractable congestive heart failure in early infancy. Early primary closure of all defects is thus indicated. There is a slightly increased risk and morbidity associated with repair of these infants, which relates mainly to their poor preoperative condition. In contrast, neonates and young infants with associated coarctation of the aorta should first have the coarctation repaired through a left thoracotomy if feasible. If they cannot be weaned from the ventilator or continue to have symptoms after the coarctation repair, prompt repair of the VSD is advised during the same hospitalization. In the recent era, however, studies have also shown that the single-stage approach of simultaneous VSD and coarctation repair via a median sternotomy can be performed with comparably low morbidity and mortality.

There are a few caveats to this approach: (1) coarctation and associated multiple muscular defects in which pulmonary artery banding may be done at the time of coarctation repair via the same incision, (2) coarctation and associated large outlet septal (subpulmonary) defect in which simultaneous primary repair is indicated as this type of VSD does not usually undergo spontaneous closure, and (3) VSD and associated interruption, which are best simultaneously repaired though a midline approach.

About 25% of infants undergoing repair of isolated VSD have some noncardiac morphologic syndrome or pathologic condition (i.e., Down's syndrome, VACTERL syndrome, tracheoesophageal fistula, etc.) associated with their VSD. In very symptomatic patients, it is often difficult to quantify the contribution to symptoms of a medium-sized defect. Early closure of the cardiac defect is, therefore, reasonable.

**TECHNIQUE OF REPAIRING VENTRICULAR SEPTAL DEFECTS**

For premature infants or small patients younger than 2 months of age (or <3.5 kg in weight), the technique of profound hypothermic circulatory arrest may be used for repair. The right atrial appendage is cannulated with a single 16-Fr right-angled venous cannula and the ascending aorta is cannulated with an 8- or 10-Fr cannula.
The ductus arteriosus is ligated while the patient is being cooled. The ductus should always be ligated before the circulation is arrested to prevent air from entering the aorta inadvertently. The right atrial appendage is incised around the SVC. The ductus is ligated once the patient has been drained. For older infants, bicaval cannulation is used and the repair is done with either normothermia or mild hypothermia (32 to 26°C) and cold blood cardioplegia. A conventional method for cannulating the superior vena cava (SVC), in especially with very small infants, is to first cannulate the right atrial appendage with a small but straight venous cannula and commence cardiopulmonary bypass (CPB). After commencement of CPB, that cannula is passed into the SVC and a caval tape placed around the SVC. The ductus is ligated once CPB is commenced.

After the aorta has been clamped and the heart arrested with cardioplegia, the right atrium is opened with an oblique incision (Fig. 80.2). A pump sucker is placed in the left atrium via a patent foramen ovale or creation of an ASD via a stab incision in the atrial septum to keep the operative field dry. Alternatively and depending on the size of the patient, the pump sucker or LV vent can be placed through the left atrial appendage or the right superior pulmonary vein.

Occasionally, the defect is small enough to close using interrupted horizontal mattress suture of felt pledged 5–0 polypropylene sutures. More typically, some sort of patch material is needed for repair and polyester (Dacron) velour is the most commonly used patch material. Alternatively, fresh or glutaraldehyde treated autologous pericardium or polytetrafluoroethylene (Gore-Tex) surgical patch may be used. The advantage of using Dacron is the vigorous endocardial reaction that it stimulates, expediting the spontaneous closure of small residual defects that may remain after closure.

Conoventricular defects are usually repaired through the right atrium, which is opened with an oblique incision parallel to the right AV groove (Fig. 80.2). A small retractor is used to retract the tricuspid anterior leaflet to visualize the VSD. This retractor can then be rotated cephalad to expose the superior margin of the defect in the vicinity of the anteroseptal commissure. Gentle caudal traction on a small pump sucker placed through the VSD brings into view the superior and anterior margins of the defect. The anterosuperior triangle where the aortic valve, tricuspid annulus, and parietoinfundibular fold meet is the most difficult area to expose and therefore the most common site of residual lesions. Attaching the VSD patch to trabeculated RV muscle in this area as opposed to true conus or even aortic valve annulus may result in residual “intramural” VSDs that are challenging to repair.

The VSD is repaired with a Dacron-felt patch, which is cut slightly larger than the defect but with a similar shape. Patch material can be sewn in place with continuous suture technique, although an interrupted technique with felt pledgeted sutures has been well described. As viewed by the surgeon through the tricuspid valve, a polypropylene suture is passed through the right side of the interventricular septum, close to the muscle of Lancisi, approximately 2 mm away from the edge of the septum. The suture is extended caudally until exiting through the septal leaflet of the tricuspid valve adjacent to the annulus. The other end of the suture is continued along the superior margin of the VSD with great care not to injure the tricuspid valve. Once this aspect is complete, this suture is continued as a horizontal mattress suture via the septal leaflet and medial margin of the patch that allows the patch to lie below the leaflet. The two ends of the suture are then tied on the right atrial side of the tricuspid valve with or without a pledget (Fig. 80.3). If the septum is very friable or sutures appear to have torn through the septal muscle, it is advisable to add interrupted pledgeted horizontal mattress sutures to secure the patch and avoid dehiscence.

Upon completion of the VSD patch, the sucker is withdrawn from the PFO and the left atrium instilled with saline solution as a deairing maneuver. Depending upon surgeon preference, the lungs are inflated as a Valsalva maneuver to further deair the left heart prior to PFO closure. The PFO is then closed with a single 5–0 polypropylene suture. The tricuspid valve is tested for
competence and repaired if necessary. The right atrium is then closed in a running manner, typically as an epicardial closure inverting any endocardial tissue.

In the case of abundant tricuspid valve chordae or attachments to the septum, the VSD is better visualized by incising the septal leaflet of the tricuspid valve approximately 2 mm from the annulus (Fig. 80.4). By reflecting the leaflet anteriorly, the VSD is exposed with clear, easily visualized margins. The leaflet is then reapprorximated using a continuous suture, typically the same suture anchoring the Dacron patch to the septal leaflet. An alternative approach, although more challenging, is to divide the obstructing chordae to the septal leaflet and then repair by suturing the chordae to the septum or to the patch using Gore-Tex sutures.

An alternative approach to a VSD is through a right ventriculotomy. This approach is convenient in cases of RV muscle hypertrophy that require resection. It is also a useful approach in some cases in which the most anterosuperior aspect of the VSD is difficult to visualize through the tricuspid valve. In these cases, a vertical ventriculotomy is performed parallel to the left anterior

---

Fig. 80.3. Transatrial closure of a ventricular septal defect using a continuous suture technique. The first suture is placed just inferior to the muscle of Lancisi and about 3 mm from the edge of the defect. To the right of this suture, the conduction fibers are vulnerable up to the point where the suture is passed through the tricuspid septal leaflet. To the left of the first suture is the "safe" area. (Inset) The completed repair.

Fig. 80.4. The tricuspid leaflets may be detached 1 to 2 mm from the annulus to improve exposure in some conoventricular or inlet septal defects. Note that the atroventricular node penetrates the right trigone of the central fibrous body at the anteroseptal commissure of the tricuspid valve.
descending artery. Great care must be used to inspect the surface of the ventricle for the coronary pattern. An oblique incision is recommended in situations in which the right coronary originates from the left anterior descending and crosses the RV outflow tract or when there is a “dual supply” left anterior descending with a large conal branch extending from the right coronary artery. The VSD is then closed in a continuous manner (Fig. 80.5).

Repair of Inlet Septal Defects

These defects are generally repaired through the right atrium similar to conoventricular defects. Detachment of the septal leaflet is rarely necessary because the inlet (AV canal type) defects are easily exposed through the tricuspid valve. In these cases, it is important to make the patch ovoid or even in a semi-lunar shape as the defect tends to be less circular. A circular patch can interfere with the tricuspid valve. It is important to differentiate an inlet septal defect from a muscular septal defect in the inlet septum because, in the latter, the bundle of His runs in the thin rim of muscle separating the VSD from the tricuspid valve annulus.

Repair of Conal Septal Defects

Defects in the infundibular septum are approached through the pulmonary valve via a transverse incision in the main pulmonary artery (Fig. 80.2) or through the aorta itself. Conal septal defects are juxta-arterial, the superior margin of the defect being the pulmonary and aortic valve annuli. These are frequently separated by a thin, fibrous rim that is inadequate itself to support sutures. In the repair, interrupted pledgeted sutures are placed through the annulus of the pulmonary valve so that the pledgets lie within the right ventricle below the valve (Fig. 80.6). The inferior margin of the defect is closed with a patch if necessary otherwise buttressed to the annulus with a pledgeted suture in those VSDs measuring <3 mm in size. In these cases, the conduction tissue is remote from the margins of the VSD. In the case of conal septal defects with aortic insufficiency due to a prolapsing leaflet, the aortic valve must be inspected. Typically, closure of the VSD alone resolves the Venturi or “windsock” effect of prolapse and associated insufficiency. The right coronary leaflet is most commonly involved and may be resuspended if necessary by performing a Trusler-type resuspension of the commissures. Yacoub describes concomitant resuspension of the valve leaflets with VSD closure.

Repair of Muscular Ventricular Septal Defects

Midmuscular defects are closed in a similar manner to conoventricular defects, through the right atrium. When both a conoventricular and sizeable mid-muscular defect are present, one large patch may be used to close both defects in order to avoid injury to the conduction system. Anterior muscular defects are closed either through the tricuspid valve or via a ventriculotomy (Fig. 80.6). Multiple muscular defects maybe obscured by trabeculations in the right ventricle. Often these, trabeculations may be divided in order to adequately visualize the VSD. If the margins of the muscular defect cannot be identified through the tricuspid valve, it may be beneficial to pass a right angle clamp through the mitral valve and probe the ventricular septum carefully through the left side. Two pieces of Dacron or felt may then be used to “sandwich” the defect between the two layers of felt (Fig. 80.7).

Apical muscular defects and multiple “Swiss cheese” defects are the most difficult to repair. Many of these defects will close spontaneously. If they cause significant heart failure in infancy, PA banding is recommended. Upon repair, they are approached through the right atrium. However, if they cannot be repaired satisfactorily through the tricuspid valve, they may be approached via an apical left ventriculotomy. Upon doing so, the apical defects are well visualized and may be patch closed with running suture. An alternative therapy is the percutaneous approach with deployment of the Amplatzer device.

RESULTS OF OPERATION

Hospital mortality associated with the closure of isolated VSDs is <1%. Incremental risk factors for mortality are (1) multiple defects resulting in a Swiss cheese septum, (2) associated additional left-to-right shunts such as large atrial septal defects, and (3) severe associated noncardiac anomalies. Small patient size is no longer a risk factor for mortality, although prematurity and size <2 kg may be an indicator of increased morbidity.

Intraoperative transesophageal echocardiogram is performed routinely in the operating room upon separation from CPB to evaluate for the presence of a residual VSD, aortic or tricuspid valve competence, and ventricular function. If there is a question about the significance of a residual
Chapter 80: Ventricular Septal Defects

Fig. 80.6. Part of the anterior and septal leaflets of the tricuspid valve has been detached to improve exposure of a conoventricular and midmuscular septal defect. The penetrating bundle lies in the muscle bridge between the two ventricular septal defects. (A) The defects are closed using a single composite patch to avoid injury to the conduction tissue. (B) Once this has been completed, the tricuspid leaflets are sutured back on the annulus with a continuous 5-0 polypropylene suture.

Fig. 80.7. Closure of multiple anterior muscular defects through a short vertical right ventriculotomy. (A) The defects are sandwiched between two strips of felt or pericardium, one placed inside and the other outside the right ventricle parallel to the left anterior descending coronary artery. (B) Interrupted horizontal mattress sutures are used.
VSD, direct measurement of pulmonary artery pressure and oxygen saturations can be made and the Qp:Qs estimated. Small residual defects (<3 mm) usually close spontaneously and only need reoperation in symptomatic patients with a Qp:Qs ratio of exceeding 1.5:1 or if pulmonary artery pressures remain significantly elevated. Further, cardiac intervention is required in fewer than 5% of patients and long-term survival is excellent after surgery. Complete heart block occurs in approximately 1% to 3% of patients. A right bundle branch block is usually present in patients undergoing right ventriculotomy for closure. The presence of a right bundle branch block postoperatively is not associated with any long-term morbidity.

**SUGGESTED READINGS**

clamp through the conoventricular defect and exploring the ventricular septum. The entrance points in the right ventricle can then be identified and trabeculae divided to expose the margins of the defect for accurate closure. Most apical midmuscular and conoventricular and conoapical hypoplasia defects can be closed with a high degree of certainty at primary operation. However, anterior muscular defects remain problematic, because they may be difficult to expose through the atrium. In some cases, these defects can be approached through the aortic valve or a right ventricular outflow tract incision. In situations of multiple muscular defects, the Toronto group has described suturing together the trabeculae with fine sutures working through the tricuspid valve. In this manner, the entrance points of defects in the right ventricle can be closed and even multiple muscular defects can satisfactorily dealt with.

In situations where the margins of the muscular defect cannot be readily identified, it may be possible to pass a right-angled clamp through the mitral valve from a transatrial septal approach across the defect into the right ventricle. A large polypropylene suture can then be brought back into the left ventricle and left atrium and a piece of Teflon felt cut larger than the anticipated left ventricular side of the defect. The patch can then be secured with the suture and brought through the mitral valve on to the left side of the septum. The suture is then brought through a similarly shaped Teflon-felt patch on the right ventricular side and tied. In this manner, the defect is sandwiched between the two layers of felt and the actual direct margins of the defect do not have to be identified. This technique can be particularly useful in "Swiss cheese"-type ventricular septal defects or occasional anterior muscular defects that are obscure.

The advent of transcatheter closure devices has aided surgical intervention for patients with multiple VSDs. In patients in whom residual defects are present or where there are multiple midmuscular defects that can be approached with a transcatheter device, either transcatheter closure before operative closure of remaining defects or after closure of the surgically accessible defects may be associated with a high degree of success.

There has been a great deal of interest in the use of Amplatzer and clamshell-type VSD closure devices. Although these devices can be deployed in the catheterization laboratory, the approach, across the tricuspid valve, may be difficult. There has been great interest in a hybrid approach in which a standard sternotomy is made, and using a percutaneous approach with a needle in the right ventricle, a guide wire is passed across the defect under echocardiographic guidance and then an Amplatzer device deployed with the heart beating off cardiopulmonary bypass under echo guidance. These techniques have the advantage of being able to close even fairly remote apical muscular defects with high degrees of success and avoid the need for cardiopulmonary bypass. As additional experience is gained with these techniques, greater use of hybrid approaches is likely to occur, and even defects that are normally accessible through the right atrium may be closed with a percutaneous approach to avoid the need for cardiopulmonary bypass.

Perimembranous VSD devices are being developed and may supplant surgical therapy for many typical conoventricular VSDs. However, the close association of the aortic valve with the superior rim of the VSD may result in some problems with these devices over time, and the incidence of heart block has not completely been identified with the current generation of transcatheter conoventricular closure devices. Nevertheless, the advent of the VSD occluder devices has made pulmonary artery banding for VSDs virtually unnecessary. An additional area of controversy is the approach to patients with coarctation of the aorta and large conoventricular defects. In infants in whom there is a degree of arch hypoplasia in association with a very large conoventricular defect, which is a common association, we have elected to primarily repair both defects through a midline sternotomy with patching of the aortic arch, which relieves the arch obstruction completely. Although in a small percentage of cases these large defects might close spontaneously, the avoidance of pulmonary artery banding and significant shunting early in life controls congestive heart failure immediately and has been associated with good outcomes in our patients.

The presence of residual VSD after attempted surgical closure remains a problem. Most commonly with conoventricular defects or malalignment defects, it can be difficult to expose the anterosuperior aspect of the defect, and residual defects can be present in this location. In addition, in patients with tetralogy of Fallot, conus muscle bundles can masquerade as the margin of the defect, and the patch may be attached more on the ventricular muscle than the superior rim of the defect, leaving an abnormal connection from the left ventricle to the right ventricle underneath the aortic valve and obscured by the trabecular muscle. Often these defects are best approached through the aortic valve, where the superior margin of the patch can be readily identified, and either direct primary closure with sutures to the base of the right coronary leaflet of the aortic valve or additional patch closure can be undertaken.

It has been shown that residual peri-patch ventricular septal defects of <3 mm generally will close over time and rarely require surgical reintervention. However, there are situations where sutures placed in the base of the septal tricuspid valve leaflet in conoventricular defects can tear through the delicate tissue if not supported by buttressed sutures, and in these cases it is possible to develop a left ventricle to right atrial shunt. This particular circumstance seems to result in elevated right atrial pressures which can be associated with pleural effusions and chylothorax. The magnitude of shunt may be larger than a ventricular level shunt and many of these patients will require reoperation to resolve the pleural effusions even though the relative size of the defect is quite small.
Aortopulmonary Window
Moritz C. Wyler von Ballmoos, Michael E. Barnes, and James S. Tweddell

EPIDEMIOLOGY, EMBRYOLOGY, AND ANATOMY
Aortopulmonary window is a rare defect and accounts for about 0.1% to 0.2% of all structural congenital cardiac defects. Major academic centers could anticipate taking care of one or two infants with aortopulmonary window per year. Antenatal diagnosis of aortopulmonary window is challenging and delayed diagnosis may occur; the actual defect prevalence at birth is hence more difficult to estimate.

Aortopulmonary window is caused by failure of fusion of the two opposing conotruncal ridges that are responsible for separating the truncus arteriosus into the aorta and pulmonary artery. The aortopulmonary window, therefore, occurs between the two structures that normally result from septation of the truncus arteriosus, namely, the ascending aorta and the main pulmonary artery. Normal anatomy of the aortic and pulmonary valves separates this defect from the persistent truncus arteriosus. The similarity among conotruncal defects raises the question of a common underlying pathogenesis, but anatomic studies suggest that it develops by a different mechanism than truncus arteriosus. Furthermore, to date, no genetic association or environmental risk factors have been linked to aortopulmonary window.

A classification of aortopulmonary window based on the location has been proposed by Mori dividing aortopulmonary window into three types; proximal (type I), distal (type II), and total (type III). The classification introduced by the Society of Thoracic Surgeon adds a fourth, “intermediate” category accounting for the fact that this defect likely has a continuum of morphologies. For patients with aortopulmonary window without additional lesions, it is the size rather than the location of defect that impacts management and outcome (Fig. 81.1).

Origin of the right pulmonary artery from the ascending aorta and arch hypoplasia with interruption or coarctation are additional anomalies occurring with large aortopulmonary windows. With increasing size of the aortopulmonary window aberrations in flow result in abnormal incorporation of the right sixth arch, destined to become the right pulmonary artery, such that the right pulmonary artery arises from the rightward aspect of the ascending aorta. Similarly, with large aortopulmonary windows flow patterns can be disturbed such that there is preferential flow through the ductus arteriosus and diminished flow in the developing aortic arch resulting in distal arch hypoplasia including coarctation or interrupted aortic arch. It has been suggested that when associated with interrupted aortic arch, aortopulmonary windows are larger with greater distal extension. The Congenital Heart Surgeons’ Society multi-institutional study of aortopulmonary window with interrupted aortic arch found that all types of aortopulmonary window were more or less equally represented among patients with interrupted aortic arch (Fig. 81.2). Aortopulmonary window is not associated with DiGeorge syndrome, suggesting that aortopulmonary window is a distinct malformation not related to abnormalities of the conal septum, such as interrupted aortic arch with ventricular septal defect (VSD), tetralogy of Fallot, and persistent truncus arteriosus.

In reports based on the cumulative experience at high-volume centers, aortopulmonary window was associated with other defects in 58% of cases, the most common being ventricular and atrial septal defect, interrupted aortic arch or coarctation of the aorta, tetralogy of Fallot, and transposition of the great arteries. Abnormal origin of the coronary arteries is also commonly associated with aortopulmonary window. The coronary arteries may arise from the edge of the defect, or the origin may occur just on the pulmonary artery side of the defect.

PRESENTATION, DIAGNOSTIC CONSIDERATIONS, AND INDICATIONS FOR SURGERY
Critical to timely diagnosis and early repair, antenatal diagnosis of aortopulmonary window was first reported in 2002. Simple aortopulmonary window may not be identified by fetal echocardiography because equal pressure in the ascending aorta and pulmonary root in the fetus results in minimal detectable flow through the defect. Posterior deviation of the outflow septum that is characteristic of patients with interrupted aortic arch with a ventricular septal defect and would prompt further interrogation of the arch by the fetal echocardiographer, is lacking in the fetus with aortopulmonary window. The antenatal diagnosis of aortopulmonary window with interrupted aortic arch has only recently been reported.

The presentation of patients with aortopulmonary window may be different depending on the size of the window, associated other defects, and age at presentation. Although small, restrictive aortopulmonary windows do occur; generally, the communication is large, and patients present in the first weeks of life when pulmonary vascular resistance drops and increased pulmonary blood flow results in congestive heart failure. The clinical presentation is then similar to that of other patients with left-to-right shunts, such as patent ductus arteriosus (PDA) or VSD. This presentation includes signs of congestive heart failure such as tachypnea, diaphoresis, poor feeding, and inadequate weight gain. In early infancy, cyanosis is usually not a prominent feature, but with large defects, bidirectional shunting can produce systemic desaturation. With delayed diagnosis and persistent pulmonary overcirculation, remodeling of the pulmonary vasculature, and ultimately pulmonary hypertension occur.

Physical examination demonstrates a tachypneic infant with accessory respiratory
Chapter 81: Aortopulmonary Window

The diagnosis is routinely made with 2D Doppler echocardiography. The location and size of the communication as well as associated anomalies are carefully identified. Echocardiography of the conotruncal region will identify the defect and associated shunt and the diagnosis of aortopulmonary window is confirmed when two separate semilunar valves can be identified. For surgical planning, echocardiographic examination should identify the coronary anatomy, the size and distal extent of the aortopulmonary defect as well as associated lesions such as anomalous origin of the right pulmonary artery and interrupted aortic arch. Echocardiography as the sole imaging modality has been shown to be accurate and sufficient for preoperative evaluation of even complex congenital defects including aortopulmonary windows with or without associated other defects.

Although using cardiac catheterization to assess the origin of the coronary arteries is theoretically appealing, the large defect occurring just above the sinuses of Valsalva combined with the tremendous pulmonary flow makes assessment of coronary artery anatomy with catheterization impractical. Cardiac catheterization should thus be reserved for the patient who presents after early infancy and therefore is at risk for elevated pulmonary vascular resistance.

Those patients who are found to have an elevated pulmonary vascular resistance should undergo testing with pulmonary vasodilators to determine whether the pulmonary vascular resistance can be reduced prior to surgical correction of the defect. The use of magnetic resonance imaging for the diagnosis of aortopulmonary window has been reported in adults.

The presence of an aortopulmonary window is an indication for surgery. If left untreated, infants die of intractable heart failure or rapidly develop pulmonary vascular obstructive disease. Medical therapy is limited to the preoperative period and for patients with irreversible pulmonary hypertension, which poses the only contraindication to immediate repair of the defect.

**PREOPERATIVE MANAGEMENT**

Because of the challenges with early diagnosis of aortopulmonary window, it tends to present with symptoms of heart failure. Initial resuscitative efforts for patients presenting in shock are aimed at improving systemic output by limiting excessive pulmonary blood flow and are similar to those used in the patient with single-ventricle anatomy and unobstructed pulmonary blood flow or patients with truncus arteriosus. For the patient with a large aortopulmonary window, this often requires intubation and mechanical ventilation as well as sedation and sometimes neuromuscular blockade to achieve a balanced circulation. The use of hypercapnea and minimizing the fraction...
of inspired oxygen (FiO₂) will increase the pulmonary vascular resistance, decrease left-to-right shunting, and improve systemic oxygen delivery. Inotropic support may be required. Prostaglandin infusion is necessary to maintain ductal patency in patients with aortopulmonary window and interrupted aortic arch or coarctation. These measures should be successful in restoring systemic output, and the patient should go to surgery without a metabolic acidosis.

**SURGICAL TECHNIQUE**

A median sternotomy incision is used for aortopulmonary window regardless of associated abnormalities. The anatomy should be carefully assessed (Fig. 81.3). The external extent of the aortopulmonary window and the coronary arteries should be identified. Coronary arteries involved in the defect can be seen arising from the area of the communication and coursing down the proximal aorta before reaching the myocardium. The position of the right pulmonary artery should be noted.

**Simple Aortopulmonary Window**

The right and left pulmonary arteries should be loosely encircled with snares so that once cardiopulmonary bypass is established, pulmonary flow can be controlled (Fig. 81.4). General anesthesia can produce a drop in pulmonary vascular resistance, resulting in excessive pulmonary blood flow at the expense of systemic perfusion. It is sometimes helpful to snare one of the branch pulmonary arteries to limit excessive pulmonary blood flow while continuing with preparation for cardiopulmonary bypass. The aorta should be dissected nearly circumferentially distal to the extent of the aortopulmonary window to allow for subsequent placement of the cross-clamp. After the administration of heparin, the aortic cannula is placed in the ascending aorta near the origin of the innominate artery (Fig. 81.4). If there is an associated atrial septal defect or VSD, bivacal cannulation should be undertaken; otherwise, a single venous cannula can be used. Cardiopulmonary bypass is begun and simultaneously the branch pulmonary arteries are snared. A left ventricular vent is placed through the junction of the right superior pulmonary vein and left atrium. A cardioplegia cannula is placed in the ascending aorta. For simple aortopulmonary window, moderate hypothermia to 32°C is adequate. The aorta is cross-clamped distal to the communication. Cardioplegic solution is infused while the pulmonary arteries are snared. The defect can be repaired via an incision in the window itself, through the aorta, or through the pulmonary artery (Fig. 81.5). An approach through the window is preferable because the origin of the coronary arteries can be easily assessed and the patch placed such that an abnormal coronary ostial origin is incorporated into the aorta. In addition, there is less potential for compromise of either of the great vessels or injury of the semilunar valves. The incision is initiated in the anterior–superior portion of the window, and, after the origin of the right coronary artery is identified, the incision is extended proximally, transecting the anterior half of the window. After the origins of the coronary arteries and the right pulmonary artery are identified, an appropriately sized patch of polytetrafluoroethylene (PTFE) or

---

**Fig. 81.3.** External view of aortopulmonary window. The area of communication between the great vessels can be easily identified. The extent of the defect and the origins of the right pulmonary artery and right coronary artery should be identified. As in this figure, the right coronary artery (arrow) can be sometimes seen originating near the inferior margin of the defect and coursing proximally on the aorta before taking its normal position in the atrioventricular groove. This finding should prompt careful internal inspection for abnormal origin of the coronary artery from the inferior ridge of the defect or the pulmonary artery.
Fig. 81.4. Preliminary steps in the repair of a simple aortopulmonary window. The left and right branch pulmonary arteries are loosely encircled. The aorta is cannulated beyond the distal extent of the aortopulmonary window so that there is adequate room for a cross-clamp. Generally, a single venous cannula placed through the right atrial appendage is used for venous drainage. After cardiopulmonary bypass has begun, the branch pulmonary artery snares are tightened. A left ventricular vent (not shown) is placed through the right superior pulmonary vein.

Fig. 81.5. Aortopulmonary window can be repaired via an incision in the window itself, through the aorta, or through the pulmonary artery.
Section III: Congenital Cardiac Surgery

pericardium is secured to the posterior wall of the defect using continuous suture (Fig. 81.6). The anterior incision in the window is then closed, incorporating the patch into the suture line (Fig. 81.7). Rewarming to normothermia is begun as the window is closed. The aortic root is deaired, and the cross-clamp is removed. Preparation for weaning from cardiopulmonary bypass includes placement of a pulmonary artery line through the right ventricular free wall as well as a left atrial line placed through the vent site. A milrinone infusion is initiated prior to weaning from cardiopulmonary bypass because this provides both inotropy and pulmonary vasodilation. Additional pulmonary vasodilators, such as inhaled nitric oxide, should be available especially in the older infant.

Repair of Aortopulmonary Window with Interrupted Aortic Arch

Aortopulmonary window with interrupted aortic arch is usually a large defect and is more frequently associated with abnormal origin of the right pulmonary artery (Fig. 81.8). A median sternotomy incision is used. Initial preparation is the same as for simple aortopulmonary window; again, the branch pulmonary arteries are loosely encircled with snares. Because of the large aortopulmonary communication, a single arterial cannula can be used. This is placed in the ascending aorta (Fig. 81.9). Flow to the distal half of the body will be through the aortopulmonary window and then via the ductus arteriosus. After cardiopulmonary bypass is established, the branch pulmonary arteries are snared and a left ventricular vent is placed. The patient is cooled over a period of at least 30 minutes to a bladder temperature of 18°C. During the cooling period, the aortic arch, head vessels, ductus arteriosus, and proximal descending thoracic aorta are mobilized. After reaching the target temperature, circulatory arrest is established, the head vessels are snared, and a C-shaped vascular clamp is placed across the descending thoracic aorta at least 1 cm distal to the insertion of the ductus arteriosus, and cardioplegic solution is infused via the arterial cannula. With the branch pulmonary arteries, descending thoracic aorta, and head vessels occluded, cardioplegic solution will be directed into the coronary arteries. The entire procedure can be performed using deep hypothermic circulatory arrest, or alternatively continuous cerebral perfusion can be used by selectively perfusing the innominate artery. The ductus arteriosus is ligated near the pulmonary artery, and all ductal tissues is excised from the descending thoracic aorta. The undersurface of the proximal aortic arch is incised, and the incision is continued into the ascending aorta. The descending thoracic aorta is then brought up and anastomosed to the undersurface of the aortic arch and distal ascending aorta. Construction of the aortic anastomosis is facilitated by holding the descending thoracic aorta in a C-clamp (Fig. 81.10). This provides for close approximation while the anastomosis is performed. After reconstruction of the aortic arch, a cross-clamp is placed between the aortopulmonary window and the reconstructed arch and cardiopulmonary bypass is re-established. Alternatively, a single period of deep hypothermic circulatory arrest can be used for the entire repair. The window is approached as described. Again, the origins of the right pulmonary artery and coronary arteries are assessed (Fig. 81.11). A patch of PTFE or pericardium is placed to close
Fig. 81.7. Approach through the aortopulmonary window (continued). The patch is secured to the posterior margin of the aortopulmonary window using a continuous suture technique. Anteriorly, closure of the arteriotomy in the aortopulmonary window incorporates the patch.

the window such that the right pulmonary artery is incorporated into the main pulmonary artery trunk and the lumen of the right pulmonary artery is not compromised. The patient is rewarmed, monitoring lines are placed, and weaning from cardiopulmonary bypass is conducted as for simple aortopulmonary window.

An alternative approach to repair of aortopulmonary window with interrupted aortic arch may be necessary in cases in which there is little distal ascending aorta or proximal arch present. In this case, additional patch augmentation of the arch anastomosis and proximal great vessels may be necessary to complete reconstruction; this technique is described in Figs. 81.12–81.15.

**Catheter-Based Approaches**

The utility of transcatheter closure is limited by the large size of the defect, the small size of patients with correspondingly small femoral vessels, and the potential for complications related to anomalous origin of the coronary arteries that are not easily nor consistently identified prior to intervention. Nevertheless, device closure of aortopulmonary window may be suitable for small defects in which the risk of anomalous origin of the coronary arteries is low, specifically those with a more distal location.

**SURGICAL COMPLICATIONS AND POSTOPERATIVE CARE**

For simple aortopulmonary window and even aortopulmonary window with interrupted aortic arch, postoperative inotropic support should be minimal. As in other patients with large left-to-right shunts, there is potential for acute elevation of pulmonary vascular resistance with the development of critically low cardiac output after repair. If inotropic support becomes necessary, milrinone is a good first-line agent because of its vasodilatory effects on the pulmonary vasculature. Patients operated on in the first 2 weeks of life should be at low risk for pulmonary vascular resistance elevation and may be candidates for early extubation. Older patients may benefit from sedation and neuromuscular blockade for the first 12 to 24 hours. In higher risk patients, it is reasonable to monitor pulmonary artery pressure and trends in mixed central venous oxygen saturation. If pulmonary hypertension develops, then in addition to milrinone, inhaled nitric oxide should be started promptly. If ongoing dependence on inhaled nitric oxide complicates weaning from mechanical ventilation, then transitioning to sildenafil may be considered.

**RESULTS OF SURGERY**

As with other defects, the trend toward early repair along with the advances in diagnosis and perioperative management have substantially improved outcomes over the last decades. In the current era, early mortality following repair of uncomplicated aortopulmonary window approaches zero and long-term outcome should be excellent. Early morbidity includes pulmonary artery stenosis and residual aortopulmonary septal defects.

In a pooled analysis of 370 patients, from 22 reports over 6 decades the median age at surgery was 3 months (ranging from neonates to 27-year-old adults) and 58% of the patients had associated defects. There was one reported death during surgery in all patients with isolated aortopulmonary window (128 patients). No late death was reported for this group, but some of the patients needed reintervention for residual shunting or pulmonary artery stenosis in older series and in cases where simple ligation of the aortopulmonary window was performed. In the group with associated
Section III: Congenital Cardiac Surgery

**Fig. 81.9.** Cannulation for repair of aortopulmonary window and interrupted aortic arch. The right and left branch pulmonary arteries are loosely encircled with snares. Unlike interrupted aortic arch with ventricular septal defect, a single aorta cannula is satisfactory because distal perfusion can be carried via the aortopulmonary window and a ductus arteriosus to the lower half of the body. Aortopulmonary window and interrupted aortic arch are rarely associated with ventricular septal defect, and a single venous cannula is usually all that is required. After establishment of cardiopulmonary bypass, the branch pulmonary artery snares are tightened. During the period of cooling, the brachiocephalic vessels are mobilized and loosely encircled with snares.
Fig. 81.10. Repair of aortopulmonary window and interrupted aortic arch. After the establishment of deep hypothermic circulatory arrest or continuous cerebral perfusion, a C-clamp is placed on the descending thoracic aorta approximately 1 cm distal to the insertion of the ductus arteriosus. The ductus arteriosus is ligated and divided. Residual ductal tissue is excised from the proximal descending thoracic aorta. By placing gentle traction on the C-clamp, the open end at the descending thoracic aorta is brought up to the undersurface of the proximal aortic arch and distal ascending aorta. An anastomosis is constructed between the descending thoracic aorta and distal ascending aorta/proximal arch with continuous suture.

Fig. 81.11. Repair of aortopulmonary window and interrupted aortic arch (continued). After reconstruction of the aortic arch, full cardiopulmonary bypass can be reestablished, and an aortic cross-clamp is placed between the arch reconstruction and the aortopulmonary window. Alternatively, the entire procedure can be carried out using one period of deep hypothermic circulatory arrest. Again, the aortopulmonary window is approached via an incision in the window itself. A patch of polytetrafluoroethylene or pericardium is placed such that the origin of the right pulmonary artery is connected to the main pulmonary artery trunk and the lumen of the right pulmonary artery is not compromised. The anterior margin of the patch is incorporated into the arteriotomy closure.
defects, 35 patients (17%) died during or immediately after surgery. Seven additional patients (3.4%) died during follow-up that varied in length but was >2.5 years in all reports (median follow-up 6.5 years). Importantly, these estimates include the experience from six decades and in more recent series the mortality approaches zero even for cases of aortopulmonary window with associated defects. In three studies reporting long-term outcomes, actuarial survival was between 84% and 90% at 10 years and freedom from re-intervention was 43% to 70% at 5 to 10 years after the initial procedure including patients with associated defects. Among these studies, associations with higher morbidity and mortality were found for the combination of aortopulmonary window with another defect, for the simple ligation of the window, and for the transpulmonary repair technique.

Between 1983 and 2009, 25 patients with aortopulmonary window and associated lesions have undergone repair at the Children’s Hospital of Wisconsin. Patients were divided into two categories based on the presence of important additional lesions. Simple aortopulmonary window \( (n = 12) \) included those patients with an isolated aortopulmonary window with or without an atrial level communication. Complex aortopulmonary window \( (n = 13) \) included
those patients with important additional lesions including interrupted aortic arch or coarctation of the aorta (n = 8), VSD (n = 1), pulmonary atresia with VSD and anomalous origin of the right coronary artery (n = 1), pulmonary atresia with intact ventricular septum and partial anomalous pulmonary venous return (n = 1), aortopulmonary window with d-malposed great vessels (n = 1), and congenital absence of the left pulmonary artery with pulmonary artery hypertension (n = 1). There were no deaths early or late in the simple aortopulmonary window group. In the complex aortopulmonary window group, there was one early death in the patient with aortopulmonary window, pulmonary atresia, and absent left pulmonary artery, and pulmonary hypertension.

Long-term follow-up is indicated to look for the development of branch pulmonary artery stenosis. For patients with aortopulmonary window and interrupted aortic arch, long-term observation for recurrent coarctation is indicated.

SUGGESTED READINGS

EDITOR’S COMMENTS

As noted by the author, aortopulmonary window is a rare congenital cardiac condition that presents in infancy with severe congestive failure and pulmonary overcirculation. Preoperative stabilization is imperative for low operative morbidity and mortality. Ventilatory maneuvers preoperatively can aid in stabilization of these patients. Because these maneuvers are often temporary, however, prompt resuscitation and early operation are indicated in virtually all infants with this condition.

Many operative techniques have been described for closure of aortopulmonary window. The one most commonly used, however, is the technique described here, in which the window is opened anteriorly, and after careful identification of the edges of the defect, an intra-aortic or intrapulmonary patch is placed to close the defect and separate the great vessels. In many cases, we have elected to divide the aortopulmonary window completely to carefully identify the origins of the coronary arteries and then patch the aortic and pulmonary sides separately. This can be especially useful if there is stenosis of the right pulmonary artery at its origin, which occasionally occurs. In these cases, the origin of the right pulmonary artery can be patched with the closure of the pulmonary artery.

In isolated cases of aortopulmonary window, in which the window is distally located and relatively small, it may even be possible to simply divide the defect or ligate the defect as one would a ductus arteriosus. These situations are rare, however, and can avoid the need for cardiopulmonary bypass. In this circumstance, direct identification of the origin of the coronary arteries is very important to avoid leaving a coronary coming from the pulmonary artery side of the defect.

In situations where aortopulmonary window is associated with interrupted aortic arch, we have elected to perform a more radical arch reconstruction. Because there is often very little distance distal to the aortopulmonary window and the take-off of the innominate artery and carotid vessels, we will generally ligate the ductus arteriosus, excise ductal tissue, and then make an incision into the left subclavian artery (if a type B interruption is present) or widely open the descending aorta (if a type A interruption is present), removing all ductal tissues. The aortopulmonary window is then opened and superiorly the incision is carried up into the origin of the left carotid artery for a short distance. The descending aorta is then anastomosed to the superior aspect of the incision in the ascending aorta and carotid, creating natural tissue approximation in this region. A generous patch of pulmonary homograft is then used to augment the undersurface of the aortic arch to take tension off the suture line and ensure that no kinking or narrowing of the anastomosis creates later arch obstruction and to avoid compression of the left main stem bronchus. This patch is then fashioned in such a way as to augment the ascending aorta and at its proximal portion to close the aortopulmonary window. With division of the aortopulmonary window, the pulmonary arterial side can be separately patched with a small patch of pulmonary homograft material to prevent any distortion or limitation of flow into the branch pulmonary vessels.
Coarctation of the aorta can present as a severe and emergent problem in a neonate or as a subtle and essentially asymptomatic problem in an older child (or adult). This chapter focuses primarily on coarctation in neonates or infants because it is in that population that many of the important issues of coarctation are highlighted and best appreciated. In addition, this is the population that is most frequently treated with surgical repair of coarctation of the aorta. Between January 2007 and December 2010, 75% of the 3,667 patients who underwent surgical repair of coarctation of the aorta as recorded in the Society of Thoracic Surgeons Congenital Heart Surgery Database were under 1 year of age. Sixty-three percent of these patients were 30 days of age or younger.

Coarctation is a form of left ventricular outflow tract obstruction (LVOTO) and imposes an increase in afterload to the left ventricle. It is often but not necessarily found in association with a variety of other important cardiac defects, and these can have a crucial effect on the physiology of the defect and on the patient's presentation. In its "pure" form, coarctation is simply a constriction, or narrowing, of the aorta that usually occurs near the site of insertion of the duc tus arteriosus. Because of this typical location, coarctation is often described as being "juxtaductal," and this term is used to distinguish the more common forms of coarctation from a less common form that can involve the aorta proximal to the ductus arteriosus and extend into the transverse aortic arch. This latter type is sometimes referred to as "preductal" coarctation, and because it will usually present early in infancy, it can also be referred to as "infantile coarctation." In practice, the use of the terms "juxtaductal" and "preductal" is not of critical importance as long as the extent of the coarctation is appreciated by the surgeon (Fig. 82.1).

Because of the obstruction to left ventricular (LV) outflow, as well as to distal aortic flow that is created by the coarctation, infants will generally suffer from severe LV failure manifested by poor distal perfusion and tachypnea. The LV outflow obstruction commonly results in pulmonary hypertension, and therefore "secondary" right ventricular (RV) hypertrophy is common in newborns with severe aortic coarctation. The LV failure may be reflected by a dilated, hypoco ntractile left ventricle with reduced output, and for this reason, the gradient across the coarctation site is not an indicator of the severity of the defect. The RV and LV features may be nicely demonstrated by transthoracic echocardiography. Furthermore, a well-performed two-dimensional echocardiogram will demonstrate the anatomy of the aortic arch and the great vessels and the discrete area of aortic narrowing near the ductus. Flow to the distal aorta can be severely restricted, and patency of the ductus arteriosus is often essential in the newborn to preserve perfusion to the lower body (Fig. 82.1). Therefore, neonates with coarctation should be started on an intravenous infusion of prostaglandin E1 (PGE1). Maintaining ductal patency with PGE1 infusion will also allow decompression of the pulmonary circulation resulting from downstream obstruction of the LV. In neonatal coarctation, the RV may provide most of the perfusion in the descending aorta, and because the RV pressure may equal systemic pressure (especially if there is an associated ventricular septal defect [VSD]), there can be essentially no difference in the pressure above and below the coar tation. Therefore, the pressure gradient between the upper and the lower body will underestimate the severity of the coar ctation. If no VSD is present, the descending aorta may be perfused with systemic venous blood from the RV and thereby results in the "differential cyanosis" that has been described for this lesion, with the lower body appearing more cyanotic than the upper body.

It is important to look for other commonly associated defects, which can occur anywhere along the "left heart/aorta complex." A bicuspid aortic valve is present in over 50% of patients with coarctation of the aorta. Other associated defects include mitral stenosis (often with mitral anomaly such as single papillary muscle), hypoplastic left ventricle (defined as an LV volume of <20 ml/m2), endocardial fibroelastosis (a generalized scarring of the LV endothe lium that appears as "brightness" on echocardiographic examination and that probably represents LV subendocardial ischemia), VSD (often with posterior malalignment of the infundibular septum that narrows the subaortic area), aortic stenosis (valvar or subvalvar), and atrial septal defect (ASD). All of these defects can be recognized by echocardiography, and it is not usually necessary to perform cardiac catheterization in these critically ill infants. The severity of the problem and the long-term prognosis are related to (1) age (young age, such as newborn, increases the risk), (2) the number and extent of associated defects, and (3) the actual anatomy of the defect (greater risk is incurred in patients whose defect extends proximal to the left subclavian artery).

Initial management of the newborn patient with aortic coarctation requires improving distal perfusion to the lower body by restoring the patency of the ductus arteries with an intravenous PGE1 infusion. Intubation and mechanical ventilation may be necessary due to the 15% to 20% incidence of apnea that occurs with PGE1 infusion. Once the patient has been stabilized, complete diagnostic assessment can be accomplished. This can be usually limited to an echocardiogram, which should demonstrate the anatomy of the aortic arch and isthmus, patency of the ductus arteriosus, the coarctation segment, and any important associated cardiac defects. It is not necessary to perform a cardiac catheterization for diagnostic purposes, but catheterization (or other form of imaging) should be done when there is any question about the arch anatomy, the nature of the coarctation, or the significance of a related defect that might require concomitant repair. Furthermore, cardiac catheterization has a
role when an intervention is desired before coarctation repair (such as a Rashkind atrial septostomy in patients with associated transposition of the great arteries who are not candidates for proceeding directly to the operating room). Operative repair should be considered once the diagnosis is confirmed. Coarctation of the aorta is an urgent problem in neonates, and prolonged medical management has a limited role reserved for unusual circumstances. There are currently several operative techniques for repair of aortic coarctation. Each has advantages and disadvantages, and the surgeon should be knowledgeable about each of these options. In most instances, repair is most easily and satisfactorily accomplished through a left thoracotomy, but occasionally median sternotomy is a useful approach and is discussed later.

**SURGICAL APPROACH: GENERAL CONSIDERATIONS**

The majority of coarctations can be exposed and repaired through a left lateral thoracotomy. Preferably, an arterial monitoring line should be placed in the right thoracotomy. Preferrably, an arterial monitoring line should be placed in the right thoracotomy. Preferably, an arterial monitoring line or a blood pressure cuff can be placed on a lower extremity. A pulse oximetry monitor should be placed on a lower extremity as well. The patient is placed in the right lateral decubitus position and prepped for a left lateral, muscle-sparing thoracotomy. As visualization is mostly needed posteriorly, the fourth intercostal space can be exposed via the auscultatory triangle. If additional exposure is needed, the serratus anterior muscle can be divided. The lung is retracted anteriorly and the mediastinal pleura is opened over the area of coarctation and retracted with stay sutures. Alternatively, the aorta can be approached via an extrapleural dissection. The vagus and left recurrent laryngeal nerves are then identified. The extent of the dissection of the aorta and its branches depends on the type of repair to be performed. Specifics will be discussed in the sections below. The ductus arteriosus can be encircled and securely tied just before or after the vascular clamps are placed on the proximal and distal aorta. Most patients, even infants, can have several collateral vessels arising from the aorta near the coarctation site. A Satinsky-type clamp on the descending aorta is useful to control posterior collaterals. Additional collaterals can be controlled by a variety of techniques. Small hemoclips can be placed on individual collaterals and then removed after coarctation repair. Alternatively, gold (temporary) Yasargil cerebral aneurysm clips can be used to control collaterals. These atraumatic clips can be placed to lay out of the way of the repair and easily removed at the conclusion of the operation. Proximal control can be obtained with a C-clamp that is applied to include the distal aortic arch and left subclavian artery. Distal control can be obtained with a Satinsky-type clamp as noted above or if preferred a straight or angled Debakey clamp. We do not routinely give heparin as it is unnecessary in the absence of atherosclerotic disease; however, some surgeons administer a low or moderate dose of heparin prior to clamp placement. After the clamps have been placed and the ductus has been ligated, we have found it helpful to aspirate the isolated segment of the aorta using a 22-gauge needle on a 3 ml syringe. If this portion of the aorta remains decompressed following evacuation of blood, the operation proceeds. If the aorta re-distends, a search is made for additional collateral vessels.

At the conclusion of the repair, the distal clamp is removed first to allow for deairing and initial inspection of the suture line. After alerting the anesthesiologist due to the possibility of transient hypotension, the proximal clamp is removed. At this point, pulsatile lower extremity flow should be detected by pulse oximetry. There may be an initial gradient between the upper and lower extremity blood pressures due to lower extremity vasoconstriction or to a Coanda effect that favors flow up of the innominate artery as opposed to around the transverse aortic arch; however, this should resolve within 30 minutes. The residual blood pressure gradient should be 10 mmHg or less. If there is concern about a persistently high gradient, direct measurement of aortic pressure above and below the repair may be useful. Closing the mediastinal pleura after end-to-end or subclavian flap repair depends on personal preference. Some believe that closing the mediastinal pleura over the repair can cause compression of the repair site and thereby increase the incidence of recurrent coarctation. Others believe that closing the mediastinal pleura after coarctation repair may prevent the lung from adhering to the repair site, decrease the incidence of postoperative chylothorax, and create a circumferential wrap around the repair site, which will make balloon dilation safer if recurrent coarctation occurs. After patch aortoplasty repair, closing the mediastinal pleura over the repair may not be possible.

---

**Fig. 82.1.** (A) A juxtaductal coarctation with discrete narrowing at the level of the ligamentum arteriosum. (B) An “infantile” or “preductal” coarctation with distal aortic perfusion maintained across a patent ductus arteriosus. In these patients, the aortic arch is usually hypoplastic, as shown.
and it may cause compression of the newly enlarged aorta and produce a suboptimal outcome.

**SUBCLAVIAN FLAP REPAIR**

The technique of subclavian flap repair was once considered by many authorities to be the procedure of choice for neonates and infants. However, we do not favor it and recommend against its routine use. The technique requires division of the subclavian artery and turning it down as a flap to augment the area of coarctation (Fig. 82.2). Those who favor this procedure believe that it is simple and safe, and that the patch of subclavian artery will grow with the patient and therefore will lead to lower incidence of recurrent coarctation or late aneurysm formation. Unfortunately, recurrent coarctation does occur after this procedure with about the same incidence as after other commonly used procedures, and late aneurysm development has also been reported after this procedure. The subclavian flap procedure has the disadvantage that it requires permanent division of the left subclavian artery, and although this may be well tolerated in most patients, it can lead to long-term weakness of the left arm. Subclavian steal phenomenon has been described if the vertebral artery is left intact on the distal subclavian segment. Division of the left subclavian artery is problematic in the occasional patient with anomalous origin of the right subclavian artery below the coarctation site because in these patients, permanent loss of

---

**Fig. 82.2.** (A) The coarctation is exposed through a left thoracotomy, and the aortic arch and descending aorta are controlled with clamps. The left subclavian artery and ductus arteriosus are encircled; collateral vessels can be temporarily controlled with hemoclips. (B) The ductus arteriosus is ligated, and the subclavian artery is ligated and divided as far distal as possible. It is also important to tie the vertebral artery (first branch off the subclavian artery) to reduce the possibility of late subclavian steal syndrome. An incision is then made through the subclavian artery and extended onto the descending aorta through the area of coarctation. (C) The subclavian artery is then sewn as a flap to cover the incision on the descending aorta. (D) The finished subclavian flap procedure provides augmentation of the juxtaductal area. The hemoclips previously placed on collateral vessels can be removed.
the left subclavian artery leaves no way to follow pressures above the coarctation site. Although some have suggested techniques for reimplanting the left subclavian as an augmentation patch without division and with relief of more proximal problems, these procedures are cumbersome, unnecessary, and less attractive than alternatives. Finally, and importantly, this procedure does not address hypoplasia of the aortic arch that is proximal to the left subclavian artery—a frequent finding in neonatal coarctation.

**PATCH AORTOPLASTY**

Several groups have advocated repair of discrete coarctation using a large patch of prosthetic material like Dacron, polytetrafluoroethylene (PTFE; Gore-Tex), or cryopreserved homograft (Fig. 82.3). Unlike the subclavian flap procedure, this technique does not require division of the subclavian artery, and the patch can be much larger than the subclavian flap patch. Furthermore, the patch can be extended proximally onto the aortic arch when necessary. Late aneurysm formation opposite the patch

---

**Fig. 82.3.** (A) When the coarctation is discrete and juxtaductal, vascular occlusion clamps can be placed on the aortic arch and descending aorta after the anatomy is exposed through a left thoracotomy. The ductus arteriosus is encircled with a ligature. A Satinsky-type clamp on the descending aorta can be useful in controlling posterior collaterals. An incision is then made across the area of coarctation. (B) The coarctation ridge is left intact. This is usually the narrowest part of the aorta and is usually opposite the ligated ductus arteriosus. (C) A large patch of either prosthetic or homograft material can then be placed with running monofilament suture. This patch material should be large enough to restore a normal size to the aortic lumen. (D) The completed repair provides augmentation of the aorta in the juxtaductal region.
has been reported by some, and this has tempered enthusiasm for this technique. More recent studies have suggested that the occurrence of these aneurysms may be related to easily controlled technical factors such as the type of prosthetic material used and how the coarctation ridge is managed. Most late aneurysms have been associated with the use of Dacron as compared with PTFE. Avoiding resection of the coarctation shelf has also contributed to reducing the incidence of this complication. Using a large patch of PTFE will compensate for the relatively minimal intrusion of the posterior ridge into the aortic lumen. Patch aortoplasty has also been described using a technique in which the coarctation tissue is resected and the back wall of the aorta is anastomosed, with a patch then placed over the anterior wall. However, this more complicated technique may not be justified, considering the good results with simpler patch aortoplasty without resection of the coarctation shelf. The recurrence rate after patch aortoplasty is very low, and this remains a very acceptable option for some patients. It is especially useful for recurrent coarctation, or in adult-sized patients, when mobilization of the aorta is limited.

**END-TO-END AND EXTENDED END-TO-END ANASTOMOSES**

The original coarctation repair was accomplished by resection of the coarctation region and end-to-end (ETE) anastomosis of the proximal and distal segments. This repair still plays a large role in the surgical treatment (Fig. 82.4). In infants, where the narrowing of the aorta can extend into the aortic arch (Fig. 82.1B), the anastomosis can be fashioned in a manner such that it uses the underside of the aortic arch to enlarge the anastomotic area (Fig. 82.5). This latter technique has been referred to as extended-ETE anastomosis. ETE anastomosis is the most common coarctation repair technique recorded in the STS Congenital Heart Surgery Database in a recent report of over 5000 patients, comprising over 75% of all reported cases. For ETE or extended-ETE repair, adequate mobilization of the proximal aortic arch to the level of the innominate artery, the proximal subclavian artery, and the descending thoracic aorta is important to achieve a tension-free repair. The aorta can be divided above and below the site of ductal insertion and the excess ductal tissue removed. It is usually only necessary to place a tie on the pulmonary end of the ductus; this will stay in place quite well after division of the ductus as long as enough tissue remains distal to the tie. The ETE anastomosis can be performed using a fine, running, nonabsorbable monofilament suture. The use of absorbable suture or interrupted rather than running anastomosis has not been consistently shown to decrease the incidence of recurrent coarctation. Care should be taken to not purse-string the anastomosis. The major advantage of the ETE techniques is that they do not require division of the subclavian artery nor do they use any prosthetic material. Furthermore, these techniques allow resection and removal of all remnant ductal tissue in the aorta, and this may play a role in limiting restenosis as well as the

---

**Fig. 82.4.** End-to-end resection and anastomosis are easily accomplished through a left thoracotomy. (A) The proximal ductus arteriosus is securely tied. Vascular clamps control the aortic arch and the descending aorta. When present, collateral vessels can be controlled with hemoclips. The area of coarctation is excised and removed. (B) The two ends of the aorta are then anastomosed using a running monofilament suture. (C) This provides a normal appearance to the reconstructed aorta, and in most patients there is little difficulty in mobilizing the aorta to be reconstructed in this manner.
Fig. 82.5. An extended end-to-end resection can also be performed through a left thoracotomy. (A) It is necessary to place the proximal clamp across the left subclavian and left common carotid artery. This clamp should extend onto the ascending aorta and occlude part of the innominate artery so that the proximal incision on the underside of the aorta can extend proximally as far as the origin of the left common carotid (or farther, if necessary). The ductus arteriosus is ligated, and a distal clamp is placed on the descending aorta. It is important to mobilize the descending aorta as far distally as possible, and hemoclips can be used to control collateral vessels. These hemoclips can be removed at the completion of the procedure. (B) The incision on the underside of the aortic arch is carried as far proximal as necessary. The incision on the descending aorta is enlarged so that it will match the size of the proximal incision. (C) The two ends of the aorta are then anastomosed using running suture, and this provides augmentation of a hypoplastic aortic arch.

INTERPOSITION GRAFT

Even though ETE repair is now our preferred method of repairing discrete aortic coarctation in neonates and young infants, this technique may not be suitable for repairing aortic coarctation in older children and adults or in recurrent coarctation. In these patients, it may be difficult to adequately mobilize the aorta proximal and distal to the coarctation segment to provide a tension-free ETE anastomosis. A prosthetic interposition graft consisting of Dacron or PTFE can be used for repair in these patients. This technique should be reserved for patients only when it is possible to place an adult-size graft (>18 to 20 mm). Extra-anatomic bypass using prosthetic graft for the repair of aortic coarctation should be avoided except in unusual circumstances like complex recurrent coarctation. In many older patients, the use of endovascular stents deployed in the catheter lab is becoming an attractive and frequently applied option.

REPAIR VIA STERNOTOMY

Aortic coarctation can also be approached via a median sternotomy (Fig. 82.6). In these cases, the patient should be placed on cardiopulmonary bypass and cooled to a nasopharyngeal or rectal temperature of 16°C to 18°C. During the cooling period, the entire aortic arch and head vessels can...
Aortic coarctation, especially when it is associated with a hypoplastic aortic arch and other intracardiac defects, can be approached through a median sternotomy. (A) With the patient on cardiopulmonary bypass and cannulated through the ascending aorta and the right atrium, the aortic arch, the head vessels, and the descending aorta are aggressively mobilized. The ductus arteriosus can be divided between ligatures, and gentle traction on the ligature attached to the pulmonary arteries will retract the left pulmonary artery away from the area of coarctation. At the same time, gentle upward traction on the distal ligature will help to elevate the descending aorta so that it can be adequately dissected. (B) After hypothermic circulatory arrest is instituted, the aortic cannula is removed. Snares on the head vessels are secured, and an incision is then made in the underside of the aortic arch as well as on the descending aorta, as shown. (C) These two openings are then connected with fine, running monofilament suture, providing reconstruction of the aorta as well as the hypoplastic aortic arch. (D) If the two aortic segments are separated (such as may be present in interrupted aortic arch) such that significant tension is created with the anastomosis, the posterior wall of the aorta can be connected, and the anterior portion of the repair can be augmented with a patch (usually homograft), as shown. (E) The completed aortic repair. (F) Occasionally (such as in redo operations for coarctations), a sternotomy approach can be used to enlarge a recurrent coarctation. In this case, the patient is cooled on cardiopulmonary bypass and circulatory arrest is instituted. An incision is then made through the narrowest portion of the aorta. The incised area is then repaired with a patch and the patient is then replaced on bypass and rewarmed.
be dissected from the surrounding tissue. Once the patient is on cardiopulmonary bypass, the ductus arteriosus can be ligated. In cases that approach aortic arch interruption (type A interruption), distal cooling may be limited from the aortic infusion cannula, and an additional arterial cannula can be placed in the main pulmonary artery and advanced across the ductus arteriosus into the distal aorta. A snare around the ductus, and this cannula (or alternatively, around the branch pulmonary arteries), can improve distal perfusion and cooling. After sufficient cooling, the patient’s head is packed with ice, cardiopulmonary bypass is stopped, and the arterial cannula is removed. Snares placed around the previously dissected head vessels are occluded. (The surgeon also has the option of placing the arterial cannula into the innominate artery and snaring it so that low flow, continuous perfusion to the head can be provided. Some surgeons sew a shunt to the innominate artery to accomplish this, but we have found it quite convenient to simply advance the arterial cannula into the innominate if we choose this technique. In these cases, a clamp needs to be placed on the descending aorta to limit back bleeding into the surgical field from collateral flow. There are no compelling data to favor this technique over a short period of circulatory arrest.) The ductus arteriosus can be divided, and the distal aorta can be elevated by gentle traction on the distal ligature. This maneuver will facilitate dissection of the aorta well beyond the stenotic segment. In some instances, a vascular clamp placed as far distal as possible on the descending aorta will help to keep it elevated in the surgical field, improving the surgical exposure. All residual ductal tissues in the descending aorta near the ductal insertion should be excised. If the coarctation segment is discrete, a simple ETE repair can be performed (Fig. 82.6). If the coarctation is associated with arch hypoplasia, repair can be achieved by a combination of suturing the back wall together and using a patch to augment the arch and the repair site. Homograft is preferable in infants, especially if the entire aorta is being augmented, such as in stage 1 palliation for hypoplastic left heart syndrome (HLHS). Gore-Tex works well in older children, especially if the area is a recurrence and is surrounded by scar tissue. The sternotomy approach is convenient when the patient has significant associated cardiac defects that can be repaired at the same time or in patients with recurrent coarctation in whom control of the aorta to enable adequate access to the most proximal extent of the lesion would be challenging from the thoracotomy approach.

COMPLICATIONS

The most dreaded complication of coarctation repair is paraplegia. In an extensive study of aortic coarctation repairs in the STS Congenital Heart Surgery Database, there were no occurrences of paraplegia in close to 1000 reported cases, suggesting that the current incidence is less than previously reported and indicating that the risk of spinal cord injury is so low that it may be hard to study methods for limiting its occurrence. This has been reported to occur in 0.4% to 0.5% of patients undergoing coarctation repair. Risk factors are difficult to identify, but in some series, an aberrant retroesophageal right subclavian artery or a VSD and patent ductus arteriosus appears to put the patient at higher risk. Absence of adequate collateral vessels has also been implicated as a risk factor, but it is not always possible to delineate the adequacy of collaterals in infants, especially because they are often brought to surgery without preceding angiographic studies. Even with angiography, these tiny collaterals cannot always be visualized. Furthermore, the techniques for coarctation repair in infants are identical regardless of the extent of any collateral vessels. The use of shunts or monitoring of the distal aortic pressure has no role in infant coarctation but is commonly recommended for coarctation repair in older patients, where the use of left heart bypass for low distal pressures is appropriate and feasible. Although it would seem logical that the length of aortic cross-clamp time would relate to the incidence of paraplegia, this has not been supported by published information. Nevertheless, most surgeons attempt to limit the aortic cross-clamp time and generally try to perform the repair with clamp times of <20 to 30 minutes. Hypotension may also
be a contributing factor. Occlusion of the aorta with cross clamps will cause upper body hypertension; however, this should be allowed in order to maintain lower body perfusion which occurs through smaller collateral vessels. The presence of hyperthermia during aortic cross-clamping has also been linked to some cases of postcoarctectomy paraplegia. In neonates, rectal or nasopharyngeal temperatures of 34°C to 35°C can be achieved simply by turning the ambient room temperature down at the beginning of the procedure. Older patients may require active surface cooling with a cooling blanket. Although there has been some investigation into ways to prevent paraplegia (such as by identifying the arterial supply to the anterior spinal cord before surgery), this complication is not preventable by any reliable method, and families should always be informed of its potential. Other complications include hemorrhage, left recurrent laryngeal nerve palsy, chylothorax, postoperative hypertension (especially in older children), and abdominal pain (mesenteric arteritis). Hemorrhage is usually a result of tension on the suture line and can be mitigated by adequate dissection and use of a running suture to disperse the tension on individual loops. The left recurrent laryngeal nerve is visualized during mobilization of the ductus arteriosus or ligamentum arteriosum, and the potential for nerve injury can be reduced by careful dissection and judicious use of electrocautery. Chylothorax occurs in 2% to 5% of patients after repair of coarctation. This is usually caused by transection of small lymphatic vessels during the dissection for repair. In most instances, the leak will resolve with conservative management such as with dietary manipulation, but excessive drainage often requires reopening of the thoracotomy and suture ligation of the tissue that is leaking chyle. When we have seen patients with this degree of excessive drainage, it has not been necessary to give the patients cream stained with methylene blue, as suggested by some. Upon reopening the thoracotomy, the area that is “seeping” is obvious and easily controlled with figure-of-eight sutures. Abdominal pain may present in as many as one-third of patients who have hypertension after coarctation repair. Treatment for hypertension and abdominal pain includes β-blockers and “bowel rest” with intravenous fluids as necessary. It is less common for neonates and infants to require treatment of hypertension, and the increasing frequency of coarctation repair in the first year of life has largely reduced the incidence of hypertension as an important postoperative complication.

**RESULTS**

Despite the seriousness of this defect in neonates, surgical results are excellent. Hospital mortality in neonates after ETE or extended-ETE coarctation repair in the Society of Thoracic Surgeons Congenital Heart Surgery Database is 2.4%. For infants, the in-hospital morality rate is 1.0% and for children 1 to 18 years of age 0.3%. Surgical mortality is usually related to other factors such as associated defects, the size of the left ventricle, and the extent of the coarctation. Longer term survival appears to approach that of the general population. Depending on the age and weight of the patient at operation, the technique used, the quality of the initial repair, and the factors beyond control such as growth at the repair site, up to 20% of patients may develop a recurrent coarctation (defined as a gradient across the repair site of >20 mmHg). In most instances, this can be successfully dilated by balloon angioplasty, and surgical intervention is rarely preferred for recurrent coarctation. Late hypertension occurs mainly in older children and adults. Recurrent coarctation should be excluded as a cause of this finding. Late aneurysm formation is becoming less common and may be more often associated with balloon dilatation as opposed to primary coarctation repair techniques.

**SPECIAL SITUATIONS**

**Coarctation and Ventricular Septal Defect**

Aortic coarctation can be commonly associated with a VSD. In all cases, the coarctation should be repaired. These infants are usually in fairly significant congestive heart failure because of the LVOTO from the coarctation and the left-to-right shunt from the VSD. At the time of coarctation repair, the VSD can be dealt with by (1) pulmonary artery banding, (2) VSD closure (via a sternotomy with one-stage repair or with separate thoracotomy and sternotomy incisions during one operative setting), or (3) coarctation repair alone with nothing done for the VSD. In the latter instance, the patient can be observed postoperatively and referred for VSD closure as indicated for the treatment of that lesion as a separate entity. Previously reported Congenital Heart Surgeons Society (CHSS) data suggest that the safest approach is coarctation repair with pulmonary artery banding, but we prefer complete one-stage repair when it is apparent that the VSD will require surgical intervention. In particular, we recommend VSD closure concomitant with coarctation repair when the VSD is large (and especially when the LVOT tract is small—but acceptable, including patients within the spectrum of interrupted aortic arch) or when the VSD is in a location that is not associated with spontaneous VSD closure (e.g., supracristal or posterior malalignment). We have done this through a sternotomy as well as through two separate incisions, and both provide excellent results. We do not favor pulmonary artery banding as palliation for a VSD, although this technique is applied successfully by some and should not be discounted in appropriate circumstances. In a review of the STS Congenital Heart Surgery Database, there was no advantage or disadvantage of one technique versus another for this combination of lesions and options.

**Balloon Angioplasty for Native Coarctation**

Balloon angioplasty has a limited role in the treatment of native coarctation in neonates. Results have been marginal with a high incidence of early recoarctation and development of aortic aneurysms at the coarctation site. Furthermore, there seems to be a disturbingly high incidence of paraplegia in patients who come to surgical coarctation repair after unsuccessful balloon angioplasty, and it is postulated that this may be related to the decreased stimulation for development of collateral circulation once the pressure gradient across the stenotic area has been partially relieved by angioplasty. The excellent results with surgical repair of native coarctation in neonates make balloon angioplasty a much less attractive treatment option in this population. Therefore, balloon angioplasty of native coarctation in neonates should be reserved for unusual circumstances where operative repair is not possible or desirable. In most cases, PGE infusion can be continued until the complicating issue has been resolved and the child has been stabilized. In rare circumstances, such as a child presenting with cardiac arrest and resultant decreased ventricular function and a closed ductus arteriosus, balloon angioplasty may provide for a period of stabilization and recovery of myocardial
function after which the child can undergo surgical repair. When an infant requires nonsurgical intervention for an aortic coarctation, the use of an intravascular stent may be preferable to balloon angioplasty alone, since excessive dilation of the fragile aortic tissue can be avoided. Of course, when these patients recover from their complicating issues, they will ultimately need surgical enlargement of the stented portion of the aorta.

Balloon angioplasty and when indicated stent placement as an alternative to surgical repair have better long-term results in older patients. Although these procedures are not without risk of paraplegia and late aneurysm formation, the risk of recurrent coarctation is acceptable when compared with surgery. The minimum age for consideration for balloon angioplasty is 1 to 2 years of age. Patients over 20 to 25 kg are candidates for combined balloon angioplasty and stent placement. Smaller patients are generally not good candidates for stent placement due to the inability of the stents to be dilated to adult size.

**Coarctation and the Hypoplastic Left Ventricle**

Aortic coarctation commonly exists in the spectrum of lesions that constitute hypoplastic left heart syndrome. In the case of unequivocal hypoplasia of the left ventricle, the coarctation is repaired with patch augmentation as part of a standard Norwood procedure. Occasionally, the size of the left ventricle is borderline (approximately 20 ml/m²) with regard to whether it is adequate to support the entire systemic circulation. Instead of staged toward a univentricular physiology, it is possible to repair the aortic coarctation by using a patch technique so that the ductus arteriosus can be left open (on PGE, infusion) after the procedure. This will serve to decompress the pulmonary hypertension that these patients may have postoperatively and to maintain systemic perfusion while the left ventricle recovers. If the left ventricle is inadequate to support the systemic circulation, right-to-left ductal blood flow will persist and the patient will need to be staged to a univentricular physiology. However, if the left ventricle is adequate to support the entire systemic circulation, blood flow in the ductus will change to left to right after the left ventricle recovers from the coarctation repair. The ductus arteriosus is then allowed to close by stopping the PGE, infusion. Occasionally, the ductus in these patients is large and will not close after cessation of the PGE. In these cases, it may be necessary to tie the ductus surgically.

**Recurrent Coarctation**

The incidence of recurrent coarctation ranges between 5% and 20%, depending on (1) the age of the patient at operation, (2) the extent of the original coarctation lesion, (3) the technique used for coarctation repair, and (4) the length of the follow-up period. Reintervention for these patients should be considered if the peak-to-peak gradient (by cardiac catheterization) across the coarctation site is >20 mmHg (a peak instantaneous gradient, by echocardiography, of >35 mmHg). Surgery can be challenging because of the adhesions and scar tissue around the aorta and lung from previous surgery. As a result, it can be very difficult and hazardous to gain proximal control of the aortic arch for the placement of a vascular clamp. Repeat ETE reconstruction is nearly impossible in these patients because the aorta cannot be mobilized adequately without placing excessive tension on the suture line. The treatment of choice for recurrent coarctation is balloon angioplasty. If balloon angioplasty is not successful and reoperation is necessary, patch aortoplasty should be considered. This can be done either through a thoracotomy or through a sternotomy on cardiopulmonary bypass with a limited period of hypothermic circulatory arrest. Alternatively, an extra-anatomic bypass graft from the ascending to the descending aorta can be used for complex recurrent coarctation, especially ones with a long segment of arch hypoplasia. We generally discourage this approach, believing that patch augmentation, even of a diffuse area of stenosis, is preferable to any extraanatomic bypass. We have seen difficulty in patients treated with these types of extra-anatomic bypass if they present for future surgery. When this extra-anatomic solution is chosen, it can be performed either through a right thoracotomy or a median sternotomy without using cardiopulmonary bypass, depending on the area that is being bypassed.

**SUGGESTED READINGS**

Although numerous techniques have been used for coarctation repair, all of the accepted techniques have been associated with excellent results with very low morbidity and mortality. The risk of death after coarctation repair now approaches zero for most children even with complex associated defects, except those associated with severe forms of LVOTO. Coarctation of the aorta in isolation, without associated congenital heart defects and of such severity as to not require immediate repair in infancy, is generally repaired in our institution when the patient is younger than 1 year of age. The exact timing of repair of coarctation in asymptomatic individuals remains controversial. Whereas later repair beyond 1 to 2 years of age is associated with a low incidence of late recurrence, the presence of a significant afterload on the ventricle with resulting hypertrophy may alter LV mass and compliance late in life. In addition, some patients, even after successful coarctation repair, continue to have proximal arterial hypertension, possibly related to an abnormal renin–angiotensin system or compliance differences in the aorta above and below the coarctation repair site. Many of these patients have refractory hypertension despite a completely unobstructed anastomosis.

The advent of successful balloon dilation for recurrent coarctation has permitted extension of early coarctation repair to younger than 1 year of age in the majority of patients and may help decrease the pressure load on the left ventricle. The subclavian flap technique for repair of coarctation of the aorta in infants, as popularized by John Waldhausen, has the advantage of being performed rapidly, and can be done with a single Satinsky-type partial occlusion clamp placed across the base of the ductus arteriosus incorporating the descending aorta and the arch of the aorta. The subclavian flap is ligated distally and divided, and the flap can be rapidly opened and sewn down across the coarctation site. We have not found it possible to resect much coarctation shelf in most of these children because there is often residual ductal tissue and the material is extremely friable. We have elected to use the subclavian flap only in situations in which a rapid anastomosis needs to be constructed or in children in whom ductal patency is being maintained after the coarctation repair is complete. Patch repair as advocated by the authors is another good choice. In patients in whom the ability of the ventricle to withstand coarctation repair is questionable because of LV volume overload, it is possible to perform a subclavian flap or patch repair, leave the ductus open, and then suture the ductus temporarily after repair while observing the effects on ventricular function and cardiac output or to leave the ductus patent and allow spontaneous closure after discontinuation of prostaglandin therapy. If patients with a relatively small LV volume continue to require ventilatory support after coarctation repair and ductal closure, conversion to a Norwood-type operation can be performed through the midline at a separate procedure.

Controversy continues regarding the use of patch material for coarctation repair in infants and older children. Although significant late problems have developed with the use of Dacron patches in the aorta, aneurysm formation has often been opposite the site of the patch, consistent with abnormalities of flow in the region of the coarctation repair. Thus, although PTFE patch has not been associated with late deterioration, the same concerns about late aneurysm formation must be considered. In addition, PTFE may bleed significantly when used proximally in the ascending aorta, and therefore, we have not utilized PTFE preferentially for coarctation repair except in exceptional circumstances. Like the authors, we have preferred to perform one-stage coarctation repair and VSD closure in children in whom the VSD is large and in whom there is associated arch hypoplasia and in those patients in whom the VSD is of a type not likely to spontaneously close. Care must be taken during coarctation repair in these children to tailor the pulmonary homograft patch adequately so that as it is brought down toward the ascending aorta, it is tapered so that a gentle take-off in size of the aorta is created to prevent kinking of the ascending aorta where the size changes abruptly to the patched arch.

In general, we have not elected to perform primary ETE anastomoses through a sternotomy incision because any tension on the anastomosis can result in bleeding that may cause stenosis of the repair site when repair stitches are used to control hemorrhage. In the same manner as for reconstruction for interrupted aortic arch, we have elected to augment the entire arch with a portion of pulmonary homograft material or to create an ETE anastomosis at the level of the subclavian and carotid vessel and then augment the undersurface with a patch of pulmonary homograft to take tension off the anastomosis. This has resulted in a lower incidence of recurrent coarctation in our patients.

Other centers have reported good results with a low risk of recoarctation with direct anastomosis of the descending aorta to the ascending aorta in patients with significant arch hypoplasia or with division of the isthmus beyond the left subclavian artery, transection of the aorta with an end-to-end anastomosis of the ascending to descending aorta, and then anastomosis of the proximal ascending aorta to the side of the newly reconstructed aortic arch. This approach is rarely necessary.

If subclavian flap repair or ETE anastomosis is performed, we have elected to routinely close the mediastinal pleura over the repair site in the hope of decreasing the possibility of late aneurysm formation and to allow better control of any disruption at the time of balloon dilation if recurrent stenosis occurs. Although pseudoaneurysm formation at coarctation repair has been extremely uncommon, we have seen this occur with primary disruption in at least one older individual. Control of the localized hemorrhage by mediastinal pleural closure can permit salvage of these patients even if aortic disruption occurs. If closure of the pleura will compromise the repair by compression, it is omitted.

The management of recurrent coarctation not amenable to balloon angioplasty remains problematic. In most individuals, it is not possible to create an ETE anastomosis after a previous coarctation repair by any of the usual techniques, and mobilization of the aorta can be difficult and create excessive tension on an ETE suture line. Therefore, recurrent coarctation may best be treated by patch augmentation of the coarctation site. We tend to use patch augmentation with either PTFE or pulmonary homograft in these individuals, usually with cardiopulmonary bypass and a brief period of circulatory arrest to decrease the risk of paraplegia in older children. Because these patients often have inadequate collateral supply, they appear to be at greater risk for the development of paraplegia postoperatively.

(continued)
The use of graft material for bypass of recurrent coarctation segments should be discouraged. Although in exceptional circumstances such grafts may be necessary, we have seen at least two individuals who presented late after graft bypass of recurrent coarctation segments with pseudoaneurysm formation and aortobronchial fistulae. The extensive scarring in the chest after these operations and the protrusion of the graft to the adjacent lung complicated repair of the pseudoaneurysm. Thus, if a graft is to be placed, we prefer to place it in the anatomic location with an ETE anastomosis and, if at all possible, to cover the graft with mediastinal pleura to prevent erosion into adjacent structures or to contain pseudoaneurysm formation.

Unusual circumstances in which recurrent coarctation is present in association with complex arch hypoplasia or previous extensive thoracotomies that have been performed occasionally require extra-anatomic bypass. In situations where the aortic arch and coarctation are not readily accessible due to previous surgery or there are other complicating factors, it is simple to create an ascending aorta-to-descending aorta bypass intrapericardially using an adult-size Dacron graft anastomosed to the side of the ascending aorta and then to the descending aorta posteriorly in the intrapericardial space above the level of the diaphragm. These extra-anatomic bypasses appear to have a decreased incidence of pseudoaneurysm formation compared with extra-anatomic bypass performed in the left chest and can readily relieve any residual gradients, usually without the need for cardiopulmonary bypass.

An area of controversy is the use of balloon dilation and stent implantation in native coarctation in adults. In some cases, this approach may be the most desirable because repair of coarctation in older adolescents or adults is associated with difficulty in mobilizing the arteries for direct anastomosis, and large collateral vessels in the chest wall may be associated with significant bleeding. Although the results with the use of stents for native coarctation appear to be good in the short term, long-term follow-up will be necessary to see whether the incidence of pseudoaneurysm formation or late gradients will limit the use of this technique. Nevertheless, in older patients the relative risk and benefit of catheter-based intervention versus surgical treatment would tend to favor catheter intervention, should there be a low incidence of late complications. Paradoxical hypertension, however, can occur with both catheter and surgical approaches.

The use of stents in younger patients has now been reported to be associated with recurrent stenosis requiring multiple stent redilations often requiring stent fracture as patients grow. The use of covered stents should be limited to patients who can have an adult-size stent implanted at the primary procedure.

It has now become common to use stents in recurrent coarctation in older individuals. The advantages of stent implantation are the decreased risk of recurrent obstruction and good relief of any residual gradients. Nevertheless, the long-term potential complications of a stent implanted into the wall of an abnormal aorta with abnormal compliance at the stent site have not been addressed and deserve further study. Nevertheless, the use of stents has significantly decreased the recurrence rate even after balloon dilation of recurrent obstruction at the coarctation repair site.

Postoperative complications after coarctation repair are infrequent. The most common complication, as noted, is paradoxical hypertension, which is often treated best by infusion of a short-acting β-blocking agent such as esmolol. The use of nitroprusside is less effective in controlling hypertension after coarctation repair, and very large doses of nitroprusside may be needed to control the blood pressure. In addition, nitroprusside may increase the force of ventricular ejection and predispose to possible aortic dissection in patients with abnormal aortic tissue. Therefore, we have elected to use esmolol as the primary treatment of significant hypertension postcoarctation repair. In most patients, the β-blocker can be discontinued within 24 hours after the operation without recurrence of hypertension.

Although enthusiasm has developed for the use of balloon dilation for native coarctation in infants in some centers, we discourage the use of this technique. The results of primary repair of coarctation have become excellent and result in a low incidence of recurrent coarctation or late aneurysm formation. The use of balloon dilation, which does not remove ductal tissue and may result in a primary disruption of the endothelium, seems an unattractive option in patients in whom an operative procedure may be associated with excellent early and late results. This is especially true because most infants who require coarctation repair have associated congenital anomalies that should be addressed promptly.
Interrupted Aortic Arch Complex
Richard G. Ohye, Takaaki Suzuki, Eric J. Devaney, Jennifer C. Hirsch-Romano, and Edward L. Bove

Interruption of the aortic arch (IAA) is a congenital anomaly characterized by complete discontinuity of blood flow between two portions of the aorta. This malformation may exist as a long-distance physical separation between adjacent segments or in the form of discontinuity between adjacent lumens of vessels that are otherwise connected externally. The latter anomaly is more commonly considered among discussions of coarctation of the aorta and is not discussed further here. IAA occurs uncommonly as an isolated lesion, being frequently associated with a number of complex intracardiac defects. Therefore, the diagnosis and management of IAA complex is best considered in combination with the entire cardiac anomaly. Recent advances in the management of IAA and the associated cardiac defects have resulted in a significant improvement in the overall outcome for patients with this complex anomaly. The approach of a single-stage repair of all coexisting defects simultaneously with the IAA has been shown to be a safe and effective management protocol.

ANATOMY

The aortic arch is that portion of the aorta between the innominate artery and the ductus arteriosus, and interruption of the arch may occur between any of the arch vessels. According to the classification originally described by Celoria and Patton (Fig. 83.1), type A occurs when the aorta is interrupted just distal to the origin of the left subclavian artery, between that vessel and the insertion of the ductus arteriosus itself. In this type, a fibrous cord is frequently found connecting the proximal and distal portions of the arch. The most common variety, type B, occurs between the origins of the left common carotid artery and the left subclavian artery. This type accounts for approximately two-thirds of all cases of IAA. In the rarest form, type C, the interruption occurs between the innominate and left common carotid arteries. This type is seen in only 5% of patients.

Associated cardiovascular anomalies are nearly always present in IAA. The most common condition is that of an isolated ventricular septal defect (VSD). In a multi-institutional study by the Congenital Heart Surgeons Society (CHSS), which analyzed 250 neonates entered into the study over a 5-year period by 29 participating institutions, isolated VSD was present in 183 patients (73%). Other commonly associated lesions included truncus arteriosus, transposition of the great arteries (TGA) with VSD, and various forms of single ventricle. The frequency of associated anomalies, as found in the CHSS report, is shown in Table 83.1.

The VSD in patients with IAA is frequently of the malalignment type and is commonly associated with posterior deviation of the infundibular (outlet) septum. The displacement of the infundibular septum to the left of the posterior limb of the septal band results in narrowing of the left ventricular outflow tract and the potential for subaortic obstruction. Anomalous origin of the right subclavian artery from the descending aorta frequently occurs with IAA and is associated with a greater prevalence of subaortic obstruction secondary to reduced flow in utero through the left ventricular outflow tract and the aortic valve. Additional levels of left heart obstruction may also occur at the aortic valve leaflets, aortic annulus, mitral valve, and the ascending aorta.

PRESENTATION AND DIAGNOSIS

In the majority of patients, the diagnosis of IAA is first made on the discovery of signs and symptoms of congestive heart failure within the first few days of life. Lower extremity pulses may be poorly palpable or not palpable at all. In some cases, the diagnosis is not suspected until ductal closure occurs. When the ductus remains patent, flow to the lower body remains unobstructed, and the elevated pulmonary vascular resistance normally found in the newborn delays the expected increase in pulmonary blood flow through the VSD. This combination effectively delays the development of heart failure. Abrupt ductal closure, however, results in profound acidosis, cardiovascular collapse, and shock as lower body perfusion is severely reduced. Resuscitation with an infusion of prostaglandin E1 to maintain ductal patency should be established when the diagnosis is made. If shock has occurred and there is associated renal and hepatic dysfunction, administration of dopamine is generally used as well. A period of a few days may be necessary to allow recovery of end-organ function before operative repair is performed. During this time, careful control of ventilation is needed to avoid hyperventilation, which serves to increase pulmonary blood flow and may worsen systemic perfusion further. In addition, treatment of associated conditions, including sepsis, necrotizing enterocolitis, and coagulation abnormalities, must be performed. Because 22q11 monoallelic microdeletion is a commonly associated condition in patients with IAA, occurring in 27% of patients in the CHSS report, careful control of calcium balance will often be necessary. All transfused blood should be radiated to avoid graft-versus-host disease until the diagnosis of 22q11 monoallelic microdeletion is definitively excluded.

The diagnosis of IAA can be accurately made from two-dimensional Doppler/echocardiographic studies. Cardiac catheterization with aortic angiography is rarely needed to define the anatomy. The exact site of the interruption in addition to the location of the branch vessels and the distance between interrupted segments should be determined. The presence of an anomalous origin of the right subclavian artery may be more difficult to diagnose by echocardiography but would not significantly alter the operative approach. In addition to the anatomy of the aortic arch, it is important to define the intracardiac anatomy in anticipation of a complete one-stage repair. The location
and boundaries of the VSD, particularly in relation to the left ventricular outflow tract, aortic valve, and pulmonary valve, must be accurately seen. The majority of VSDs occur in the outlet portion of the septum, but other locations as well as additional defects must be sought. Although accurate measurement of a gradient across the left ventricular outflow tract is not possible in the presence of a nonrestrictive VSD and patent ductus arteriosus, some guidelines are helpful in predicting those patients who are likely to develop important left ventricular outflow tract obstruction after repair. When the measured ratio of the smallest diameter of the left ventricular outflow tract normalized to the diameter of the descending thoracic aorta at the level of the diaphragm is 1.0 as measured by echocardiography in diastole or is 0.6 when measured in systole, we have found that the risk of subaortic obstruction after closure of the VSD is high and that efforts to resect or incise that portion of the infundibular septum that is deviated posteriorly beneath the aortic annulus are beneficial in avoiding or reducing postoperative obstruction. Other groups have suggested other preoperative echocardiographic measurements, including cross-sectional area of the left ventricular outflow tract indexed to body surface area, subaortic diameter index, and subaortic diameter Z score. However, the optimal parameter, which consistently displays a high degree of sensitivity and specificity, remains elusive.

spiral this incision. The anastomosis is performed with a continuous technique using 6-0 or 7-0 absorbable or nonabsorbable monofilament suture. In cases of type A IAA, the transverse aortic arch may be hypoplastic, as it is frequently seen with coarctation of the aorta. The anastomosis should be spatulated to enlarge the transverse arch using the distal aorta, bringing the suture line proximally to the level of the innominate artery to ensure that there is no residual narrowing.

The total elapsed circulatory arrest time at this point of the procedure is generally no more than 12 to 15 minutes, allowing ample time for VSD closure through an incision in the right atrium. Alternatively, bicaval cannulation can be utilized, rather than single atrial access. If this approach is employed, cardiopulmonary bypass may be resumed at this point for the VSD closure to minimize circulatory arrest time. Occasionally, when there is deficiency or absence of the infundibular septum and overriding of the VSD by the pulmonary valve, optimal exposure is best achieved through an incision in the main pulmonary artery. Transatrial exposure of the defect is usually accomplished easily with traction sutures placed on the anterior and septal leaflets of the tricuspid valve, and an appropriately trimmed patch of polytetrafluoroethylene material is placed with a continuous 6-0 polypropylene suture. When there is coexisting posterior deviation of the infundibular septum (Fig. 83.4), it has been our routine practice to perform a wedge resection of the septum through the VSD (Figs. 83.5–83.7). On occasion, an incision in the septum alone is performed, which is usually sufficient to enlarge the left ventricular outflow tract. The atriotomy is closed, and the cannulae are reinserted for cardiopulmonary bypass if the VSD was closed under circulatory arrest, with air being evacuated through a generous needle hole in the ascending aorta. Rewarming is accomplished, during which time epicardial pacing wires are placed on the right atrium and ventricle. After bypass is discontinued, one or two additional catheters are placed in the right atrium through the cannulation purse string. Left atrial pressure monitoring lines may also be placed. Routine sternal closure over a mediastinal drain is performed; occasionally, sternal closure is delayed if there is hemodynamic compromise or significant edema.

An alternative to deep hypothermic circulatory arrest for the repair of IAA is regional cerebral perfusion. For this technique, a limited amount of flow is delivered to the brain through the innominate artery. The ascending aorta cannula is placed near the base of the innominate artery. The patient is cooled and otherwise prepared in the same manner as for circulatory arrest. Cerebral oxygen saturation by near infrared spectroscopy may be employed to monitor cerebral perfusion, and a right radial arterial line can be inserted to monitor perfusion pressure. At the time that circulatory arrest would be initiated, the aortic cannula is advanced up the innominate artery and snared in place. Flow is started at 5 cm³/kg/min and gradually advanced to 30 to 50 cm³/kg/min, while...
monitoring cerebral oxygen saturation for a return to baseline (and pressure if a right radial arterial line is present). The arterial cannula in the pulmonary artery is removed, the venous return is collected by the venous cannula(e), and the remainder of the procedure is identical to that performed during circulatory arrest. While many centers have adopted this approach in an effort to provide better neurodevelopmental outcome, currently there are no data to suggest a benefit, particularly when compared with circulatory arrest times less than 20 to 30 minutes.

**SPECIAL CIRCUMSTANCES**

**Interrupted Aortic Arch with Aortic Valve Hypoplasia or Atresia**

When left ventricular outflow tract obstruction secondary to hypoplasia or atresia of the annulus of the aortic valve is present in conjunction with a VSD, one of two modifications of the Damus–Kaye–Stansel procedure may be used to bypass the aortic valve, depending on the specific anatomy. The approach is tailored to achieve an optimal surgical result with respect to a widely patent, tension-free aortic reconstruction, while avoiding compression of adjacent structures, such as the left main stem bronchus and pulmonary artery. One option is to divide the distal ascending aorta and repair the IAA by direct anastomosis. This reconstructed distal aortic segment, which may be augmented with a patch of allograft material, is then sutured end-to-end to the divided proximal main pulmonary artery. The proximal ascending aorta is then sewn end-to-side into the main pulmonary artery. This method of repair can be facilitated by performing a Lecompte maneuver. Alternatively, the ascending aorta may be transected at the level of the divided main pulmonary artery. The IAA is repaired forming the posterior wall for a modified Norwood-type augmentation patch of the aorta, as is described below for IAA with single ventricle. This reconstructed aorta is then sewn end-to-end to the proximal pulmonary artery, incorporating the proximal ascending aorta, as in a modified Norwood procedure.

Chapter 83: Interrupted Aortic Arch Complex

865

Interrupted Aortic Arch Complex

Following either technique of aortic reconstruction, the VSD is closed to channel left ventricular blood to the pulmonary valve and a conduit is interposed between the right ventricle and the pulmonary artery bifurcation. While we prefer a single-stage approach, the pulmonary artery bifurcation may alternatively be closed with a patch, and pulmonary blood flow is provided through a modified Blalock-Taussig shunt, deferring complete repair until a later date.

The third alternative for patients with IAA and aortic valve hypoplasia, with or without VSD, is a Ross/Konno procedure. The ascending aorta is divided and the proximal ascending aorta and aortic valve are resected. The IAA is repaired, generally by forming a posterior wall at the site of the interruption, with an anterior Norwood-type patch augmentation.

The pulmonary autograft is harvested in the usual manner and a standard Ross procedure is performed. For the Konno portion of the operation, it is often not necessary to fully divide the ventricular septum and place a patch to enlarge the left ventricular outflow tract. It is generally sufficient to divide the aortic annulus and simply incise the septum up to, but not through the endocardium of the right ventricular outflow tract (Fig. 83.8). A wedge of muscle can also be resected from the septum to further enhance unobstructed left ventricular output.

Interrupted Aortic Arch with Truncus Arteriosus

When interrupted aortic arch is associated with truncus arteriosus, significant modifications in the technique of repair are required. Nearly all interruptions are type B, although a single patient with type A has been seen in our center (Fig. 83.9). The ascending aorta distal to the origin of the ductus arteriosus and the pulmonary arteries are usually quite small in this condition. The arterial cannula is placed into the distal ascending aorta as it will be subsequently augmented, and the branch right and left pulmonary arteries are occluded at the onset of cardiopulmonary bypass. During cooling in preparation for circulatory arrest or regional cerebral perfusion, the innominate, left carotid, and left subclavian arteries are mobilized and encircled with snares for subsequent occlusion, as described in the preceding section. The remaining ascending and proximal descending aorta are also mobilized. Once circulatory arrest or regional perfusion is established, the ductus arteriosus is excised, and the orifices of the right and left pulmonary arteries are excised from the aorta with a button of adjacent arterial tissue that is as large as is feasible. The large opening in the proximal ascending aorta resulting from the excision of both the ductus arteriosus and the pulmonary artery bifurcation is extended superiority along the medial side of the ascending aorta and into the base of the left carotid artery (Fig. 83.10). Primary end-to-end anastomosis with the descending aorta is then begun, using a running suture technique and placing the descending aorta and left subclavian artery distal to the ascending aorta beginning at the base of the left carotid artery. The large defect remaining below this portion of the anastomosis is then reconstructed and further augmented with a patch of allograft tissue beginning from the sinus of Valsalva and carrying it upward into the lower aspect of the primary arch anastomosis (Fig. 83.11). In this manner, two potential problems are avoided. First, placing the descending aorta too far proximally onto the ascending aorta may result in obstruction to the left pulmonary artery or compression of the left mainstem bronchus and residual aortic obstruction between the trunca l valve and the anastomosis of the aortic arch. Second, this technique also maintains the potential for growth because neither the suture lines nor the prosthetic material are placed circumferentially. After completion of this aspect of the procedure, the VSD is then repaired in the usual manner generally on full cardiopulmonary bypass. The right ventricleto-distal pulmonary artery continuity is established with a cryopreserved allograft or valved bovine jugular conduit.
Fig. 83.8. After removal of the aortic valve and harvesting of the autograft, a partial thickness septal incision is performed to enlarge the aortic annulus (left). If necessary, a septal myomectomy may be performed for subaortic stenosis (right). In the region of the incision, the autograft is anastomosed directly to the endocardium of the right ventricular outflow tract (inset).

Interrupted Aortic Arch with Transposition of the Great Arteries

Single-stage arterial switch and IAA repair are performed for TGA with IAA with few modifications. The arch anastomosis is performed first in a manner identical to that described in the section on IAA with VSD. Because the ascending aorta will be transected for the arterial switch and relocated posterior to the pulmonary artery bifurcation, the division is performed a few millimeters distal to the sinotubular ridge to foreshorten the ascending aorta and avoid kinking.

Interrupted Aortic Arch with Single Ventricle

When IAA coexists with single ventricle, the technique of repair must be individually tailored to the specific anatomy. In the usual situation, IAA is found with TGA and tricuspid atresia or with double-inlet left ventricle (Fig. 83.12). In these conditions, there will be unrestricted pulmonary blood flow and a restrictive or potentially restrictive outlet (bulboventricular) foramen that will result in subaortic obstruction. Therefore, the initial operative procedure must be designed to relieve all levels of systemic outflow tract obstruction and to control pulmonary blood flow. This is best accomplished with a modified Norwood procedure, which augments the entire ascending aorta and aortic arch with a patch of cryopreserved pulmonary allograft material (Fig. 83.13). The ascending and descending portions of the arch are sutured directly only along their posterior walls and the undersurface is opened distally for at least 1 to 2 cm in length. The ascending aorta is divided above the valve and opened posteriorly as well. The allograft patch is then used to augment the entire aorta, which is then sutured end-to-end to the proximal main pulmonary artery, incorporating the proximal end of the ascending aorta to ensure unobstructed coronary blood flow (Fig. 83.14). A 3.5-mm modified Blalock–Taussig shunt is routinely used, with a 4-mm shunt reserved for infants >3.8 to 4.0 kg. This technique of aortic reconstruction bypasses the restrictive outlet foramen with the pulmonary valve, allows appropriate size matching of the main pulmonary artery and augmented ascending aorta, and...
Fig. 83.11. A direct anastomosis is made between the descending aorta and the distal ascending aorta–proximal left carotid artery. The proximal ascending aorta is augmented with allograft tissue or prosthetic material. (Reprinted with permission from Baue AE, Geha AS, Hammond GL, et al. eds. Glenn’s Thoracic and Cardiovascular Surgery. 6th ed. Norwalk, CT: Appleton & Lange; 1994:1217.)

avoids circumferential suture lines or prosthetic grafts in the arch repair.

POSTOPERATIVE MANAGEMENT

When single-stage repair of IAA and associated intracardiac defects is performed, the early postoperative management is similar to that for any neonate or young infant undergoing a complex cardiac repair. Mechanical ventilation is generally required for 2 to 4 days, and extubation is carried out after excess edema is mobilized. If weaning from the ventilator is unsuccessful, diaphragm paralysis from phrenic nerve injury, upper airway obstruction secondary to left recurrent laryngeal nerve injury and resultant vocal cord paralysis, and tracheal compression from the reconstructed aortic arch must all be investigated. Inotropic support with low- or intermediate-dose dopamine (5 to 10 µg/kg per minute) is routinely used and should be all that is necessary to maintain hemodynamic stability. When more significant levels of support are required, a detailed search for residual hemodynamic lesions must be carried out. Doppler/echocardiography is useful in diagnosing ventricular dysfunction, residual VSD, left ventricular outflow tract obstruction, tamponade, and atrioventricular or semilunar valve regurgitation. Residual aortic arch obstruction may be diagnosed or highly suspected by simple four-limb blood pressure recordings, although if cardiac output is low, gradients may be underestimated. Cardiac catheterization should be used if any doubt remains as to the cause of low cardiac output.

In patients with a single ventricle, who have undergone aortic arch repair and a systemic-to-pulmonary artery shunt, systemic output is dependent on the delicate balance between the systemic and pulmonary vascular resistances. Residual arch obstruction is extremely poorly tolerated and usually results in rapid deterioration. Excessive pulmonary blood flow is generally not a problem provided the correct size shunt is placed. Reduction of systemic vascular resistance with the appropriate medications is of benefit in improving oxygen delivery to the tissues.

OUTCOMES

Survival

Early and late survival for patients with IAA and VSD treated by single-stage repair has steadily improved over the past decade. The results for 60 consecutive neonates undergoing simultaneous arch and intracardiac repair (excluding single ventricle patients) between 1986 and 1994 at the University of Michigan are shown in Table 83.2. Although this series includes patients with coarctation in addition to IAA, the management and outcomes were sufficiently similar, especially considering all were younger than 1 month of age at the time of repair. Early mortality was 11.6% for the entire group; overall mortality (early plus late) was 15%. Not surprisingly, those patients with isolated VSD had a better
outcome than those with more complex intracardiac defects. Among 37 neonates with coarctation or IAA and isolated VSD, there were three early deaths (8%) and only one late (noncardiac) death. For the 23 neonates with coarctation or IAA and more complex anomalies, there were four early deaths (17%) and one late death.

The results reported from the multi-institutional study by the CHSS were less optimistic. Among 174 neonates with IAA and VSD undergoing repair, survival was 73%, 65%, and 63% at 1 month, 1 year, and 4 years, respectively. In contrast to the series from Michigan, myotomy or myectomy in the presence of narrowing of the subaortic area was found to be a risk factor for death in the CHSS report. Paradoxically, the CHSS data showed that repair without concomitant procedures to address subaortic narrowing (myotomy/myectomy, Damus–Kaye–Stansel) was a risk factor, as was subaortic narrowing itself, leaving no clear solution to that difficult problem. In a more recent IAA follow-up study by the CHSS, data from 447 IAA patients at 33 institutions from 1987 to 1997 revealed a 21-year freedom from death of only 60% overall.

Recurrent Arch Obstruction

Late complications are specific to the type of intracardiac defect repaired or to the expected difficulties that arise after palliation for those patients with single ventricle lesions. The patient should always be monitored for residual or recurrent arch obstruction, and treatment is usually indicated for resting gradients in excess of 30 mmHg. Residual gradients of 20 mmHg occurred in only 2 of 53 late survivors (3.7%) of simultaneous neonatal arch repair for either IAA or coarctation and intracardiac repair of associated defects performed in our institution between 1986 and 1994. No patient has required reoperation for recurrent arch obstruction (mean follow-up, 23 months; range, 1 to 78 months) and two patients found to have gradients in excess of 20 mmHg satisfactorily treated with balloon dilatation. Both of these patients had coarctation of the aorta, were repaired early in our series, and neither had an extended arch anastomosis, which is now routinely used.

These results compare quite favorably with other published rates of recurrent arch obstruction.

In the CHSS study of late outcomes for 447 patients undergoing IAA repair, there were 119 patients who required a total of 158 interventions for recurrent arch obstruction. Competing risks analysis revealed that at 15 years, 32% had died
without a first arch reintervention, 29% had undergone a first arch reintervention, and 39% remained alive without an arch reintervention. Of those patients who had undergone a first arch reintervention, at 15 years 22% had died without a second reintervention, 31% had undergone a second arch procedure, and 47% remained alive without a second arch procedure.

**Recurrent Left Ventricular Outflow Tract Obstruction**

Left ventricular outflow tract obstruction remains a significant source of late postoperative morbidity and mortality. From 1991 to 2001, 27 neonates underwent primary repair for IAA and an isolated malalignment-type VSD at our institution. Fifteen of these patients with the smallest subaortic areas were felt to be at risk for early or late postrepair subaortic obstruction. Consequently, these patients underwent transatrial myectomy or myotomy of the infundibular septum concomitant with the VSD closure and IAA repair, as described above. Those patients requiring myectomy/myotomy (Group I) had significantly smaller subaortic diameters (3.7 ± 0.9 mm), when compared with those who had only IAA with VSD repair (Group II, 4.5 ± 0.7 mm; \( P = 0.0231 \)). This remained significant when indexed to BSA (0.83 ± 0.16 vs. 0.99 ± 0.13 cm (BSA)\(^{0.5} \); \( P = 0.012 \)). There was no difference in the mean aortic \( z \)-value between groups. There were two hospital deaths in Group I and one in Group II. No late deaths have occurred. No patient in Group II has required re-operation. Six patients required nine reoperations for left ventricular outflow tract obstruction, all of whom were in Group I and underwent myectomy/myotomy at the initial operation. Five of those patients underwent resection of a new subaortic membrane. Only one patient required myectomy for recurrent muscular subaortic obstruction. The mean interval between initial operation and first reoperation was 3.7 ± 4.1 years (range 0.5 to 9.5 years). Three patients required a second reoperation, primarily related to aortic valvar stenosis. These data reflect the continuing improvement in hospital survival (89%, 24/27) for single-stage IAA with VSD repair in the neonatal period. They also support an approach tailored to the degree of subaortic narrowing, with resection or incision of the infundibular septum at the time of primary repair for those patients felt to be at risk for residual or recurrent subaortic stenosis.

While these patients continue to be at risk for other levels of left ventricular outflow tract obstruction, this approach was very effective in preventing or prolonging the interval to recurrent muscular subaortic stenosis when compared with other published series. The late follow-up of the CHSS IAA cohort revealed that 69 patients required 100 interventions for recurrent left ventricular outflow tract obstruction. Competing risks analysis demonstrated that 15 years after repair, 33% had died without a first reintervention for left ventricular outflow tract obstruction, 18% had undergone a first reintervention and remained at risk, 1% had undergone a first reintervention and were no longer at risk, and 48% remained alive without a first reintervention for left ventricular outflow tract obstruction. Of those patients having a first reintervention for left ventricular outflow tract obstruction, competing risks analysis demonstrated that at 15 years following the initial reintervention, 13% had died without a second reintervention, 44% had undergone a second reintervention, and 43% remained alive without a second reintervention for left ventricular outflow tract obstruction.

### SUGGESTED READINGS

EDITOR’S COMMENTS

As noted by the authors, the results with repair of IAA in isolation or in association with other complex congenital heart disease have increasingly improved such that now the majority of infants with these conditions have satisfactory single-stage complete repair. The earlier poor results with neonatal single-stage repair led several surgeons to advocate pulmonary artery banding and arch reconstruction with artificial grafts or with the carotid artery to reestablish arch continuity. However, the late problems with the development of subaortic obstruction and the necessity of replacing these conduits during growth have led to almost universal adoption of single-stage primary repair as the treatment of choice for this condition. In rare cases, patients with interrupted aortic arch may be hemodynamically severely unstable or patients may be of very low birth weight. In such rare cases, it is possible to consider using a hybrid strategy for initial palliation with placement of bilateral pulmonary arterial band and stenting of the ductus arteriosus. This approach may allow for growth of the ascending aorta and improvement in other organ system dysfunction prior to a complete operative repair. Dr. John Brown has reported good results with arch reconstruction with carotid artery turn-down and PA bandings in a recent series. Minor variations in operative technique are used in many centers. We have elected in virtually all cases to avoid a direct circumferential primary anastomosis of the descending aorta to the ascending aorta and have used direct anastomosis over one half of the circumference of the arch in its most superior aspect with incision into the head and neck vessels and then augmentation of the undersurface of the arch with a generous patch of pulmonary homograft material. In this manner, native aorta is primarily anastomosed to allow for growth, and the arch is additionally enlarged to prevent any tension on the anastomosis. When bleeding is encountered in IAA repair with primary anastomosis, additional sutures to control bleeding may result in narrowing at the area of reconstruction; use of pulmonary homograft to augment the arch prevents this problem. With this technique, we have not found it necessary to divide an aberrant right subclavian artery in type B interruption and have left the right subclavian in place, incising the left subclavian artery at its origin as well as the left common carotid artery and sewing the carotid and subclavian together in their superior extent as part of the arch reconstruction.

The most difficult issue in repair of IAA with associated VSD is the issue of the subaortic infundibular septum, which may cause significant subaortic obstruction. As noted by the authors, it is not readily possible to identify those patients preoperatively who have significant subaortic obstruction by either echocardiography or catheterization because most flow goes across the VSD to the pulmonary arteries preoperatively. The difficulty in identifying patients with significant outflow tract obstruction may account for the fact that in the CHSS data, the narrowness of the subaortic region as determined by echocardiography did not correlate with outcome, leading the group to advocate primary repair in all circumstances. In spite of this recommendation, we have elected not to perform primary repair in some infants with very small subaortic regions, especially when the aortic valve annulus itself is severely hypoplastic.

A small number of infants have very significant hypoplasia of the aortic valve annulus and associated bicuspid aortic valve with very severe subaortic outflow tract obstruction. In these patients we have elected to perform a Yasui procedure, as described in this chapter, baffling the VSD to the pulmonary artery and reconstructing the aortic arch as in the Norwood operation with connection of the right ventricle to the pulmonary bifurcation with a homograft conduit. The incidence of development of subaortic obstruction after complete repair of IAA with associated VSD is significant. Even with resection of some subaortic muscle, recurrent obstruction can occur. The muscle is difficult to excise in very small infants, and the resection, if carried superiorly enough, can damage the aortic valve. In addition, once the resection is performed, the superior most extent of the VSD patch is difficult to anchor because there is little tissue remaining in this location. Alternate methods of dealing with the subaortic muscle have been described. When possible, we prefer to place the VSD patch on the left ventricular side of the muscle superiority and then bring the suture line to the right ventricular side on the inferior margin to avoid the conducting tissue. In this manner, the pressure of the left ventricle pushes the subaortic infundibular muscle away from the outflow tract during systole and seems to cause less stimulus for hypertrophy of this muscle, which can then develop into later outflow tract obstruction. If exposure is good, certainly resection is a reasonable approach. Starnes has recommended closure of the VSD via the pulmonary artery with pulling of the infundibular muscle to the right ventricle to address the subaortic outflow tract obstruction. The follow-up with all of these techniques has been relatively short, and the possibility of late development of residual outflow tract obstruction remains a concern.

The authors of this chapter have described an excellent result with myectomy in their series of interrupted aortic arch repairs with reoperation necessary primarily for the development of subaortic membranes. We have seen a significant incidence of recurrent subaortic obstruction by membrane, but in addition, a significant number of these patients have aortic arch hypoplasia and aortic valve abnormalities and may come to a Ross–Konno operation relatively early.

Regardless of the technique for dealing with the subaortic infundibular muscle and interrupted aortic arch, a significant incidence of recurrent left ventricular outflow tract obstruction and need for reoperation has been reported in most series. Although patients with even small aortic annulus and subaortic area can successfully undergo single-stage complete repair as a neonate, it is not infrequent for these patients to have a bicuspid aortic valve and recurrent outflow tract obstruction, which requires a Ross–Konno operation as a second procedure often within the first 6 months of life. The results with these repairs, however, have continued to improve such that the overall survival with repair of interrupted aortic arch now approaches 95% in many centers.
VALVAR AORTIC STENOSIS

Pathology

Valvar aortic stenosis in children is most commonly congenital in etiology. The leaflets are thickened and dysplastic, with variable degrees of commissural fusion. The valve is typically bicuspid in morphology but may be tricuspid or even unicuspid. Stenosis of the right and left cusps is associated most frequently with fusion. Obstruction results from decreased leaflet mobility and a reduction in effective orifice size. Small annular size may also be present, further impeding left ventricular ejection.

Clinical Presentation and Diagnosis

Neonates with critical aortic stenosis develop symptoms of congestive heart failure and impaired systemic perfusion consequent to closure of the ductus arteriosus. Prompt diagnosis and institution of therapy are, therefore, necessary to prevent rapid deterioration and death.

Older children present less acutely, often with the finding of an asymptomatic heart murmur on routine physical examination. Feeding difficulty in infants and decreased exercise tolerance in older children may be observed as the severity of obstruction increases. Later symptoms include exertional angina, congestive heart failure, and syncope. Physical findings generally are limited to the cardiovascular examination: a harsh systolic ejection murmur at the right upper sternal border radiating to the neck, S4 gallop, and poor upstroke of the carotid pulse. An ejection click may indicate the presence of a bicuspid valve.

Chest X-ray is usually nondiagnostic. The electrocardiogram may show left ventricular hypertrophy. Echocardiography is the principal diagnostic method for the evaluation of left ventricular outflow tract obstruction (LVOT). Two-dimensional echocardiogram allows assessment of the LVOT and aortic valve morphology including leaflet number, degree of thickening, and mobility. In addition, left ventricular cavity size, the presence and severity of left ventricular hypertrophy, and ventricular function can be assessed. Color Doppler imaging accurately identifies the level of obstruction, allowing a distinction between valvar, subvalvar, and supravalvar stenosis. Doppler measurement of blood flow velocity across the valve provides an estimate of the peak pressure gradient. Progression of disease and timing of intervention, therefore, can be determined in a noninvasive manner in most cases.

With accurate echocardiographic assessment, cardiac catheterization is rarely required in the diagnostic evaluation of aortic stenosis. Direct simultaneous measurement of left ventricular pressure and aortic pressure is the most accurate method for assessing the outflow tract gradient. However, identification of the precise level of obstruction may not be possible. Elevation of left ventricular end-diastolic pressure indicates impaired diastolic function. Left ventriculography allows assessment of ventricular systolic function and may outline the valve leaflets, providing some assessment of morphology.

Treatment

Neonatal Critical Aortic Stenosis

Critical aortic stenosis diagnosed in the newborn period constitutes a medical emergency. A neonatal presentation indicates severe outflow obstruction that requires urgent intervention. Initial stabilization includes endotracheal intubation and inotropic support. Prostaglandin infusion will establish or maintain patency of the ductus arteriosus and improve systemic perfusion. Emergency aortic valvotomy previously was the treatment of choice, performed soon after resuscitation. In the current era, percutaneous transcatheter balloon aortic valvotomy has supplanted surgical valvotomy in most centers. Transcatheter valvotomy is performed in the catheterization laboratory, with the advantages of rapid relief of obstruction and avoidance of cardiopulmonary bypass and aortic cross-clamping. Regardless of the technique, neonatal aortic valvotomy is considered a palliative procedure for most patients, with 41% undergoing reintervention within 10 years.

In a small subset of neonates with critical aortic stenosis and small left ventricular size, it may be difficult to determine whether a biventricular approach with aortic valvotomy/replacement or a single-ventricle approach with the Norwood procedure is more appropriate. Several studies have attempted to identify preoperative predictors for the suitability of single ventricle versus biventricular repair in this challenging population. However, none of these studies have established a universally adopted set of criteria, and patient triage to a single versus biventricular pathway is the subject of a current multi-institutional study sponsored by the Congenital Heart Surgeons Society.

Neonates with Multilevel Left Ventricular Outflow Tract Obstruction

Neonates with multiple levels of LVOTO are a complex group. Surgical options must be tailored to the particular anatomic considerations (Fig. 84.1). Neonates undergoing single-ventricle palliation can be managed with a staged approach, consisting of a Norwood or modified Norwood operation. Hybrid palliation, with implantation of a ductal stent and concomitant bilateral pulmonary arterial banding, is another recently developed option. This strategy, however, is currently reserved for marginal candidates with contraindications to standard Norwood-type palliation, or as a bridge to heart transplantation, with few centers using Hybrid palliation as the preferred approach. Heart transplantation is an attractive strategy for infants with severe atrioventricular valve regurgitation,
visceral heterotaxy, or poor systemic ventricular function.

Neonates undergoing biventricular repair have several potential options depending upon the associated intracardiac and arch pathology. Infants with combined valvar aortic stenosis and aortic arch obstruction can be managed with standard patch aortoplasty concomitant with either a neonatal Ross operation or a mechanical aortic valve replacement with an annular enlargement procedure (Konno aortoven-triculoplasty). Our institutional preference has been to manage these patients with aortic valve replacement and Konno, as results with the neonatal Ross operation have been poor, especially in neonates with associated mitral valve abnormalities. The presence of a ventricular septal defect adds an additional level of complexity, with options including those discussed above, arch repair with closure of the ventricular septal defect, or Yasui reconstruction.

**Valvar Aortic Stenosis in Older Children**

The objectives of surgical treatment of aortic stenosis are relief of symptoms and reduction of the risk of sudden death. Sudden death is related directly to the severity of obstruction and correlates with the peak systolic gradient, although it is reported to be <1%. Stenosis is considered severe when the mean echocardiographic gradient is ≥40 mmHg, moderate when it is between 25 and 40 mmHg, and mild when it is <25 mmHg. Surgery is indicated in any symptomatic patient regardless of severity and in asymptomatic patients with severe stenosis. Although surgery is not recommended for asymptomatic patients with mild stenosis, there is controversy about the management of asymptomatic patients with moderate stenosis. Surgical management should be considered on an individual basis. The authors generally recommend surgery in patients who demonstrate reduced left ventricular function, a strain pattern on electrocardiography, or abnormal exercise testing.

The two options for surgical management of aortic stenosis are valvotomy and aortic valve replacement. Valve replacement in children poses unique challenges that are not seen in the adult population. The smallest mechanical and bioprosthesis valves available (15 to 19 mm) may be too large for the annular size of smaller children. Even when replacement is feasible, unless an “adult-sized” valve is implanted, somatic growth eventually results in recurrent outflow obstruction due to patient–prosthesis mismatch. In addition, re-replacement with an appropriately sized valve may be limited by restricted annular growth from the original prosthesis. These limitations may necessitate concomitant performance of an annulus-enlarging procedure such as a Konno aortoventricu-loplasty. Posterior enlargement procedures such as the Nicks or Manougian procedures are often insufficient in children. These options are discussed in detail in later sections.

The choices of prosthetic valves for children are more limited than are those for adults. Bioprostheses do not require anticoagulation, but calcific degeneration occurs at an accelerated rate compared with adults, limiting their use in children. Mechanical prostheses maintain their structural integrity and generally have excellent freedom from reintervention or re-replacement, but require anticoagulation with warfarin. Anticoagulation can be achieved safely in children, but issues of compliance, inconsistent diet, and potential for injury increase the risk of bleeding and thromboembolic complications in this patient population. A recent paper by Alsoufi and colleagues demonstrated that the use of either homograft or bioprosthetic valves in children was associated with an increased risk of valve-related reoperation (82% at 15 years) compared with both mechanical valve implantation and the Ross operation. However, long-term survival was excellent (86% at 15 years) in patients having homograft or bioprosthetic valve replacement, underscoring that these valve types can be useful in female patients or those in whom anticoagulation cannot be administered.
Surgical Procedures

Aortic Valvotomy

Surgical aortic valvotomy is usually performed via a median sternotomy. A single right atrial cannula provides venous drainage, and the aortic cannula is placed as distally as possible. Some surgeons advocate closed valvotomy that is performed by passing dilators of increasing size (usually up to 1 mm larger than the preoperative echocardiographic aortic annulus diameter) through the aortic valve; the dilators are introduced through a purse string in the left ventricular apex. This technique can be performed through a left thoracotomy without the need for cardiopulmonary bypass. The authors believe that open valvotomy with direct visualization of the aortic valve allows more precise leaflet separation, resulting in better relief of gradient and a decreased risk of significant aortic insufficiency.

The aorta is clamped, and cardioplegia is delivered via the aortic root. A transverse aortotomy is made just above the sinotubular junction, with care taken to avoid injury to the right coronary artery and the aortic valve leaflets. The valve is inspected carefully. Fused commissures are opened precisely with a scalpel (Fig. 84.2). The incisions are not extended to the aortic wall, since this may result in loss of support and aortic insufficiency (Fig. 84.3). Excessive fibrous tissue, if present, is excised from the leaflets. Fibrous attachments between the base of the leaflets and the aortic wall are divided to maximize leaflet mobility.

Despite these steps, the effective orifice may be inadequate, particularly in smaller bicuspid valves. Ilbawi and colleagues described a technique of extended valvotomy for these patients. Circumferential incisions are made above the true commissures and raphes. They reported a low incidence of aortic insufficiency and significantly lower gradients compared with standard valvotomy. The aortotomy is closed precisely to avoid supravalvar narrowing, and the cross-clamp is removed. The patient is weaned from cardiopulmonary bypass with mild inotropic support (dopamine 5 µg/kg/min and milrinone 0.5 µg/kg/min). The adequacy of repair is assessed by transesophageal echocardiography and direct measurement of pressure in the left ventricle and ascending aorta. Modified ultrafiltration is performed before decannulation.

Early mortality in older infants and children undergoing aortic valvotomy is reported currently to be <2%, and late mortality is rare. Reintervention for progressive regurgitation or restenosis may be required, but this generally occurs later than in neonates. The reoperation rate in children over 1 year of age at the time of the initial valvotomy is 2% at 10 years but then increases 3.3% per year.

Aortic Valve Replacement

Aortic valve replacement is required when valvotomy is not sufficient to reduce the transvalvar gradient adequately, or in patients with greater than mild aortic insufficiency. In larger children with adequate annular size, simple replacement of the valve is performed as it is in adults. Prosthesis selection should be individualized to the patient’s lifestyle and activity level. The authors generally avoid porcine and bovine bioprostheses as well as
allograft implantation because of the rapid degeneration and early failure observed in children. The remaining options, therefore, are limited to mechanical prosthesis and pulmonary autograft.

Aortic valve replacement with a mechanical prosthesis is performed via a median sternotomy. A single right atrial or two-stage venous cannula provides venous drainage, and the ascending aorta is cannulated distally. The aorta is clamped, and in the absence of significant aortic insufficiency, cardioplegia is infused in the aortic root. After aortotomy, additional cardioplegia is delivered every 30 minutes through a retrograde coronary sinus catheter and by direct coronary ostial perfusion. A left ventricular vent is placed through the left atrial appendage or the right superior pulmonary vein.

A transverse aortotomy is made and is extended into the noncoronary sinus of Valsalva. The aortic valve leaflets are excised. Interrupted pledgeted mattress sutures are placed circumferentially around the annulus. In smaller patients, intra-annular placement may be preferable to avoid coronary ostial obstruction by the sewing ring. The sutures are passed through the sewing ring, and the valve is parachuted into place. After the sutures are tied, the prosthetic leaflets are assessed carefully to ensure unhindered mobility. The aortotomy is closed, and the aortic clamp is removed. The patient is weaned from cardiopulmonary bypass with mild inotropic support. Transesophageal echocardiography is used to assess prosthetic function. Modified ultrafiltration is performed before decannulation.

Hospital mortality after mechanical aortic valve replacement in children is 0% to 5%. Early complications include permanent heart block in 3% and acute endocarditis in 2% of these patients. Late complications relate primarily to anticoagulation. In reports of long-term follow-up, valve thrombosis occurs in 0% to 2% of patients. This sometimes can be managed pharmacologically with thrombolytic agents but frequently requires urgent surgical thrombectomy or valve replacement. Embolic events are reported in 2%, and significant bleeding episodes occur at a rate of 0.15% per patient year. Freedom from reintervention or re-replacement is approximately 86% at 20 years but is increased in younger patients having smaller prostheses.

**Ross Procedure**

Ross reported aortic valve replacement with a pulmonary autograft and allograft reconstruction of the right ventricular outflow tract in 1967. In the absence of significant size discrepancy or connective tissue disease, the Ross procedure is the preferred technique for aortic valve replacement in small children. In larger children, it is frequently preferred over mechanical prosthesis to avoid the need for anticoagulation.

The approach is via a median sternotomy. The venae cavae are cannulated individually, and the ascending aorta is cannulated distally. The aorta is clamped, and in the absence of significant aortic insufficiency, cardioplegia is infused in the aortic root. Cardioplegia may also be delivered retrograde through a coronary sinus catheter and by direct coronary ostial perfusion after an aortotomy. Additional cardioplegia is delivered every 30 minutes during the cross-clamp period. A left ventricular vent is placed through the left atrial appendage or the right superior pulmonary vein.

The aorta and the pulmonary trunk are separated, and the pulmonary trunk is opened transversely just proximal to the bifurcation. The pulmonary valve is inspected to identify any pathology that would preclude its use as an aortic valve replacement. Transection of the pulmonary trunk is then completed. A right-angle clamp is passed carefully through the leaflets into the right ventricular outflow tract, and a site for proximal transection is identified in the infundibular free wall approximately 5 mm below the level of the valve. A transverse infundibular incision is made and carried to the infundibular septum at each end. The infundibular septum is scored with a scalpel blade. A plane can be developed between the subconal muscle and the underlying interventricular septum. Dissection in this plane completes the harvest, and the autograft is stored in normal saline solution before implantation. The resulting posterior raw surface is cauterized. In their practice, the authors also apply a thin layer of biological sealant to ensure hemostasis. In dissecting the autograft, care must be taken at the leftward extent of the septal dissection to avoid injury to the first septal perforating branch of the left anterior descending coronary artery. The pulmonary artery is sized, and an appropriate allograft is thawed and prepared for reconstruction of the right ventricular outflow tract.

The aorta is transected just above the sinotubular junction. The aortic valve leaflets are excised, and the left and right coronary arteries are excised with a generous button of aortic wall. The autograft is oriented by alignment of the commissures.
A proximal anastomosis is then constructed. Interrupted simple braided sutures are used for smaller patients, although a continuous technique with polypropylene sutures can be used in larger children and teenagers. The coronary buttons are anastomosed to incisions in the respective autograft sinuses of Valsalva. The distal aortic anastomosis is constructed with a running polypropylene suture. Air is evacuated from the left side of the heart, and the aortic clamp is removed. Continuity between the right ventricle and the pulmonary artery is restored by interposing the previously thawed allograft in the reperfused, beating heart. The patient is weaned from cardiopulmonary bypass with mild inotropic support. Transesophageal echocardiography is used to assess autograft and allograft function as well as left ventricular wall motion. Modified ultrafiltration is performed before decannulation in children with an operative weight below 20 kg.

The results of the Ross procedure are reasonable in carefully selected pediatric patients. Early mortality is 0% to 6%, occurring primarily in infants under 5 months of age. However, patients with concomitant mitral valve disease or aortic arch hypoplasia, even when judged to have adequate biventricular physiology, fare poorly with the Ross operation. A recent paper by Shinkawa and colleagues from the University of Michigan reported a 36% early mortality in this subgroup. Similarly, Hickey and colleagues reported a 31% early mortality rate in infants younger than 3 months, and an actuarial 1-year survival <50% for neonates. Complications occur infrequently and include bleeding, arrhythmia, heart block, and stroke. Actuarial survival for all patients is 84% at 1 year and 77% at 5 years. Aortic root dilatation is common late after the Ross procedure in children and warrants careful echocardiographic follow-up.

**Konno Aortoventriculoplasty**

Annular enlargement is required in children with small aortic annular size requiring aortic valve replacement. Nicks and colleagues and Manougian and Seybold-Epting described techniques for posterior annular enlargement that have been used successfully in adults. However, the resulting increase in annular size is generally inadequate to allow insertion of even a small prosthetic valve in small children. Konno and coworkers described a technique of anterior enlargement that more effectively increases annular size and relieves coexistent subvalvar stenosis.

The approach is via a median sternotomy. The venae cavae are cannulated individually, and the ascending aorta is cannulated distally. The aorta is clamped, and in the absence of significant aortic insufficiency, cardioplegia is infused in the aortic root. Additional cardioplegia is delivered every 30 minutes during the cross-clamp period. A left ventricular vent is placed through the left atrial appendage or the right superior pulmonary vein.

A vertical aortotomy is made and is carried onto the right ventricular outflow tract well to the left of the origin of the right coronary artery. Care is taken to avoid injury to the pulmonary valve. The aortic valve leaflets are excised, allowing visualization of the left and right ventricular aspects of the infundibular septum. An incision is made across the aortic annulus into the infundibular septum. Injury to the conduction tissue is avoided by placing this incision to the left of Lancisi muscle. A diamond-shaped patch of Dacron is fashioned, and the inferior portion is sutured to the edges of the septal incision with interrupted pledgeted mattress sutures. An appropriately sized prosthetic valve is then inserted as was described for aortic valve replacement. Anteriorly, the valve sutures are passed through the prosthetic patch. The superior portion of the patch is used to close the ascending aorta. The right ventricular free wall is enlarged with a patch of bovine pericardium. Air is evacuated from the left side of the heart, and the aortic clamp is removed. The patient is weaned from cardiopulmonary bypass with mild inotropic support. Transesophageal echocardiography is used to assess prosthetic function, patch leaks, and left ventricular wall motion.

A modification of this technique can be used for annular enlargement in conjunction with the Ross procedure. A Ross–Konno is an ideal procedure in infants or children under 2 years of age, whose size precludes implantation of at least a 21-mm prosthesis or larger. The pulmonary autograft is harvested with a triangular portion of right ventricular free wall that is used as the septal patch.

In light of the complex form of LVOTO seen in pediatric patients who require the Konno or the Ross–Konno procedure, early and late results are quite good. On average, the annulus is enlarged to twice the original size, often allowing insertion of an adult-sized prosthesis (23 or 25 mm) in most patients over 3 years of age. Operative mortality for the Konno procedure with prosthetic valve replacement is 5% to 15%. Ten-year actuarial survival is 92%. Ten-year freedom from reoperation with a mechanical prosthesis is 80% to 89%. The linearized rate of reoperation is approximately 3.9% per year and is increased among patients undergoing a Konno to correct aortic valve pathology in conjunction with annular hypoplasia. An important and often underappreciated complication of the Konno procedure (with or without concomitant Ross operation) is pulmonary regurgitation, which occurs at a cumulative incidence of 10% at 16 years postoperatively. Operative mortality for the Ross–Konno procedure is 0% to 7% even in children under 1 year of age. Postoperative complications include bleeding, arrhythmia, heart block, and left ventricular dysfunction. No permanent effects on ventricular function are present at long-term follow-up.

**SUBVALVAR AORTIC STENOSIS**

Subaortic stenosis in children results from either a discrete fibrous membrane or, less commonly, diffuse, fibromuscular tunnel-like stenosis (Fig. 84.4). The discrete subaortic membrane is probably an acquired lesion that is rarely seen in infants, albeit with “anatomic precursors.” Often, a ring of fibrous tissue is present that is adherent to the septum anteriorly, extending posteriorly to the right and left fibrous trigones and to the anterior mitral leaflet. Associated subaortic anomalies are present in 31% of these patients, including anomalous

---

**Fig. 84.4.** Sagittal section of the heart with a discrete subaortic membranous obstruction.
septal insertion of the mitral valve, accessory mitral valve tissue, anomalous papillary muscles, and anomalous muscular bands. In addition to outflow obstruction, aortic insufficiency develops in more than 50% of these patients from turbulence-induced leaflet deformity or direct attachment of the membrane to the aortic leaflets.

Tunnel-like subaortic stenosis is a congenital lesion in which the subaortic region is diffusely hypoplastic. Thickened septal myocardium and endocardial fibrosis contribute to outflow tract obstruction.

**Clinical Presentation and Diagnosis**

Patients with discrete subaortic stenosis usually present in childhood with an asymptomatic murmur detected on physical examination. Chest pain, syncope, and congestive heart failure may develop with worsening obstruction. A systolic ejection murmur without an ejection click is heard on auscultation. A diastolic decrescendo murmur may be heard at the left lower sternal border when a discrete subaortic membrane causes aortic insufficiency. Tunnel-like fibromuscular stenosis often presents in infancy but is otherwise indistinguishable from a discrete membrane on the basis of signs and symptoms. The evaluation is similar to that elucidated for valvar aortic stenosis, with echocardiography being the main diagnostic test. Chest X-ray is usually nondiagnostic, and electrocardiography shows left ventricular hypertrophy.

**Discrete Fibrous Subaortic Stenosis**

Surgical excision of a discrete fibrous subaortic membrane is indicated for relief of symptoms, for severe obstruction (mean gradient >30 mmHg), and when moderate-to-severe aortic insufficiency is present. Asymptomatic patients with mean gradients <30 mmHg and without significant aortic insufficiency do not require surgery but should be followed with serial echocardiograms to detect progression. There is controversy about asymptomatic patients with moderate obstruction and mild aortic insufficiency. Some centers advocate prophylactic excision in all cases, citing the low risk of surgery and the benefit of preventing aortic insufficiency. However, clinically important progression is not universal, and factors determining at-risk substrates are debated. Furthermore, the efficacy of early surgery is controversial because of the variable outcomes in patients undergoing early surgical intervention coupled with a high postoperative prevalence of both recurrent stenosis and aortic regurgitation even after successful relief of subaortic obstruction. Patients with a mean echocardiographic gradient >30 mmHg, close proximity of the membrane to the aortic valve, and membrane extension to the mitral valve are at higher risk for progressive obstruction and should undergo surgical repair. Older age and a gradient above 30 mmHg are independent risk factors for progressive aortic insufficiency and are indications for repair.

The surgical approach is via a median sternotomy. A single right atrial or a two-stage venous cannula provides venous drainage, and the ascending aorta is cannulated distally. The aorta is clamped, and in the absence of significant aortic insufficiency, cardioplegia is infused in the aortic root. A transverse aortotomy is made and is extended into the noncoronary sinus of Valsalva. Edwin and colleagues recently reported a novel hexagonal six-point traction technique to provide improved exposure of the subaortic region. This method involves the placement of three commissural traction sutures along with three additional traction sutures placed at the nadir of each aortic valve leaflet. The nadir sutures not only elevate the subaortic region and improve visualization but also keep the aortic valve leaflets retracted against the aortic wall during the resection. The aortic valve leaflets are retracted gently, allowing visualization of the membrane in the left ventricular outflow tract.

The membrane is grasped anteriorly with a skin hook or a traction suture. A radial incision is made into the membrane, initiated just to the left side of an imaginary line descending from the right coronary ostium, extending just into the underlying septal myocardium. The membrane is then excised circumferentially in a counterclockwise direction by blunt dissection (Fig. 84.5). Care is taken to avoid injury to the anterior leaflet of the mitral valve and the aortic valve leaflets (Figs. 84.6 and 84.7).
Fig. 84.6. Blunt dissection is initiated. The membrane is enucleated, not excised.

Fig. 84.7. The enucleated membrane is sometimes removed as a complete, circumferential ring.
Resection of additional septal muscle is performed to ensure complete excision of the membrane. Yacoub and colleagues advocate the additional resection of fibrous tissue in the left and right fibrous trigones.

The aortotomy is closed, and the aortic clamp is removed. The patient is weaned from cardiopulmonary bypass. Transesophageal echocardiography is used to assess relief of obstruction and aortic insufficiency. After resection of discrete subaortic membrane, mortality approaches zero. Permanent heart block and iatrogenic pericardial effusion are rare. Pericardial pericardiotomy is performed to ensure complete excision of the subaortic membrane, but relief of the obstruction is obtained with no permanent heart block and no hemodynamically significant residual ventricular septal defects. More long-term follow-up is required, but freedom from reoperation at 3 years has been found to be 95% to 100%.

Placement of a left ventricular apicoaortic valve conduit has been described for patients with severe outflow tract obstruction considered not amenable to conventional repair. The authors believe that nearly all patients can be treated more definitively with resection and a modified Konno procedure.

**SUPRAVALVAR AORTIC STENOSIS**

Supravalvar aortic stenosis is the least common form of LVOTO. The underlying biochemical mechanism is abnormal elastin synthesis that is related to mutations in the chromosome region 7q11.23. This may occur in association with Williams syndrome, as an autosomal-dominant familial trait, or as a sporadic finding.

The pathologic lesion in supravalvar stenosis is a thickening of the aortic wall that results from collagen deposition and smooth muscle hypertrophy in the media as well as hyperplasia and fibrosis of the intima. The narrowing is localized to the sinusoidal junction in 85% of cases, with either an hourglass or a discrete membranous morphology. Diffuse hypoplasia is present in 15% of cases and involves the entire ascending aorta, occasionally extending to the transverse arch and the descending aorta. Although the site of stenosis may be localized, it is important to recognize that the pathologic process involves the entire aortic root, may coexist with important valvar aortic stenosis, and can also include peripheral pulmonary artery stenoses. Coronary ostial stenosis, most commonly involving the left coronary artery, occurs in 25% of these patients.

### Clinical Presentation and Diagnosis

Patients with supravalvar aortic stenosis typically present in the first year of life with feeding or exercise intolerance, angina, or syncope, although cardiovascular findings are present in less than one-third of these newborns. The presence of characteristics ascribable to Williams’ syndrome should increase the index of suspicion. About 10% of patients are asymptomatic.

As with other causes of LVOTO, chest X-ray findings are nonspecific. The electrocardiogram shows left ventricular hypertrophy. ST-segment and T-wave abnormalities consistent with ischemia may be seen in patients with coronary artery involvement. Two-dimensional echocardiography is the usual method of diagnosis in patients with supravalvar aortic stenosis. Decreased aortic caliber, increased wall thickness, and abnormal leaflet mobility are identified. Localized stenosis can be distinguished from the more diffuse pattern, and the extent of distal involvement can be assessed. Coronary ostial involvement as well as concomitant subaortic stenosis can also be detected. Cardiac catheterization is performed routinely to assess patients with supravalvar stenosis when surgical repair is being considered. It is the only method for accurate measurement of the peak systolic gradient. Aortography distinguishes the localized type from diffuse hypoplasia and accurately defines the distal extent of narrowing. Coronary ostial stenosis can also be detected and characterized.

### Treatment

Surgical repair of supravalvar aortic stenosis is indicated in symptomatic patients as well as in asymptomatic patients with a peak catheter-measured systolic gradient $>50$ mmHg. The goals of repair are to relieve outflow obstruction and restore normal geometry to the aortic valve and sinuses of Valsalva. Expectant management of asymptomatic patients with lower LVOT gradients is acceptable since lesion regression has been documented in an important proportion of these patients coupled with a similar overall survival in patients treated with and without operative intervention.

The approach is via a median sternotomy. A single right atrial cannula provides venous drainage, and the aortic cannula is placed as distally as possible. The aorta is clamped, and cardioplegia is delivered via the aortic root. Surgical repair...
techniques have evolved considerably since the first description by McGoon in 1961, mainly in an effort to obviate distortion of the aortic root and sinuses and restore a more normal geometric configuration. McGoon and colleagues first performed a longitudinal aortotomy, beginning above the area of narrowing and extending into the noncoronary sinus of Valsalva. The stenotic ridge is excised, and a diamond-shaped patch of bovine pericardium, Dacron, or Gore-Tex is used to augment the ascending aorta. With the recognition that distortion of the aortic valve and sinuses of Valsalva may contribute to outflow obstruction, techniques were developed to maintain greater symmetry of the sinuses.

Doty and associates described an inverted Y-incision into the noncoronary and right coronary sinuses of Valsalva (Fig. 84.8). The incision in the right sinus is placed well to the left of the origin of the right coronary artery. A pantaloon-shaped patch enlarges both the ascending aorta and the sinuses (Fig. 84.9). Brom advocated augmentation of all three sinuses. The aorta is transected at the area of narrowing. Incisions are made into each sinus of Valsalva. The sinuses are augmented with triangular patches, and the augmented root is reanastomosed to the ascending aorta. Myers and Waldhausen and their associates described an innovative technique to achieve three-sinus augmentation using autologous tissue, termed the slide aortoplasty (Figs. 84.10–84.12).

The aorta is transected at the area of narrowing, and incisions are made in the sinuses as with Brom technique. Three incisions are made in the ascending aorta opposite the aortic valve commissures, and the aorta is reapproximated. Variations of this technique include excision of the stenotic segment and the use of an autologous ring of pulmonary artery to enlarge the sinuses.

Regardless of the technique, the coronary ostia should be inspected carefully to identify any obstruction that may be present. When ostial wall thickening is present, a Brom repair is used, with the extension of the left coronary sinus incision into the left main coronary artery. Patch repair of the sinus is continued onto the coronary artery, with resultant coronary osteoplasty. Coronary obstruction from leaflet adherence to the stenotic ridge is relieved by careful separation of the fused leaflet and resection of residual tissue around the ostium. Diffuse narrowing of the left main coronary artery requires coronary artery bypass. A saphenous vein graft may be preferable since progressive arteriopathy may involve the subclavian artery and limit internal mammary artery flow.
Fig. 84.10. Supravalvar aortic stenosis repair as described by Myers starts with transection of the aorta at its narrowest point.

Fig. 84.11. Three vertical incisions are made in the proximal and distal aorta.
Patients with diffuse hypoplasia pose a greater surgical challenge. A combination of the techniques discussed above must be tailored to the specific findings that are encountered. Involvement of the transverse arch and descending aorta requires extensive augmentation using deep hypothermic circulatory arrest or low-flow bypass with continuous cerebral perfusion.

It is difficult to assess the results of surgery for supravalvar aortic stenosis because of the variability of pathologic findings, the diversity of the techniques employed, and the relatively small number of patients in each reported series. No consistent differences in short- or long-term outcome were noted between techniques augmenting one, two, or all three sinuses of Valsalva, though Kaushal and colleagues and Metton and colleagues reported superior outcomes (less aortic insufficiency or stenosis, and reduced reoperation rate) with the Brom technique. Freedom from reoperation at 10 years is 70% to 85%, and 10-year actuarial survival is 90% to 95%. Reoperation and late death most commonly are related to progressive valve dysfunction, not recurrence of supravalvar stenosis.

SUGGESTED READINGS

**EDITOR’S COMMENTS**

Balloon dilation techniques have essentially supplanted surgery as the primary treatment for critical aortic stenosis of newborns and infants. These catheter interventions have a mortality rate that is virtually identical to surgical mortality rates for the same condition. Maintenance of ductal patency during the procedure is useful in aiding distal perfusion and for resuscitation after the procedure. Thus, surgical approaches to valvar aortic stenosis are relegated to cases in which initial balloon attempts have failed or there are other associated conditions. In a newborn with critical aortic stenosis, even direct exposure of the aortic valve is difficult, and usually valvotomy is performed in a relatively blind manner either antegrade with a dilator or retrograde from above with a clamp or dilator. Thus, there is little benefit to operative dilation in these patients over balloon dilation except for the benefit of supporting the patient on cardiopulmonary bypass. Surprisingly, even though the aortic valve in these infants is a structure that often appears very dysmorphic, late aortic valve development appears quite good in many cases, and the aortic valve can have a long-lasting improvement in orifice area and especially normal anatomic and physiologic function. In most patients, however, eventual additional valve procedures will be necessary because of either restenosis or progressive calcification of a bicuspid valve.

Recently, there have been reports from Dr. John Brown in a surgical series of aortic valvotomy in critical aortic stenosis in newborns and in young infants with excellent results. In Dr. Brown’s center, the results of surgical balloon valvotomy appear to be superior to the results with balloon aortic valvuloplasty in terms of delaying reoperation for valve repair or replacement and limiting the amount of aortic regurgitation. In spite of these excellent results, now a very few centers have the option of a primary surgical approach to aortic stenosis, with catheter intervention essentially having supplanted surgical therapy for this condition.

Patients who have only moderate improvement in valve function with balloon dilation can undergo repeat dilation and the most common complication is production of aortic regurgitation. Patients can then be stabilized, with aortic regurgitation, often for several months or years before valve replacement with the Ross procedure is necessary. Thus, the need for Ross aortic valve replacement in neonates is extremely unusual. In older infants and children in whom balloon dilation has been unsuccessful in relieving obstruction, direct aortic valvotomy may be valuable. As noted by the authors, incision into a true raphe should be avoided if possible. However, raphes can be debrided to aid mobility of the leaflet and to improve the effective orifice area of the valve. This can often be accomplished without significant development of regurgitation. In patients in whom there is significant fibrotic thickening of the aortic valve leaflet edges, debridement and thinning of the valve leaflets can be undertaken, and the incision in the commissures can be extended back to the annulus and then along the annulus for a short distance to improve effective orifice area and to prevent tethering of the valve leaflets at the commissural attachments.

Discrete subaortic stenosis is a relatively common finding either in isolation or in association with previous cardiac repairs. It is not uncommon for patients with interrupted aortic arch and ventricular septal defect closure to develop acquired subaortic stenosis from the development of a subaortic membrane. In addition, certain patients with ativoventricular canal defects can develop these membranes after repair, and the defect has also been reported after isolated closure of ventricular septal defect. Thus, these subaortic membranes appear to be always an acquired phenomenon related to abnormalities of geometry of the left ventricular outflow tract and turbulent blood flow in this region. An important feature is the fact that these membranes are actually attached to the endocardium of the left ventricular outflow tract, and enucleation can be performed simply by (continued)
incising the junction of the membrane with the endocardium and identifying the endocardial layer. The membrane often can then be completely removed with blunt dissection and endarterectomy spatula. On occasion, the membrane can extend up onto the aortic valve leaflets, causing some thickening and valve immobility and can be associated with aortic insufficiency. In these cases, it is valuable to excise the membrane and to debride the membrane from the valve leaflets. Because the membrane is an acquired structure, it is distinct from the endocardial surface of the valve leaflet and often can be peeled off completely without any disruption of the valve’s intrinsic structure. The major problem with removal of subaortic membranes is the fact that recurrence is common. The high incidence of recurrence is not surprising considering that these are acquired defects related to the geometry of the outflow tract, and simple removal of the membrane does not alter this anatomic feature. I, therefore, believe it is important to perform a myotomy and myectomy of the left ventricular outflow tract wherever possible in association with resection of subaortic membrane to alter the geometry of contraction of the outflow tract, eliminate additional sources of obstruction, and potentially decrease the turbulent flow in the outflow tract, which can cause recurrence.

In spite of our preference to perform an extensive myotomy and myectomy in patients with subaortic obstruction, there have been reports primarily from the Hospital for Sick Children in Toronto that resection of subaortic muscle does not change the late recurrence rate after resection of subaortic membrane. However, we believe that the risk from myectomy is low and interference with the left bundle conduction in the left ventricle may change the geometry of left ventricular contraction in a favorable way that may limit the development of recurrent obstruction and therefore continue to use this technique.

Tunnel subaortic stenosis is a more diffuse process and often presents a difficult surgical problem. In most cases, there is some hypoplasia of the aortic valve annulus or abnormality of the aortic valve leaflet with diffuse hypoplasia or tunnel obstruction of the outflow tract. On rare occasions, however, the aortic valve disease may be minor, and a direct approach with septoplasty can provide adequate relief of obstruction. In our experience, however, such patients are unusual. One difficulty with septoplasty is that in true diffuse subaortic obstruction, the obstruction extends all the way to the base of the aortic valve leaflet, and therefore, the superior extent of the septal incision has to stop before the aortic annulus level is reached. Thus, there may always be a bridge of muscle tissue beneath the aortic valve leaflet that will become a potential source of obstruction. If there is an area of relatively normal outflow tract below the aortic valve, septoplasty can be very effective. In patients in whom septoplasty alone fails to relieve the obstruction because of the superior extent of the narrowing or associated aortic valve disease, we believe that a Ross-Konno autograft valve replacement supplies the best chance for long-term durability and complete relief of obstruction. Apicoaortic conduits are avoided because of the problems with late valve degeneration and abnormal coronary artery flow patterns. The use of the Ross-Konno operation has virtually eliminated the need for apicoaortic conduits in our experience.

Supravalvar aortic stenosis commonly associated with Williams syndrome represents an unusual condition but one in which good surgical results have been obtained with multiple techniques. We often have found it impossible to perform a simple patch of the ascending aorta with end arterectomy of the thickened supravalvar ridge in these patients because the ridge is often adherent to the commissural attachments of the aortic valve and excision of the ridge may result in damage to the valve commissures. The Doty technique using a Y-shaped patch has been useful, but it does not generally address the narrowing of the orifice into the left coronary ostium that is formed by the commissural attachment to the supravalvar ring posteriorly and is often associated with thickening of the endothelium and intima around the orifice of the coronary artery. Thus, we have used either a trifurcated patch to enlarge all three coronary sinuses or the technique described by Myers in which the aorta is primarily anastomosed into the base of the aortic sinuses. Although all of the techniques described can result in excellent relief of gradients across the left ventricular outflow tract, we believe that the primary anastomosis with attention to all three of the aortic sinuses permits the most optimal flow in the coronary arteries.

In many patients with Williams syndrome, there is significant hypoplasia of the ascending aorta and the aortic arch. In these cases, interdigitation of the distal aorta into the aortic sinuses for repair of supravalvar aortic stenosis is not possible. I have found it quite advantageous to patch the entire arch of the aorta with a triangular patch of pulmonary homograft material and then insert triangular patches into each of the coronary sinuses individually. The opening up of the sinus and sinotubular junction is quite effective with this technique, and then the size match is appropriate for anastomosis to the ascending aortic and arch reconstruction. In addition, if there is ostial stenosis of the left or right coronary or both, the triangular patches of homograft material can be carried down into the origin of the coronary artery itself, creating essentially an arterioplasty of the proximal coronary artery in addition to enlarging the aortic sinus and relieving the supravalvar obstruction. It is important when patching the sinuses in patients with supravalvar aortic stenosis not to oversize the patches, which can splay out the sinotubular ridge and create the substrate for potential aortic insufficiency. Often these patients have significant pulmonary stenosis and branch pulmonary artery hypoplasia, and transection of the aorta to perform this operation gives good exposure to place a T-shaped patch on the main pulmonary artery and onto the branch pulmonary arteries to the hilum of the lung.

The approach to hypertrophic subaortic stenosis in infants and children is primarily surgical. The early results with surgical resection of the subaortic septal myocardium have been excellent and the long-term results good. Thus, in children with significant gradients remaining despite medical management with calcium-channel blockers or beta blockers, surgical intervention should be considered the primary treatment. We have not found
pacing to be particularly beneficial in children, and in fact there is controversy as to the beneficial effects of pacing for this condition. Extensive resection of septal muscle has resulted in virtually complete relief of gradients and good long-term outflow tract obstruction relief in children, and the incidence of significant conduction disturbance has been quite low.

The Mayo Clinic group has shown that extensive myomectomy for hypertrophic subaortic stenosis results in excellent relief of gradients long term with improvement in exercise performance and a decreased need for medical management.

When we perform left ventricular myomectomy for subaortic stenosis or for hypertrophic cardiomyopathy, we extensively debride all of the muscle to the left of the vertical incision in the ventricular septum all the way to the mitral valve to remove as much muscle as possible from the outflow tract in the area away from the conduction tissue. When associated mitral valve disease is present, valve replacement can be considered; however, the problems of prosthetic valves in children warrant a very conservative approach to valve replacement. We have elected to perform extensive muscle resection of the septum in association with primary mitral valve repair when feasible.

A particularly difficult group of patients are those with critical neonatal aortic stenosis and mitral valve disease. In some cases, the degree of aortic stenosis can mask the abnormalities of the mitral valve and after balloon aortic valvuloplasty patients may still have significant aortic stenosis and require a Ross–Konno type operation. If the mitral valve abnormality is not identified preoperatively, it can be extremely difficult to deal with the mitral valve after a Ross operation and mitral stenosis and insufficiency can cause pulmonary hypertension which decreases the durability of the right ventricular outflow tract conduit reconstruction. In patients with severe mitral abnormalities including arcade mitral valve in association with critical aortic stenosis that does not respond to balloon valvuloplasties, it is occasionally necessary to consider supra annular mitral valve replacement and Ross–Konno operation as a combined procedure. We have performed this in a few patients with good results, although the patients have often a complicated postoperative course due to relative left atrial hypertension and pulmonary hypertension. In cases in which the aortic annulus is significantly hypoplastic and the mitral valve is severely abnormal, some patients may be best served by a Norwood-type single-ventricle strategy.
INTRODUCTION

Anomalies of the aortic root typically present as either enlargement or anoma­lus communication between supravalvular aorta and left ventricular (LV) cavity. In the former (sinus of Valsalva [SoV] aneur­rism), the process develops progressively and is often associated with connective tissue disorders that manifest diminished tensile strength of the aortic wall. The latter (aortoventricu­lar tunnel) is usually a per­turbation in cardiac development that is nearly always clinically evident in the newborn period or in early infancy.

Aortic root dilation is also a late finding in children who have undergone repair of various forms of congenital heart defects, such as common arterial trunk, transposition of the great arteries, or bicommissural aortic valve. With regard to SoV aneurysm, we will focus on iso­lated dilation of a single sinus since diffuse aortic root enlargement (seen more commonly in association with other forms of congenital, atherosclerotic, or connective tissue disease) is detailed elsewhere in this book.

ANEURYSM OF THE SINUS OF VALSALVA

Morphologic Considerations

Each coronary sinus is limited inferiorly by the curvilinear hinge point of the cor­responding aortic valve cusp. The inter­commissural triangles are inferior to the festoon-like line of ventriculoaortic contin­uity (commonly referred to as “annulus”), whereas the sinotubular junction deline­ates the circular superior margin of the aortic root.

The sinuses of Valsalva are normally thinner than the tubular portion of the aorta, and this macroscopic finding is usually associated with a lesser degree of histo­logic representation of the tunica media. In patients with SoV aneurysm, this normal characteristic is accentuated. Thinning of the aortic wall with disconnection of the media from the aortoventricular junction is seen histologically and increases over time.

Figure 85.1 schematically demonstrates the anatomic relations of the aortic root with the adjacent cardiac structures as seen from the operating surgeon’s view­point. These relations account in turn for the different modes of clinical presentation that are seen with pathologic enlargement of the SoVs. Dilation of the right SoV (most common) will, therefore, typically progress in the direction of the right ventricular outflow tract, whereas the noncoronary sinus will involve either left or right atrial chambers. Isolated enlargement of the left SoV (with possible rupture into the left atrium) is the rarest form of this pathology. Although typically SoV aneurysms involve one of the three sinuses as a well-defined diverticular outpouching, two or three sinuses can be affected simultaneously by the pathologic process. A ventricular septral defect (VSD) is observed in 25% to 50% of cases.

Aneurysms of the SoVs are rare. They are observed in 0.1% of autopsy series and in 0.14% to 0.96% of large operative cohorts; they are also five times more common in patients of Asian descent.

Clinical Presentation

Pathologic SoV enlargement is often diagnosed incidentally in asymptomatic patients. Clinical presentation can occur as an aortic catastrophe (free intraperi­cardial rupture), acutely with endocardi­tis or intracardiac rupture (within right or left atrium, right ventricle), or with a more indolent clinical course during childhood. In this last mode of presenta­tion, progressive dilation, distortion, and subsequent loss of cusp coaptation can lead to clinically significant aortic valvar insufficiency.

Rupture or fistulization almost always involves the right coronary sinus, while a minority of patients have involvement of the noncoronary (up to 30%) or left coro­nary (<2%) sinuses. Perhaps, in the largest reported surgical series (149 patients with SoV aneurysm), intracardiac rupture was seen at presentation in just <50% of cases. Aortic root rupture into a neighboring cardiac chamber is furthermore a rare event in the first two decades of life. If we extrapolate from data available in young patients with connective tissue disorders, this is not surprising. In a meta-analysis of 286 patients age <20 years with Marfan syndrome, Knirsh and coworkers reported aortic dissection in only five patients (1.7%) and rupture in three patients (1.0%). All but one patient (14 years old) were 19 years of age at the time of the acute event involving the aortic root. When intracardiac rupture of a SoV aneurysm occurs, a mean survival period of 39 years has been reported in untreated patients.

When symptomatic, patients may present with chest discomfort, palpi­tations, dyspnea on exertion, or florid congestive heart failure, with diastolic hypotension and pulmonary overcircu­lation from acute left-to-right shunting between aorta and right-sided chambers. Of patients with fistulization, >60% will be symptomatic at presentation. A precor­dial continuous murmur is usually heard. The clinical picture can be that of sepsis in the setting of endocarditis (up to 20% of patients). Dyspnea or even cyanosis can result from progressive right ventricular outflow tract obstruction by an enlarging SoV aneurysm that protrudes into the right ventricle. Atrioventricular conduc­tion abnormalities are present in 10% of patients.

The diagnosis is easily confirmed by transthoracic echocardiography, with cardiac catheterization reserved for patients with significant risk factors for coronary artery disease.

Surgical Indications and Technique

Indications for surgery in patients with uniform dilation of the aortic root are
A right superior pulmonary vein vent is inserted, and the heart is arrested with either antegrade or retrograde administration of cold blood cardioplegia solution; direct intracoronary delivery is used in case of ruptured aneurysm or significant aortic regurgitation, or with retrograde coronary perfusion. If the tip of the “windsock” is palpable through the right atrium, it can be compressed manually to prevent runoff of antegrade administered cardioplegia. We use continuous topical cooling as well as carbon dioxide flooding of the surgical field to minimize retention of air within the left-sided chambers.

A transverse aortotomy is carried out and the root anatomy is assessed. An oblique right atriotomy is performed next, allowing for the identification of both ends of the aneurysm or of the fistulous tract in case of rupture (Fig. 85.2). In case of protrusion or rupture into the right ventricle, exposure can be obtained through a right atriotomy or a limited ventriculotomy (Fig. 85.3). When the fistulous tract or diverticulum is in the right ventricular infundibulum, the lesion can also be exposed through a transverse pulmonary arteriotomy. The defect must be repaired through the aortic root, using a patch of autologous or bovine pericardium to exclude the aortic inlet into the aneurysm.

Primary closure predisposes to a higher risk of recurrence (as high as 20%) or aortic valve regurgitation from deformation of the root. In case of fistulization, the opening on the atrial or ventricular side should be addressed as well. The ventricular or atrial aspect of the fistula can be closed primarily, but a patch should be used to incorporate closure of a coexisting VSD (Fig. 85.3). Great care should be taken in avoiding the atrioventricular conduction system at the time of VSD closure.

In tri-sinus enlargement of the aortic root and a functionally normal aortic valve, we attempt aortic root replacement with valve preservation. The techniques involved in aortic valve-sparing root replacement are detailed elsewhere in this book and have been successfully applied to pediatric patients as well. Need for aortic valve replacement has been reported in 30% to 50% of patients with significant preoperative aortic valve regurgitation, but with reproducible aortic valve repair techniques such as leaflet free edge suspension and mid-leaflet plication to address prolapse, the need for valve replacement has decreased in more recent series.

Alternatives to valve preservation in case of diffuse enlargement and unreparable aortic regurgitation are valve replacement with mechanical, xenograft, or homograft prostheses. The Ross procedure (pulmonary valve autotransplantation) can be considered as a potential option in patients without stigmata of connective tissue disorders.

**Results**

In a large contemporary series, Au and coworkers reported long-term results on 53 patients operated for SoV aneurysms; there was no operative mortality, and overall survival was 83% at 15 years. Over a 32-year period, 22 patients underwent repair of single SoV aneurysm at the Johns Hopkins Hospital. Nineteen patients presented with intracardiac rupture; congestive heart failure was the most frequently presenting symptom. Operative survival was 95%, and 5- and 10-year survival was 84.9% and 59.4%, respectively. The lower long-term survival in our series reflected older age at presentation, more concomitant cardiac conditions, and more acquired rather than congenital etiologies, as are seen more frequently in the Western patient population. Factors such as bacterial endocarditis, aortic valve replacement, and concomitant VSD do not appear to adversely influence operative and long-term survival. However, the preoperative presence of a VSD or significant aortic insufficiency did affect the rate of late reintervention for aortic regurgitation. In particular, prolapse of the involved cusp with leaflet fibrosis and insufficiency appeared to jeopardize long-term viability of aortic valve repair. Need for late aortic valve replacement has been reported in 25% of patients at 10 years and was typically in patients with VSD on presentation and residual aortic regurgitation at the time of discharge. Need for late reintervention for
recurrent regurgitation, prosthetic valve dehiscence, endocarditis, and thrombosis all impacted survival negatively.

**AORTICO-LEFT VENTRICULAR TUNNEL**

**Morphology**

Aortico-LV tunnel (ALVT) is an exceedingly rare condition. It represents 0.001% of all congenital cardiac anomalies; less than 150 cases were reported in the world literature up to 2012.

In this developmental abnormality, an endothelialized paravalvular communication exists between aortic root (typically the right coronary sinus) and the LV, or very rarely leading to the right ventricle by means of a ventricular septal aneurysm. The lesion can often be appreciated as a bulging and pulsatile mass, visible externally between the aorta and the pulmonary artery. Although the trajectory of the tunnel has a variable course, the supravalvular inlet is usually located in the right coronary sinus above, below, or at the level of the right coronary ostium. The ventricular opening is readily visible on retraction of the aortic valve cusps and typically located below the right coronary leaflet. The paravalvular tract is directed inferiorly and leftward into the LV. The proximal opening is usually larger and can be slit-like or oval in appearance. The tunnel can be either aneurysmal or serpiginous and narrow. There are, therefore, two distinct portions of the tunnel: (1) aortic, located between aortic opening and interventricular septum and (2) intracardiac, located within the interventricular septum and extending to the LV opening. The intracardiac portion is within the septum that forms the posterior wall of the right ventricular outflow tract. The variable morphologic features of ALVT have been summarized as types I to IV of the Hovagimian classification (Fig. 85.4).

The aortic valve is usually competent or mildly regurgitant. Coronary anomalies can be seen in 30% of patients; relatively simple cardiac defects (VSD, bicommissural aortic valve, aortic stenosis among others) are observed in up to 45% of cases.
Chapter 85: Anomalies of the Sinuses of Valsalva and Aortico-Left Ventricular Tunnel

Clinical Presentation and Diagnosis

The severity of symptoms clearly depends on the size of the aortico-LV communication and the consequent regurgitant volume. The lesion should be suspected in any neonate or infant with systolic-diastolic murmurs and congestive heart failure. Differential diagnosis includes patent arterial duct, aortopulmonary window, absent pulmonary valve syndrome, congenital coronary artery fistula, and, in older children, ruptured SoV aneurysm. Tachypnea, poor weight gain, cardiomegaly, and widened pulse pressure with bounding peripheral pulses are other typical signs and symptoms of ALVT. Rarely, cyanosis can be present, secondary to progressive right ventricular outflow tract obstruction from septal bulging beneath the pulmonary valve.

Chest X-ray typically reveals cardiomegaly, plethoric lung fields, and a tortuous ascending aorta. Transthoracic echocardiography is the diagnostic modality of choice, demonstrating the typical septal “drop-out” under the right coronary sinus. LV hypertrophy, left-axis deviation, and repolarization abnormalities are usually seen on electrocardiography. Rarely, cardiac ischemia from diastolic runoff into the fistulous tract can be present. Occasionally, it may be difficult to differentiate between aortic and paravalvar regurgitation. In such cases, aortic root angiography (with or without simultaneous occlusion of the ALVT) readily establishes the diagnosis. Magnetic resonance imaging has also been used as an alternative to angiography to define morphology.

Surgical Indications and Technique

Given the often impressive symptoms at the time of presentation and the risk of progressive aortic valve insufficiency in patients with lesser degrees of clinical acuity, operative intervention is indicated at the time of diagnosis, even in asymptomatic patients. The goal of preventing aortic valve regurgitation from progressive root distortion and secondary valvular changes is particularly relevant in small patients, in whom the alternatives to aortic valve repair are largely unsatisfactory. In case of very small ALVT diagnosed in asymptomatic patients, careful medical management and expectant follow-up can nevertheless be considered because spontaneous closure of small communications has been reported.

Intraoperatively, transesophageal echocardiography is used to assess competence of the valve and adequacy of repair after cardiopulmonary bypass.

In the absence of a septal communication, bypass is established using a single right atrial cannula and the distal ascending aorta. The left atrium is vented through the right superior pulmonary vein and systemic cooling to moderate hypothermia (24 to 28°C) is started. Because of the paravalvar regurgitation, it is important to avoid LV distension once the heart fibrillates. The aorta is, therefore, immediately cross-clamped.
and an aortotomy is performed above the sinotubular junction. Blood cardioplegia (30 cm³/kg in pediatric patients) is then infused directly into the coronary ostia and redosed at 30-minute intervals. Alternatively, retrograde cardioplegic delivery can be used as alternative myocardial protection strategy.

As in SoV aneurysm with fistula, the defect should be approached from both the aortic root and LV, and both the inlet and outlet of the ALVT closed. This is critically important since isolated inlet closure has been associated with ALVT recurrence. Concerns have been raised about the technique of closure of the ALVT inlet, as direct closure may result in distortion of the aortic valve. We favor patch closure with Gore-Tex, bovine pericardium, or autologous pericardium in infants and small children (Fig. 85.5). The ventricular outlet of the tunnel can be exposed either through the retracted leaflets of the aortic valve or directly through the tunnel, approached from the external surface between the aorta and the pulmonary root (Fig. 85.6).

---

**Fig. 85.5.** (A) Aortico-left ventricular tunnel, as typically observed arising in the right sinus of Valsalva. (B and C) Through an aortotomy, the inlet orifice to the tunnel is closed with an autologous pericardial patch. The ventricular opening of the tunnel is closed through the aorta separately, either primarily or with a second patch. LV, left ventricle; PA, pulmonary artery.

---

**Fig. 85.6.** Alternative surgical approach to repair aortico-left ventricular (Ao-LV) tunnel. Inlet and outlet orifices are exposed through the tunnel (left). Patch closure of both aortic and ventricular openings is accomplished, followed by closure of the tunnel between aorta and pulmonary artery (right). (Reprinted with permission from J Stark. Congenital Anomalies of the Sinuses of Valsalva and Aortico-Ventricular Tunnel. In Stark J, deLeval M (eds), Surgery for Congenital Heart Defects, 3rd ed. Wiley, 2006:607.)
Results

Reported operative mortality ranges between 0% and 16%. Reported complications include heart block and aortic valve regurgitation.

The major postoperative concern is the need for late reintervention. Up to 50% of patients may require late aortic valve replacement because of progressive valvar deformity (likely the result of postrepair turbulence) or aneurysmal dilation of the aortic root secondary to poor support of the right aortic cusp. Significant early or late aortic insufficiency is seen more frequently in children undergoing repair at an older age.

ALVT recurrence is rare, especially if closure is performed at both ends. If a residual small ALVT is observed, consideration may be given to coil embolization, but proximity to the aortic valve and right coronary artery orifice must be weighed carefully.

SUGGESTED READINGS

Aneurysms of the sinus of Valsalva are often identified after rupture occurs. As noted by the authors, most sinus of Valsalva aneurysms rupture into the low-pressure right atrial or right ventricular chamber. Left coronary sinus of Valsalva aneurysms, however, can rupture into the left atrium, although even in this location rupture into the right atrium or ventricle is more common. VSD is associated with approximately one-third of sinus of Valsalva aneurysms and therefore should be carefully looked for in these patients. Although fistulous communications between the sinuses of Valsalva and cardiac chambers can be approached with a catheter technique and occluder devices, surgery remains the procedure of choice because of the direct approach to each end of the fistula and the ability to either primarily close or patch these defects without significant prosthetic material. One of the more current causes of ruptured sinus of Valsalva into the atrium is related to the use of atrial septal defect occluder devices, which, when excessively large, can erode into the base of the aortic wall and aortic sinus, resulting in an aortic to atrial fistula. Complete removal of the device and surgical closure of the aneurysm would seem to be the most appropriate treatment for these complications of device intervention. The very low mortality and mortality of operative intervention should continue to lend favor to this approach.

A particular controversy is the patient with an asymptomatic sinus of Valsalva aneurysm identified on echocardiographic screening for other congenital conditions. In the presence of an isolated aneurysm of a single sinus of Valsalva, the indications for operation are unclear. One could argue that resection of the abnormal tissue in the sinus and replacement with homograft or other material may permit a better remodeling of the sinus and prevent late development of aortic insufficiency, but this is not clearly been demonstrated. In most cases, expectant observation of the aneurysm with operation if significant size increases are identified seems to be a preferred approach. In patients who have developed a rupture of the sinus of Valsalva aneurysm, even asymptomatic, operative intervention is recommended.

Aortico-left ventricular tunnel is an extremely rare defect; however, it is important to emphasize that when this defect is approached, both the aortic and ventricular ends of the tunnel should be closed. Simple closure of the aortic end of the defect can result in a chamber developing in the septum from systolic inflow, and the pulsatility in this chamber can create an aneurysm of the ventricular septum, which can distort the aortic valve annulus and cause progressive aortic insufficiency.

The embryologic abnormality of aortico-left ventricular tunnel bypasses the aortic valve and may affect aortic valve development. In some cases, these patients may have fusion of the commissures of the aortic valve leaflets and relative hypoplasia of the aortic valve annulus. In addition, the tunnel as it channels through the ventricular septum can affect flow into the pulmonary arteries and can also affect pulmonary valve development. Therefore, it is imperative to examine the valves carefully in these patients. In some cases, an aortic valvotomy may be necessary or more extensive procedure such as aortic valve replacement with a Ross operation may be a preferred approach. The extreme rarity of this condition leads to a wide variety of clinical presentations and anatomy.

The optimal technique for dealing with sinus dilation in patients with Marfan syndrome or other degenerative connective tissue diseases of the aortic root remains controversial. As discussed in this chapter, the dilated sinuses of Valsalva can be addressed by graft replacement down to the level of the aortic annulus with preservation of the commissural attachments of the aortic valve and a portion of aortic wall as in the Yacoub operation, or the valve can be resuspended inside a tubular Dacron graft as in the David operation. The excellent results with the David valve-sparing root replacement for connective tissue abnormalities has made it the preferred approach in most centers for patients with dilation of the aortic root. The valve leaflets are also abnormal in these conditions, and progressive aortic insufficiency may occur even with valve-sparing procedures, as in the David operation. Thus, if there is any concern about significant aortic valve disease or aortic insufficiency, complete replacement of the aortic root with a homograft or prosthetic valve and conduit may be the best approach. With these techniques, the operative results have been excellent in the authors’ series from Johns Hopkins University, and despite the frequent need for reoperation on other portions of the aorta or the mitral valve in these patients, late morbidity from valve replacement has been low.
Atrioventricular Canal Defects
Jeffrey P. Jacobs and Martin J. Elliott

ANATOMY

Atrioventricular (AV) canal defects have also been called endocardial cushion defects and AV septal defects (AVSDs). These defects are characterized by varying degrees of incomplete development of the septal tissue surrounding the AV valves along with varying degrees of abnormalities of the AV valves themselves. Consequently, AVSD may include defects in the inferior portion of the atrial septum, defects in the inflow portion of the ventricular septum, and defects in the tissue forming the left and right AV valves. We prefer the term AVSD because the anomaly is primarily caused by the deficiency of normal AV septal structures.

AVSDs represent a spectrum of cardiac anomalies subdivided into partial AVSDs, intermediate AVSDs, and complete AVSDs. Partial AVSDs (also known as incomplete AVSDs) have a crescent-shaped atrial septal defect (ASD) in the inferior portion of the atrial septum just above the AV valve. This defect may also be referred to as an ostium primum defect. The partial AVSDs also have varying degrees of malformation of the left AV valve, leading to varying degrees of left AV valve regurgitation. Complete AVSDs have both defects in the atrial septum just above the AV valves and defects in the ventricular septum just below the AV valves. In complete AVSD, the AV valve is the one valve that bridges both the right and left sides of the heart, creating superior and inferior bridging leaflets. Partial AVSDs and complete AVSDs represent a spectrum of cardiac pathologic conditions. An intermediate form in the middle of this spectrum has been described and termed intermediate AVSD (also known as transitional AVSD). This form of AVSD not only has two distinct left and right AV valve orifices but also has both an ASD just above and a ventricular septal defect (VSD) just below the AV valves. The VSD in this intermediate form of AVSD is often restrictive. Although these AV valves in the intermediate form do form two separate orifices, they remain as abnormal valves. Table 86.1 provides definitions for AV canal defects provided by the International Society for Nomenclature of Paediatric and Congenital Heart Disease (www.ipcc.net).

The AV valve apparatus in AVSD has been described as having either five or six leaflets. In partial AVSD (Fig. 86.1A), the AV valve apparatus is easily understood as having six leaflets. On the left side, the leaflets have been termed left superior, left lateral, and left inferior. On the right side, the leaflets have similarly been termed right superior, right lateral, and right inferior. In partial AVSD, both the right superior and inferior leaflets fuse with the ventricular septum to complete the structure of the right AV valve. The left superior and inferior leaflets similarly fuse with the septum to form the left AV valve. The commissure between the left superior and inferior leaflets represents the “cleft” of the left AV valve, which is found in partial AVSD. This cleft is equivalent to the line of abutment (or zone of apposition) of the superior bridging leaflet and the inferior bridging leaflet in complete AVSD.

In complete AVSD (Fig. 86.1B and 86.1C), it is more difficult to conceive of the common AV valve as a six-leaflet valve. A five-leaflet model is more realistic for complete AVSD. A superior bridging leaflet and an inferior bridging leaflet are always present. These bridging leaflets have variable morphology in both the amount of leaflet that crosses over the ventricular septum and the degree of chordal attachment to the ventricular septum. Furthermore, scalloping of the bridging leaflets may create the illusion of extra leaflets. In addition to the superior and inferior bridging leaflets, the five-leaflet model is completed by a left lateral leaflet, a right lateral leaflet, and a right anterosuperior leaflet.

The degree of bridging and chordal attachment by the superior bridging leaflet forms the basis for the Rastelli classification of complete AVSD originally described in 1966. The Rastelli classification does not relate to the anatomy of the inferior bridging leaflet but rather to the anatomy of the superior bridging leaflet and the inferior bridging leaflet. In a Rastelli type A defect (Fig. 86.1B), the superior bridging leaflet is effectively limited to the left ventricle, with its right margin being attached to the ventricular crest. The anterosuperior leaflet of the right AV valve is also attached to the ventricular septal crest, giving the appearance that the superior bridging leaflet is split at the ventriculoventricular septum. In many cases, chordal attachments pull the plane of the AV valve down into the VSD below the plane of the annulus. In Rastelli type C defects (Fig. 86.1C), there is a marked bridging of the ventricular septum by the superior bridging leaflet. The superior bridging leaflet floats freely over the ventricular septum without chordal attachment to the crest of the ventricular septum. Rastelli type B is somewhere between types A and C and is very rare in our experience; Rastelli type B involves anomalous papillary muscle attachment from the right side of the ventricular septum to the left side of the common superior (anterior) bridging leaflet.

The other important anatomic consideration when planning the repair of an AVSD is the location of the conduction system because it is very vulnerable during surgical repair (Fig. 86.2). The AV node is displaced posteriorly and inferiorly toward the coronary sinus. The AV conduction axis then runs from this node toward the ventricle through the crest of the ventricular septum. Here, the posteriorly displaced bundle of His is usually covered by the inferior bridging leaflet of the AV valve. Thus, the AV node lies in the tissue between the coronary sinus and the margin of the VSD, if present. The location of the AV node is altered in AVSD because the ostium primum ASD often pushes the coronary sinus posteriorly and inferiorly toward the left atrium. This distorts the triangle of
Koch and creates a second triangle called the nodal triangle. The nodal triangle is bounded by the coronary sinus, the posterior attachment of the inferior bridging leaflet, and the leading edge of the atrial septum at the septal defect. The ASD pushes the AV node and the corresponding conduction tissues posteriorly and inferiorly along with the coronary sinus. The AV node, therefore, lies at the apex of the nodal triangle in a more posterior and inferior location. The bundle then travels down on the crest of the ventricular septum under the inferior bridging leaflet on the rim of the VSD.

**DIAGNOSIS**

Patients with AVSD present in a variety of clinical conditions depending on the size of the septal defects, the direction and magnitude of the associated shunt, and the associated lesions. Patients with partial AVSD may have an asymptomatic cardiac murmur similar to those with secundum ASDs. However, when left AV valve insufficiency is more pronounced, patients may have symptoms of pulmonary congestion, cardiac failure, and dyspnea. Patients with complete AVSD are more likely to have prominent left-to-right shunting and are similarly more likely to have symptoms of congestive heart failure, fatigue, and dyspnea. Complete AVSD presents with a more
malignant course than partial AVSD. With the complete defect, severe cardiac failure is often present in infancy, and severe pulmonary hypertension will eventually develop, resulting in the death of up to 65% of infants before 1 year of age without surgical intervention. More than 50% of the patients with complete AVSD also have Down syndrome.

Physical examination often reveals a variety of cardiac murmurs. A systolic ejection murmur may be found in the pulmonary area because of increased flow across the pulmonary valve. A holosystolic apical murmur is also present when left AV valve regurgitation is significant. The ASD and VSD may also have associated cardiac murmurs.

A chest radiograph often reveals enlargement of the pulmonary artery. The film may also show right ventricular hypertrophy as symptoms of failure progress and left ventricular enlargement with significant left AV valve regurgitation. An electrocardiogram often reveals right ventricular hypertrophy and sometimes left ventricular hypertrophy as well. A vector cardiogram usually shows a counterclockwise frontal plain loop.

Echocardiography is the modality of choice for establishing a definitive diagnosis in the current era. Two-dimensional echocardiography, along with color Doppler studies, usually provides complete preoperative information for both partial AVSD and complete AVSD. Three-dimensional echocardiography is undergoing assessment in a number of centers and may ultimately help in the surgeon’s understanding of AV valve morphology and in the planning of surgery. Three-dimensional echocardiography may be especially useful when reoperating for mitral regurgitation on a patient with a previously repaired AVSD because it can help define the etiology of the regurgitation.

Cardiac catheterization is required only when clinical evidence of pulmonary vascular disease exists, making operability questionable, or when additional major cardiac anomalies coexist. A left
ventriculogram in the anteroposterior projection shows a typical "goose-neck" deformity caused by the long, narrow left ventricular outflow tract, the lower boundary of which is made up of the superior bridging leaflet. Cardiac catheterization can also be used to measure pressures, flows, and resistances in the pulmonary and systemic circuits as well as the direction and the magnitude of shunting.

**INDICATIONS**

The natural history of untreated AVSD depends on the morphology of the lesion and dictates the indications and timing of surgical intervention. Partial AVSD without significant left AV valve regurgitation has a natural history similar to that of secundum ASD. Up to 15% of patients may develop high pulmonary arteriolar resistance in their adult life. The development of symptoms in adulthood often relates to the onset of atrial fibrillation. The natural history of partial AVSD with significant left AV valve regurgitation is much worse. These patients present earlier in life, and without surgical treatment, many may die in the first decade of life. Infants with complete AVSD have an even more malignant presentation, and without surgical correction, the majority die within the first year of life.

Patients with asymptomatic partial AVSD should be treated similarly to patients with secundum ASD. Elective repair is indicated before school age unless the patient develops symptoms of heart failure or failure to thrive. A minority of patients with partial AVSD and severe left AV valve regurgitation present with severe symptomatology in the first year of life and thus require earlier surgical intervention. Those few infants with severe left AV valve regurgitation who are asymptomatic should also undergo earlier surgical intervention.

Infants with complete AVSD should undergo elective correction between 3 and 6 months of life. In the past, the management of infants with complete AVSD and trisomy 21 has been somewhat controversial and has depended on the philosophy of the individual cardiologist, the cardiac surgeon, and the family. In our view, however, they should be treated exactly as those without trisomy 21. The surgical procedure of choice for both partial AVSD and complete AVSD is complete repair of the lesion as will be described. Pulmonary artery banding to palliate symptoms of congestive heart failure plays no role in the management of these lesions except in patients with complex associated cardiac anomalies or those with severely unbalanced hearts or functionally univentricular physiology with pulmonary overcirculation. Severe pulmonary infection may also be a relative indication for pulmonary artery banding.

Contraindications to surgery are based on fixed severe elevation of pulmonary vascular resistance. Pulmonary vascular resistance of >10 units/m² of body surface area (or a pulmonary-to-systemic resistance ratio of >0.7) represents a contraindication to repair. Elevated pulmonary vascular resistance of <10 units/m² (or a pulmonary-to-systemic resistance ratio of <0.7) represents an indication for more urgent surgical intervention. The assessment of elevated pulmonary vascular resistance should include cardiac catheterization under conditions of oxygen, nitric oxide, and prostacyclin to assess reversibility.

**SURGICAL TECHNIQUE**

After routine anesthesia, preparation, and draping, a standard median sternotomy is performed followed by a thymectomy. An eccentric pericardiotomy to the left is then performed, leaving a large piece of pericardium attached to the right for later use as a patch. (Note: All operative drawings in this and subsequent figures are viewed from the surgeon's perspective.) The aorta, ductus arteriosus, and superior vena cava (SVC) are then mobilized. Identification of the ductus is best achieved by first finding the "axilla" between the right pulmonary artery and the ductus, and then finding the "axilla" between the left pulmonary artery and the ductus using traction on the main pulmonary artery. Once the right and left pulmonary arteries have been formally identified, anything remaining inbetween must be the ductus. A silk ligature is passed around the ductus but is not yet tied, with care being taken to avoid injuring the ductus.

The lateral aspect of the SVC should be mobilized with scissors to avoid diathermy damage to the right phrenic nerve. Purse strings of 5-0 polypropylene are then placed into the aorta and the right atrial appendage. An additional, longitudinally oriented, narrow, rectangular purse string is placed on the SVC about 0.5 to 1.0 cm above the junction with the right atrium (Fig. 86.4). The aorta is then cannulated. We prefer the DLP (Medtronic, Grand Rapids, MI) aortic cannula because of its flexibility. Next, the inferior vena cava (IVC) angled metal Pacifico venous cannula (DLP) is placed temporarily into the right atrial appendage. Cardiopulmonary bypass is then established (Fig. 86.5), and the ductus arteriosus is ligated with the previously placed silk ligature. Once cardiopulmonary bypass is established, the patient is cooled. Some surgeons will cool to 24 or 25°C. Other surgeons do these cases at warmer temperatures such as 32°C. With warmer...

Aorta
SVC

Fig. 86.4. Purse strings are demonstrated in the aorta, the right atrial appendage, and the superior vena cava (SVC). Note the position of the longitudinally oriented, narrow, rectangular purse string on the SVC about 0.5 to 1.0 cm above the junction with the right atrium (RA). RAA, right atrial appendage; RV, right ventricle; SVC, superior vena cava.

In order to cannulate the SVC, the temperature of the patient is maintained at 32°C. The SVC is then grasped with two mosquito hemostats on each side of the previously placed purse string. The SVC is incised longitudinally with a scalpel, and the SVC is then cannulated with the second angled metal cannula (Fig. 86.6).

temperatures, the hematocrit is kept higher while on cardiopulmonary bypass.

The SVC is then grasped with two mosquito hemostats on each side of the previously placed purse string. The SVC is incised longitudinally with a scalpel, and the SVC is then cannulated with the second angled metal cannula (Fig. 86.6).

A vent is then inserted into the right atrial appendage after the IVC cannula is removed (Fig. 86.7). The pericardial reflection anterior to the IVC is then released, and the sub-diaphragmatic IVC is exposed down to the level of the first hepatic vein. A purse string (5-0 polypropylene) is then placed directly into the IVC below the pericardial reflection (Fig. 86.8), and the IVC is cannulated with the IVC angled metal cannula. Caval tapes are passed around the IVC and the SVC; nylon caval tapes may be used or silk suture may be used as caval tapes.

The aorta is cross-clamped, the two vena cavae are snared, the right atrium is opened parallel to the AV groove, and cardioplegic solution is instilled into the aortic root (Fig. 86.9).

A right-angled instrument is then passed through the opening of the right atrium into the left atrium and up into the right superior pulmonary vein. A No. 11 scalpel blade is then used to open the junction of the right superior pulmonary vein and the right atrium between the tips of the right-angled instrument (Fig. 86.10). The vent is then passed into the left atrium and secured into position with a 6-0 polypropylene purse-string suture.

Stay sutures are then applied to the atrial wall, and the anatomy of the AV valve is inspected (Fig. 86.11). Stay sutures of 6-0 polypropylene on an 8-mm needle are then applied to approximate the “kissing points” of the bridging leaflets (Fig. 86.12). The kissing points may be defined as the points of the superior bridging leaflet and the inferior bridging leaflet that (1) intuitively come together at the center of the superior bridging leaflet and the inferior bridging leaflets, (2) usually overlie the interventricular septum, and (3) can be identified as the midpoint between the left and right chordae on each bridging leaflet.

The Two-Patch Technique

We will first describe the following operative technique: AV/C (AVSD) repair, Complete (CAVSD), Two-patch technique. Unwanted secondary chordae (which may limit exposure and whose function will partially be replaced by the new interventricular patch) can be divided. This permits elevation of a tethered bridging leaflet from the ventricular crest up to the plane of the annulus.

The size required for the VSD patch is then measured using black silk ligatures. Two pieces of black silk are trimmed. One silk measures the length of the patch by measuring the distance from the superior to the inferior margin of the annulus of the common AV valve in the plane of
Chapter 86: Atrioventricular Canal Defects

Fig. 86.6. The superior vena cava is grasped with two mosquito hemostats on each side of the previously placed purse string. The superior vena cava is incised longitudinally with a scalpel.

Fig. 86.7. The superior vena cava is cannulated with a second angled metal cannula. A vent is then inserted into the right atrial appendage after the inferior vena cava cannula is removed.

the interventricular septum (Fig. 86.13A). Inferiorly, extra length must be allowed to permit the patch to extend beyond the predicted position of the bundle. The second silk measures the depth of the patch by measuring the distance from the plane of the annulus of the freed common AV valve to the crest of the interventricular septum beyond the base of the VSD (Fig. 86.13B). The importance of this depth measurement is that it dictates the degree of elevation of the revised AV valve apparatus up to the plane of the annulus. However, the following operative technique that will be described later in this chapter supports the fact that the AV valve apparatus can be safely brought down to the crest of the interventricular septum at the base of the VSD: AVC (AVSD) repair, Complete (CAVSD), VSD closed primarily (directly), and ASD closed with patch (Nunn/Wilson).

A patch of 0.4-mm polytetrafluoroethylene (Gore-Tex) is then trimmed to size using the previously cut silk sutures as guides (Fig. 86.13C). Alternatively, a patch of Dacron may be used. This patch is then sutured into position with a 5-0 polypropylene continuous suture. We start this suture inferiorly with the suture being brought through the right AV valve close to the annulus, well away from (inferior to) the position of the bundle (Fig. 86.14). It is easiest to place this first suture by going through the inferior bridging leaflet on the right side of the interventricular septum, passing the needle behind the right-sided chordae to the inferior bridging leaflet, and then passing the needle through the corner of the crescentic Gore-Tex patch. The needle is then taken back behind the chordae before positioning the suture deep into the muscle of the septum well away from the position of the bundle but close to the annulus. This will fix the patch in good position before commencing the running suture. This first suture is facilitated by retracting the inferior bridging leaflet inferiorly using a nerve root retractor. The running suture line is then brought superiorly along the right side of the septum, weaving behind the chordae as required. The conduction system is avoided inferiorly, and the aortic valve leaflets are carefully visualized and avoided superiorly. The 5-0 polypropylene suture is brought through the superior bridging leaflet at the annular margin and is placed on a rubber-shod clamp once the superior margin is reached (Fig. 86.15).

It is now necessary to septate the valve into a left and a right component, simultaneously preparing the atrial component of the patch. Interrupted horizontal mattress sutures of 6-0 polypropylene double-armed with 8-mm needles are then placed along the crest of the interventricular patch, with the surgeon bringing them out through the superior bridging leaflet and the inferior bridging leaflet, respectively, and then through a patch of autologous pericardium, not yet detached from the right side of the pericardium (Fig. 86.16). These
sutures should start inferiorly, beginning by retracting the inferior bridging leaflet once again with a nerve root retractor. The first of these sutures is placed through the VSD patch close to the inferior VSD running suture. The needle is then passed through the inferior bridging leaflet next to the inferior VSD running suture and, finally, is passed through the attached pericardial patch. The second arm of this first 6-0 polypropylene double-armed suture should then be placed a little bit farther along the crest of the Gore-Tex patch, with the surgeon bringing it in turn through the inferior bridging leaflet in a line between the inferior arm of the VSD running suture and the kissing-point stay suture. This line is important because it will represent the line of demarcation between the left and right AV valves (Fig. 86.15). The second arm of this first 6-0 polypropylene double-armed suture is then also passed through the attached pericardial patch and held in a rubber-shod clamp. The remaining interrupted horizontal mattress sutures of double-armed 6-0 polypropylene are then placed along the crest of the interven- tricular patch, with the surgeon bringing them out through the inferior and superio r bridging leaflets, respectively, and then through the pericardial patch. We have found it to be a major advantage to keep the pericardium attached because this makes it easier to understand the relationships between the two AV valves and the atrial patch. The horizontal mattress sutures are then tied, and this brings the pericardium down to the ridge of the valve complex (Fig. 86.17). The pericardial patch is detached (Fig. 86.18A) and then swung anteriorly (Fig. 86.18B).

**Attaining Left Atrioventricular Valve Competence**

1. The first important element in left AV valve repair is the size of the VSD patch. In prior publications, we stated: “Too big a patch and the valve will not coapt, too small a patch and the valve will become stenotic at annular level.” However, the Nunn/Wilson’s modified one-patch technique has shown us that too small a patch should not be problematic because the repair can be accomplished successfully with no VSD patch at all, as will be described below.

2. The cleft in the left-sided AV valve (or zone of abutment [or zone of apposition] between the left superior bridging leaflet and the left inferior bridging leaflet) is an unsupported commissure that needs to be closed to create a neo-septal leaflet akin to the aortic leaflet of a normal mitral valve. This closure of the “cleft” (or zone of apposition between the left superior bridging leaflet and the left inferior bridging leaflet) may be achieved using one or two horizontal mattress sutures of 6-0 polypropylene reinforced

---

**Fig. 86.8.** The pericardial reflection anterior to the inferior vena cava is released and the sub-diaphragmatic inferior vena cava is exposed. A purse string (5-0 polypropylene) is then placed directly into the IVC below the pericardial reflection. The length of the IVC is exaggerated for clarity.

**Fig. 86.9.** The inferior vena cava is cannulated with the inferior vena cava angled metal cannula. Nylon caval tapes are passed around the inferior vena cava and the superior vena cava. The patient is cooled to 25°C. The aorta is cross-clamped, the two venae cavae snared, the right atrium opened parallel to the atrioventricular groove, and cardioplegic solution instilled into the aortic root.
Chapter 86: Atrioventricular Canal Defects

Fig. 86.10. A right-angled instrument is passed through the opening of the right atrium into the left atrium and up into the right superior pulmonary vein. A No. 11 scalpel blade then opens the junction of the right superior pulmonary vein and the left atrium between the tips of the right-angled instrument. The vent can then be passed into the left atrium and secured into position with a 6-0 polypropylene purse-string suture.

Fig. 86.11. Stay sutures are used to hold the atrial wall open to inspect the anatomy of the atrioventricular valve. The suction tip is useful as a retractor to examine the anatomy of the atrioventricular septal defect.

with autologous pericardial pledgets (Fig. 86.19). Alternatively, this closure of the “cleft” may be done with multiple non-pledged sutures of 6-0 polypropylene. The valve is then tested for competence by suspending the leaflets with saline (Fig. 86.20). All tension is released from all stay sutures. The autologous pericardial patch is held gently forward, and a 50-ml syringe is used to inject ice-cold saline via a size 10 nasogastric tube through the left AV valve. (Richard Jonas has described floating the valve with cold blood cardioplegia.) The valve should float up nicely and demonstrate no regurgitation (Fig. 86.21). If necessary, an additional 6-0 polypropylene suture (possibly reinforced with autologous pericardial pledgets) is placed in the cleft near the central orifice.

3. If the valve continues to leak, the problem should not be ignored. First, the location of the leak is identified: central orifice, separate orifice, or a gap between scalloped components of the bridging leaflets. If a central leak exists and the cleft is already reapproximated to the chordae, an annuloplasty, such as DeVega annuloplasty, may be performed at whatever commissures are visible. If the valve is leaking at the cleft, an annuloplasty will not help. The leaflets and the cleft must be dealt with first. Annuloplasty is supportive and cannot result in primary competence in this morphology.

4. Paradoxically, it may be better in certain circumstances not to close the cleft and to leave the superior bridging leaflet and the inferior bridging leaflet unapproximated. This is the case when the mural leaflet is tiny or absent as in the parachute arrangement of left AV valve support apparatus. There is always a balance between stenosis and regurgitation in these circumstances, and it is important to size the left AV valve using Hegar dilators to ensure good baseline information for future follow-up, and occasionally to guide the removal of an overtight stitch in the cleft, resulting in a degree of “acceptable” regurgitation.

The ASD patch is then sutured in place with continuous 5-0 polypropylene suture. The coronary sinus may be left on the left or right atrial side. If there is a large ASD or an additional secundum ASD, we often keep the coronary sinus on the left side of the heart (Fig. 86.22). It is essential to place the coronary sinus on the right side when there is a left-sided SVC. We also try to keep the coronary sinus on the right when we are concerned
Fig. 86.12. Stay sutures of 6-0 polypropylene on an 8-mm needle are then applied to approximate the “kissing points” of the bridging leaflets.

about possible postoperative left AV valve dysfunction because a high left atrial pressure may result in high coronary sinus pressure.

During closure of the ASD, care is taken to ensure that the IVC remains on the right side and that the conduction system is carefully avoided. The first stitch of the continuous 5-0 polypropylene suture used to secure the atrial pericardial patch is placed on the inferior aspect of the ASD next to the previously placed VSD running suture currently held in a rubber-shod clamp. This first stitch is placed in the same way whether the coronary sinus will be placed on the left or the right, and this stitch is used to secure the VSD suture. (Alternatively, the VSD suture can be used to suture the ASD patch into place.) If the coronary sinus is to go on the left, this continuous polypropylene suture is then used to stitch the pericardial ASD patch along the atrial wall well inferior to the bundle and out around the coronary sinus, avoiding the Eustachian valve and keeping the IVC on the right. If the coronary sinus is to go on
the right, this continuous 5-0 polypropylene suture is then used to stitch the pericardial ASD patch along the left AV valve itself at its annular margin and then onto the septum beyond the bundle. The continuous 5-0 polypropylene suture may be interrupted at the top of the ASD patch to prevent this patch from becoming constrictive. The ASD pericardial patch is trimmed as the suture line progresses and often ends up smaller than originally anticipated.

Cardioplegic solution is administered every 15 to 25 minutes throughout the cross-clamp period. After the atrial patch is sewn into position (Fig. 86.23) and all communications between the right heart and the left heart are definitely closed, the aortic cross-clamp is removed and the heart is deaired through the aortic root and the right superior pulmonary vein. The right atrium is then closed with a double layer of running 6-0 polypropylene suture on a 13-mm needle with the cross-clamp off during rewarming. Once the child is warm, ventilation is begun, deairing is completed, and the vent is removed. A left atrial pressure monitoring line may be inserted via the right superior pulmonary vein or via the left atrial appendage. The child is then weaned from cardiopulmonary bypass and modified ultrafiltration is carried out. We always use intraoperative echocardiographic assessment to define the functional status of the repair. We will redo any part of the procedure as indicated by the echocardiographic study. Protamine is then administered. Atrial and ventricular pacing wires are placed and chest drains are placed.

If the left AV valve is potentially regurgitant or dysfunctional or if any other reason exists to increase the likelihood of a redo sternotomy, a 0.1-mm-thick, low-porosity, expanded polytetrafluoroethylene pericardial membrane (Preclude Pericardial Membrane, formerly called the Gore-Tex Surgical Membrane; W. L. Gore and Associates, Flagstaff, AZ) is placed. Routine closure then follows.

**An Alternative Operative Strategy:**

**Ventricular Septal Defect Closed Primarily (Directly) and Atrial Septal Defect Closed with Patch (Nunn/Wilson)**

The modified one-patch technique involves primarily closing the VSD and then using a patch to close the ASD. Cannulation, cardiopulmonary bypass, and administration of cardioplegia are the same as in the two-patch technique. Using 6-0 polypropylene double-armed suture, multiple pledgeted horizontal mattress sutures are placed from the right side of the ventricular septum just apical to the crest of the VSD, with the surgeon bringing them out through the inferior and superior bridging leaflets, respectively, and then through the pericardial patch that will close the ASD. Again, it is advantageous to keep the pericardium attached on the right side because this makes it easier to understand the relationships between the two AV valves and the atrial patch. The horizontal mattress sutures are then tied, and this closes the VSD and brings the pericardium down to the ridge of the valve complex. The pericardial patch is detached and then swung anteriorly. The “cleft” of the left AV valve is then closed as described in the two-patch technique, and the ASD is also closed as in the two-patch technique. Backer and colleagues reported that “The modified single-patch technique produced results comparable with the two-patch technique in younger patients with similarly sized VSDs. Furthermore, the modified single-patch technique was performed with significantly shorter cross-clamp and cardiopulmonary bypass times.”
Fig. 86.16. Interrupted horizontal mattress sutures of 6-0 polypropylene double-armed with 8-mm needles are placed along the crest of the interventricular patch, with the surgeon bringing them out through the superior and inferior bridging leaflets, respectively, and then through a patch of autologous pericardium not yet detached from the right side of the pericardium. The chordae are omitted for clarity.

MANAGEMENT OF UNUSUAL VARIANTS OF COMPLETE ATRIOVENTRICULAR SEPTAL DEFECTS

Atrioventricular Septal Defect with Tetralogy of Fallot

In tetralogy of Fallot with AV canal, the common AV junction occurs in the setting of deviation of the outlet septum, producing varying degrees of aortic override. Right ventricular outlet obstruction will be present at variable levels and will have to be dealt with surgically.

The deviation of the outlet septum has consequences for the morphology of the leaflets of the AV junction and the shape of the ventricular septal crest.

In tetralogy of Fallot with AV canal, the superior bridging leaflet is always free-floating, enabling the left ventricle to access the deviated aorta. Consequently, this combination of defects does not occur in the setting of partial AVSD.

Given that such patients have a protected pulmonary vascular bed, operation is still often deferred to 2 to 3 years of age. Although the valve is larger in these older patients, valvar function and dysplasia may be paradoxically worse in the setting of chronic regurgitation with thickened dysplastic leaflets. A competent repair may, therefore, be more challenging and crucial, especially of the right AV valve, the competence of which is vital for good right ventricular function postoperatively. Right AV valve annuloplasty and/or commissuroplasty are commonly employed as a further, supportive measure for the right AV valve.

The ventricular septal patch must be tear shaped rather than elliptical, taking account of the deviated outlet septum (Fig. 86.24). The aortic margin of the patch may be difficult to access through the right atrium but can be approached through the right ventricular outflow tract that may be opened at the time of access the pulmonary valve and infundibulum.

Unbalanced Atrioventricular Septal Defect

Unbalanced AVSD is difficult to define. It could be said that there is ventricular imbalance when the ventricular cavities are of unequal size or when the common AV junction is committed preferentially to one ventricle over the other. These two problems often coexist. Not only may the overall ventricular cavity be small, but it may also lack one segment of the normal tripartite ventricular morphology, such as the apical trabecular segment.

Severe imbalance of either ventricle is approached with a univentricular, Fontan, strategy, but the cut-off ratio of ventricular size that defines which strategy should be used remains undefined. This challenge is compounded by difficulty in measuring ventricular volumes. One common approach is “eye-balling” the ventricular size with two-dimensional echocardiography; however, three-dimensional echocardiography and magnetic resonance imaging might have a future role in the decision-making process.

A small left ventricle may coexist with a solitary papillary muscle arrangement (the so-called parachute valve), left ventricular outflow tract obstruction, or coarctation, as in the setting of Shone’s syndrome. A small right ventricle may be seen with right
ventricular outflow tract obstruction or after previous pulmonary trunk banding.

The approach to the small ventricle must be individualized according to a common morphologic algorithm. Not only must the size of the cavity be assessed at operation but so must the AV valve ring size and the state of the papillary muscles. If subjectively little of the common AV valve is committed to one ventricle, then a biventricular repair will not possible irrespective of the cavity size. Thus, the surgeon must inspect the ventricles at the annular, valvar, and subvalvar levels to determine whether a biventricular approach is feasible. If a biventricular approach is chosen, the so-called cleft must often be left open to prevent left AV valvar stenosis.

Is it possible to “recruit” cavity volume through the division of muscle bundles, in a manner similar to the ventricular over-haul utilized in patients with pulmonary atresia and intact ventricular septum? This approach is being investigated. One may closely inspect the ventricular cavity for such bundles with the view of dividing them, so long as the AV valve ring is of good size and reasonably balanced.

Meryl S. Cohen, Jeanne M. Baffa, David M. Overman and colleagues are leading an initiative by the Congenital Heart Surgeons’ Society to study patients with unbalanced AVSD. They have developed echocardiographic tools to help evaluate patients with unbalanced AVSD. These tools accurately identify unbalanced AVSD and also bring into focus a zone of transition from anomalies that can support a biventricular end state and those that cannot. The atrioventricular valve index (AVVI) is expressed as the smaller AV valve area over the larger AV valve area, so that left-dominant unbalanced AVSD is expressed as right AV valve area/left AV valve area and right-dominant unbalanced AVSD the inverse. The modified AVVI is derived by dividing left AV valve area/total AV valve area. Thus, all forms of unbalance exist on a continuum from 0.0 to 1.0, with 0.0 having no left AV valve area, 1.0 having all left AV valve area, and 0.5 having exactly equal left and right AV valve areas. These tools may help determine the suitability of a given heart for univentricular or biventricular management strategies. Malalignment of the AV junction and the associated abnormalities of inflow physiology are critical in this decision-making process.

**Accessory Left Atrioventricular Valvar Orifice**

Accessory left AV valvar orifice is an unusual variant that is commonly cited as a risk factor for postoperative mortality and left AV valvar regurgitation. In these cases, the larger AV valvar orifice occurs in association with a smaller orifice that is almost always located at the junction of the inferior bridging leaflet and mural leaflet. Developmentally, these two leaflets may have failed to separate or may have fused at their tips, producing a small accessory orifice along their line of closure.

At operation, this orifice usually should not be closed because it is nearly always supported by cords and therefore is competent. Closure can result in left AV valvar stenosis. For similar reasons, the zone of apposition in the main orifice must be closed carefully, ensuring that there is no resulting stenosis.

**Deficiency of Atrioventricular Valvar Tissue**

Deficiency of AV valvar tissue is a difficult problem and can result in "on-table mortality." Although any of the leaflets may be deficient, this pathology almost always results from deficiency of the inferior bridging leaflet over the ventricular septum. Thus, the surgical approach must be tailored according to the degree and pattern of this deficiency. Here, annuloplasty may be particularly helpful in improving the degree of central coaptation of the other leaflets. Some degree of resulting valvar stenosis has to be tolerated, given that the
unwanted alternative is valvar replacement at a very young age.

**The Role of Atrial Septal Defect Patch Fenestration**

In all of the foregoing instances, the ASD may be closed with fenestration. This technique has the advantage of acting as a “blow-off” (or “pop-off”) valve when the ventricle is small, improving the postoperative hemodynamics and salvaging a difficult biventricular repair in this setting. It also gives the chance for the AV valve and ventricle to grow, redressing some of the imbalance and potentially improving AV valve function over time.

A hole is punched in the middle of a Gore-Tex patch that is sutured to the margins of the ASD or atrial septectomy. This not only prevents widening of the fenestration that can occur with an incision in autologous pericardium but also permits transcatheter closure of the hole at the appropriate postoperative time.

**SURGICAL MANAGEMENT OF PARTIAL ATRIOVENTRICULAR SEPTAL DEFECT**

The surgical management of partial AVSD has many similarities with that of complete AVSD, and repetition of the principles is not required. However, there are important differences that need to be highlighted.

**Cardiopulmonary Bypass**

Unlike complete AVSD where the patient is typically cooled to somewhere between 24 and 32°C, as described above, repair of partial AVSD is typically performed at a warmer temperature. Some will cool to 28°C, while others will repair partial AVSD at temperatures of >32°C. Some advocate normothermic repair partial AVSD and repair partial AVSD at 37°C. Cannulation is as for complete AVSD, and cardioplegia is used.

**Repair**

We assess the defect carefully using an approach similar to that described for repair of complete AVSD. Pericardial patch preparation is similar to that described for repair of complete AVSD. Stay sutures are not required, but attention should be paid to the quality of the valvar tissue above the crest of the interventricular septum. If the valvar tissue is judged to be of good quality (strong, thick, holding sutures well), we sometimes use a continuous suture of 5-0 polypropylene to secure the patch along the line of division between the right and left components of the AV valve. If the valvar tissue is of poor quality (frangible, thin, deficient, or holding sutures poorly), we prefer an interrupted suture technique using an appropriately sized suture as horizontal mattress sutures. If the valvar tissue is particularly bad, we often take a strip of autologous pericardium from the left side of the patient and use this as a buttress to the sutures along the valvar leaflets at the crest of the septum, creating a very robust sandwich (pericardium to valve to pericardium). At the inferior margin, the bundle is avoided, and the coronary sinus is positioned exactly as for complete AVSD. After the patch has been attached to the crest of the septum, the patch is swung anteriorly and the left AV valve assessed and repaired as for complete AVSD.

**SURGICAL MANAGEMENT OF TRANSITIONAL (INTERMEDIATE) ATRIOVENTRICULAR SEPTAL DEFECT**

The surgical management of transitional AVSD has many similarities with that of complete AVSD and partial AVSD, and again, repetition of the principles is not required. Cannulation, cardiopulmonary bypass, and administration of cardioplegia are the same.
Fig. 86.20. The valve is then tested for competence by suspending the leaflets with saline. The inset demonstrates the catheter used to inject the saline to float the valve.

Fig. 86.21. The valve should float up nicely, demonstrating no regurgitation.

However, there are important differences that need to be highlighted. The VSD is often quite small and may be closed with one or more 6-0 polypropylene double-armed suture placed as pledgeted horizontal mattress sutures from the right side of the ventricular septum to the AV valve. The repair of the cleft of the left AV valve may be challenging because the AV valvar tissue may be scarred and dysplastic. It is important to spend the necessary time to assess this potentially dysplastic left AV valvar tissue prior to reconstruction. Closure of the primum ASD is similar to that described for partial AVSD.

SURGICAL COMPLICATIONS AND POSTOPERATIVE CARE

Improved modern surgical techniques and modern intensive care units have drastically reduced the operative mortality for these procedures. Most centers report operative mortality of <1% for surgical intervention for partial AVSD defects. This mortality is even less if the partial AVSD is not associated with significant left AV valve regurgitation. Operative mortality for complete AVSD is <3%, and most major centers report operative mortality of <2% for this problem. The operative risk does increase in several subsets of patients, including those with severe AV valvar incompetence, those with hypoplasia of one of the ventricles, and those with pulmonary vascular disease.

Potential postoperative complications include pulmonary hypertensive crisis, left AV valvar insufficiency, and heart block. Children with significant preoperative left AV valvar regurgitation and older children with complete AVSD are at risk of postoperative pulmonary hypertensive crises. The concern for pulmonary hypertension leads to certain fundamental postoperative management principles. Children believed to be at risk for postoperative pulmonary hypertensive problems, including children in the range of 6 to 9 months (or older) undergoing repair of complete AVSD, fall into a late-extubation group. These children may be managed with a pulmonary artery line and a left atrial pressure monitoring line in situ and are often kept sedated over the first 48 hours after surgery. They are monitored for pulmonary hypertension and are in a position in which pulmonary hypertensive crises can be appropriately managed. Our first-line therapy, after conventional ventilatory support, is inhaled nitric oxide (2 to 20 ppm). Phenoxybenzamine, a long-lasting α-adrenergic blocking agent, has been used in these patients prophylactically. It is given before cardiopulmonary bypass and during rewarming at doses of 1 mg/kg. It is also given postoperatively at doses of 0.5 mg/kg per dose every 8 to 12 hours until extubation. These children remain sedated and monitored. If a pulmonary hypertensive crisis occurs, appropriate interventions can be initiated. In the current era, the use of milrinone plus or minus nitric oxide is all that is usually needed to manage these patients. With milrinone, a pulmonary hypertensive crisis is less likely to occur, and when a pulmonary hypertensive crisis does occur, nitric oxide is the first therapeutic intervention and is usually effective. Additional useful interventions in these patients include increased sedation, increased supplemental oxygen, hyperventilation to a CO₂ pressure of <25 mmHg or <3.5 kPa, and possible pharmacologic paralysis. Traditional strategies for the management of pulmonary hypertensive crisis are now rarely needed; these traditional interventions include intravenous nitroglycerin or sodium nitroprusside, intravenous aminophylline, and intravenous prostacyclin administration. If a pulmonary hypertensive crisis occurs, a 24-hour period of stability is required before attempts are made to wean the patient from the ventilator. If no pulmonary hypertensive crises
Section III: Congenital Cardiac Surgery

Fig. 86.22. The atrial septal defect pericardial patch is then sutured in place using continuous 5-0 polypropylene suture. The coronary sinus may be left on the left or right atrial side. The dotted line demonstrates the suture line if the coronary sinus is to be placed on the right atrial side. The dashed line demonstrates the suture line if the coronary sinus is to be placed on the left atrial side.

Fig. 86.23. The atrial patch is sewn into position. The inset demonstrates the relationship between the atrial patch, the ventricular patch, the right atrioventricular valve, and the left atrioventricular valve.

Fig. 86.24. In atrioventricular septal defect with tetralogy of Fallot, the shape of the ventricular septal patch must be tear shaped rather than elliptical, taking account of the deviated outlet septum.

Postoperative left AV valvar insufficiency is present to some degree in approximately 10% of patients undergoing repair of AVSD. These children are initially managed medically with afterload reduction. This may be done intravenously in the intensive care unit with nitroglycerin or nitroprusside. Long-term afterload reduction can be done orally with angiotensin-converting enzyme inhibitors such as captopril or with other oral medications such as prazosin (Minipress). A small subgroup of these patients with left AV valve insufficiency require redo operations for either left AV valvuloplasty or left AV valve replacement in the future. Reoperation should not be delayed if the child is in the intensive care unit and failing to progress.

A third potential complication after repair of AVSD is heart block. In the early days of repair of AVSD, this problem represented a leading cause of operative and postoperative mortality. This complication is not as problematic currently because it occurs with much lower frequency with careful attention to the anatomy of the conduction system, and also because, when it does occur, it can be managed appropriately. The incidence of permanent heart block in major centers repairing AVSD is <1%. Most episodes of postoperative heart block in these patients are temporary episodes caused by edema and resolve in the first 10 days after surgery. When permanent heart block does occur, it should be treated by placement of a permanent pacemaker before discharge from the hospital.

During the 4-year time interval of 2005 through 2008, the Society of Thoracic Surgeons Congenital Heart Surgery Database documented data from 2882 operations to repair AV canal defects: partial, 623 (21.5%); intermediate, 342 (11.8%); and complete, 1917 (66.3%). Mean age at complete repair (years) was as follows: partial, 6.1; intermediate, 2.9; and complete, 0.6. Median age at complete repair (years) was as follows: partial, 2.6; intermediate, 0.9; and complete, 0.4. Down syndrome was present in 1767 patients (61.1%).

Debending of the pulmonary artery was rarely performed: partial, 1 (0.2%); intermediate, 0 (0.0%); and complete, 66 (3.4%). Deep hypothermic circulatory arrest was rarely used: partial, 6 (1.0%); intermediate, 5 (1.5%); and complete, 52 (2.7%). Discharge mortality was low: partial, 2 (0.3%); intermediate, 3 (0.9%); and complete, 38 (2.0%). AV block requiring permanent pacemaker arrest occurred but was uncommon: partial, 6 (1.0%); intermediate, 2 (0.6%); and complete, 29 (1.5%). Unplanned reoperation

occur, children in this group (older patients undergoing repair of complete AVSD who are at risk for the development of pulmonary hypertensive crises) are extubated at approximately 48 hours. Younger infants undergoing repair of complete AVSD in the range of 3 to 6 months, as well as children with partial AVSD and transitional AVSD, are often not at risk for pulmonary hypertensive crises; consequently, these children are often extubated sooner, often either on the operating theater table immediately after surgery or within the first 24 hours.
prior to hospital discharge occurred in 3.9% of complete AV canal repairs. The sternum was left open in 3.0% of complete AV canal repairs. Postoperative cardiac arrest occurred in 1.9% of complete AV canal repairs. Mean postoperative length of stay (days) was as follows: partial, 5.2; intermediate, 7; and complete, 13.1. Median postoperative length of stay (days) was as follows: partial, 4; intermediate, 4; and complete, 7. Overall, 98% to 99% of patients survive complete repair of AV canal and 96% to 97% survive complete repair of AV canal with no major complications.

Long-term prognosis is excellent after repair of AVSD. Several series have reported long-term survival over 10- to 20-year periods of >90%. Long-term freedom from reoperation is similarly high except in the subgroup of patients requiring intervention for severe left AV valve regurgitation. The short-term and long-term prognoses in children with AVSD and Down syndrome are similar to those for children without Down syndrome.

**CONTROVERSIAL ISSUES**

Several issues remain controversial regarding the repair of AVSD. These include whether a single patch or two patches should be used for the repair, which type of material should be used for the patch or patches, whether the cleft in the left AV valve should be closed in partial AVSD, and where to leave the coronary sinus after repair. We prefer to use separate patches because we believe that this allows us greater ease in the reconstruction of the AV valves. By placing two patches, we believe that we are better able to avoid distorting the valves and that we have greater flexibility in creating competent AV valves. Moreover, we believe that we have greater ability to avoid conduction tissue with the use of two patches. We have also had recent success with the Num/Wilson's modified one-patch technique as described above.

We choose to use Gore-Tex or polyester (Dacron) patches for closure of the VSD. However, we prefer to use autologous pericardial patches for closure of the ASD. We also like to use pericardial pledgets to reinforce this patch closure as previously described. We believe that the pericardial closure of the ASD helps to prevent the small risk of problematic postoperative hemolysis. Otherwise, a jet of regurgitation through the left AV valve can strike a Gore-Tex or Dacron patch and subsequently lead to this hemolytic problem.

It has been proposed that the cleft leaflet in the left AV valve in partial AVSD does not need to be completely reapproximated because this valve is actually a trileaflet valve completely different in fundamental structure from a normal mitral valve. In our view, this cleft should be closed because our experience demonstrates that left AV valve cleft closure helps to prevent the development of late left AV valve regurgitation.

Finally, several options exist regarding placement of the coronary sinus on the left or right atrial side of the patch. Some advocate closing the ASD so that the coronary sinus drains to the left atrium; those who utilize this approach feel that baffling the coronary sinus to the left atrium minimizes the potential for damage to the conduction system and the development of permanent heart block. Others advocate closing the ASD so that the coronary sinus drains to right atrium; placement of the coronary sinus on the right atrial side eliminates an additional element of mixing of saturated and desaturated blood. Certainly, when a left-sided SVC drains into the coronary sinus, it is extremely important that the coronary sinus be placed on the right side of the atrial septum. It is also important to direct the coronary sinus blood flow to the right side in the setting of an unbalanced AVSD with a small left ventricle. Because the AV node typically lies at the apex of the nodal triangle, the coronary sinus can be directed to the right atrial side of the atrial patch, and the AV node can be safely avoided in the majority of circumstances. In some hearts, a sizable post-Eustachian sinus near the base of the coronary sinus allows for placement sutures that avoid conduction tissue and safely allow the coronary sinus to drain to the right atrium. In other hearts, this post-Eustachian sinus is smaller; in these hearts, it is often necessary to place the suture line within the coronary sinus ostium to keep the coronary sinus draining to the right side of the heart. By using these techniques, in the majority of circumstances one can allow coronary sinus drainage to remain in its anatomic position of the right side by paying careful attention to the anatomy of the conduction system and the nodal triangle.

**SUGGESTED READINGS**

The progressive improvement in results of repair of complete AVSD has permitted primary repair in infancy to become the procedure of choice for this condition. The incidence of the development of pulmonary vascular occlusive disease by 1 year of age has progressively decreased the optimal age at repair to the point that now elective repair can be undertaken at any age when con- genital heart failure is not controlled, and optimally between 2 and 4 months of age in most infants. We agree with the authors that pulmonary artery banding is virtually never indicated for complete AVSDs because the banding may cause increased right ventricular hypertrophy, which actually complicates the exposure of the AV valves at the time of complete repair and in our experience has resulted in less optimal exposure for the placement of the ventricular patch and reconstruction of the common AV valve. Even very tiny infants can undergo successful complete repair without resorting to banding. One subset of patients who may benefit from banding are the rare infants who have abnormal attachment of the anterior bridging leaflet that is significant enough to create left ventricular outflow tract obstruction. These patients may best be considered to have functionally single ventricle.

Partial AVSD ("ostium primum defect") is generally simple to repair, with good long-term results. However, significant left AV valve regurgitation can occur in this condition despite an adequate primary repair. We agree that closure of the cleft in the anterior mitral leaflet in this condition should be routinely performed to attempt to decrease the incidence of late AV valve regurgitation. In spite of this recommendation, some patients will nevertheless develop AV valve regurgitation despite an adequate closure and require valvuloplastic procedures at a later time. A particularly difficult subgroup of patients are those with a relatively hypoplastic left ventricle in association with primum ASD, who have a high mortality with primary repair.

Technically, our technique for repair of complete AVSDs is similar to the technique described in this chapter. We also favor a two-patch technique, which allows the best exposure of the AV valves for the assessment of competence and also permits closure of the VSD without the need to divide a common anterior bridging leaflet except in rare circumstances. If the anterior bridging leaflet is maintained undivided, the chances of dehiscence of the valve attachments to the patch become less and may decrease the need for reoperation. In addition, we have found that securing a ventricular septal patch below the common AV valve leaflets permits a suture line to which the superiorly located pericardial patch can be attached, reinforcing the suture line at the AV valves to minimize the risk of dehiscence. We have generally used Dacron for VSD closure because the patch is more flexible and small residual defects will often close spontaneously. We have elected to place the midportion of the ventricular septal patch first, and then, using gentle traction on each stitch in a running fashion, the suture line can be carried superiorly and inferiorly to complete the repair to the level of the AV valve attachments. The patch can then be trimmed again if necessary to allow the appropriate plane for attachment of the AV valve leaflets to the superior crest of the patch, which we perform in a running fashion. The common AV valve leaflets are then floated with saline solution to assess the coapting surfaces, which are then directly approximated using polytetrafluoroethylene suture, which does not cut through the tissue as readily as polypropylene suture and may avoid the need for pledget material. It is important not to evert the edges of the cleft of the mitral leaflet, which can lead to central regurgitation at the tip of the anterior mitral leaflet. In rare instances in which there is an accessory mitral valve orifice, usually posteriorly and inferiorly, the accessory orifice is not addressed in the repair. We have elected to place the coronary sinus on the right side of the atrial septal patch in essentially all patients and have not found an increased incidence of conduction defects utilizing this technique.

We use intraoperative transeosophageal echocardiography at the completion of surgery in every patient who undergoes repair of partial or complete AVSDs to assess the magnitude of mitral valve competence at the end of the procedure. Patients with more than moderate residual mitral regurgitation can then undergo immediate revision of the valve repair to decrease the incidence of late reoperation. With this technique, our experience with complete AVSD repair has resulted in a mortality of ≤2.9%, with a marked reduction in reoperation rate to <10% (Canter CE, Spray TL, Huddleston CB, Mendoloff E. Intraoperative evaluation of ativoventricular septal defect repair by color flow mapping echocardiography. Ann Thorac Surg 1997;63:592).

We have not elected to use pulmonary arterial monitoring lines in most patients with AVSD repairs because with early operative intervention, the incidence of pulmonary hypertensive events has been very low.

Patients who have a restrictive VSD in unbalanced AV canal to the right may have adequate inflow into the left ventricle for a two-ventricle repair if there is antegrade flow out the aorta and across the aortic arch. Decision making for these patients can be extremely difficult, and careful attention must be given to the attachments of the common AV valve, the inflow patterns into the ventricles, and the relative size of the AV valves and ventricles.

Dr. Elliott and associates have suggested that leaving an atrial septal defect in patients with a relatively small left ventricle or compromised left AV valve may be beneficial as a “pop-off.” Although this has been shown to be effective in some cases, it is not clear how this improves the hemodynamic situation, given that all of the blood decompressing from the left atrium will be represented back to the left atrium. It is thought perhaps that such atrial septal defects simply allow a larger capacitance of the left atrial chamber and may therefore limit pulmonary hypertension at the expense of a lower cardiac output and increased pulmonary blood flow. We generally believe that if an ASD is required to prevent severe left atrial hypertension, then the left-sided structures are probably too small for a two-ventricle repair.

With the advent of nitric oxide, pulmonary hypertensive events have become less of a cause of morbidity and mortality after repair of AVSD, resulting in marked improvement in operative results. Current operative survival after repair of these defects approaches 98%.

(continued)
In our experience, the indication for reoperation in AVSD repair has generally been left-sided AV valve regurgitation. The incidence of AV valve regurgitation after repair of complete and partially AV canal defects is higher than often believed. Review of a large number of reported series of AV canal repairs suggests that significant left AV valve regurgitation occurs in up to 30% to 35% of patients after AV canal repair, and reoperation may be necessary in 10% to 20% of these patients over time. Interestingly, despite the relatively better anatomy in partial AV canal defect, the incidence of late AV valve regurgitation requiring reoperation is as high as or higher than that for complete AV canal repair.

The patient who presents in the first few weeks of life with severe congestive heart failure with complete AV canal defect represents a difficult patient group. It is unclear why some patients do not respond to medical treatment of congestive heart failure, but in these cases pulmonary artery banding or early repair can be considered.

Rare instances of patch dehiscence have occurred that required reoperation; however, the long-term durability of the left AV valve repair remains the primary determinant of late morbidity. In many cases, the valve can be repaired at a second operative intervention either with more complete closure of the cleft of the anterior mitral leaflet or with additional annuloplasty sutures. Valve replacement should be extremely unusual after AVSD repairs.
Truncus arteriosus represents an unusual congenital heart defect in which a single arterial trunk arises from the heart, providing the origins of the coronary arteries, the true pulmonary arteries, and the brachiocephalic vessels. The defect is usually associated with a ventricular septal defect and a single, large semilunar valve. Typically, the semilunar valve contains up to four separate leaflets, which may be dysmorphic in infancy. In situations in which more than four leaflets are present, incorporation of remnants of the pulmonary valve into the truncal valve is presumed. Very rare instances of absence of ventricular septal defect in truncus arteriosus have been reported, but usually the infundibular septum is virtually absent superiorly. The presence of a main pulmonary trunk or the separation of the pulmonary arteries from the arterial trunk. From a surgical standpoint, however, the variations in the origin of the pulmonary arteries are often similar enough among the various types that separation by this classification scheme has not been as useful as the alternate scheme developed by Van Praagh. The Van Praagh classification system is described in Table 87.1. Most recently, a modified Van Praagh classification has been proposed by the Congenital Heart Surgery Nomenclature and Database project, classifying cases by the presence of confluent, or near confluent pulmonary arteries, truncus arteriosus with the absence of one pulmonary artery or truncus arteriosus in the presence of interrupted aortic arch or coarctation. The advantage of this system is that it is based on a hierarchical system and can be used interchangeably with the traditional classification systems.

Some authors have described “hemi-truncus” as a situation in which the right pulmonary artery arises from the ascending aorta and the left pulmonary artery from the right ventricle. This defect is not typically associated with a ventricular septal defect. In our opinion, it is not a variation of truncus arteriosus and is best defined as aortic origin of the right pulmonary artery. Such a description distinguishes this anomaly from the Van Praagh type 3A truncus.

The development of aortic arches and 6 varies in truncus arteriosus such that infants with hypoplasia or interruption of the aortic arch have associated large ductal connections between the truncus and the descending aorta, and infants in whom the arch is fully developed usually have absence of the ductus arteriosus.

The primary classification systems for truncus arteriosus have focused on the origins of the pulmonary arteries. The classification scheme of Collett and Edwards defines truncus arteriosus types by the presence of a main pulmonary trunk or the separation of the pulmonary arteries from the arterial trunk. From a surgical standpoint, however, the variations in the origin of the pulmonary arteries are often similar enough among the various types that separation by this classification scheme has not been as useful as the alternate scheme developed by Van Praagh. The Van Praagh classification system is described in Table 87.1. Most recently, a modified Van Praagh classification has been proposed by the Congenital Heart Surgery Nomenclature and Database project, classifying cases by the presence of confluent, or near confluent pulmonary arteries, truncus arteriosus with the absence of one pulmonary artery or truncus arteriosus in the presence of interrupted aortic arch or coarctation. The advantage of this system is that it is based on a hierarchical system and can be used interchangeably with the traditional classification systems.

Some authors have described “hemi-truncus” as a situation in which the right pulmonary artery arises from the ascending aorta and the left pulmonary artery from the right ventricle. This defect is not typically associated with a ventricular septal defect. In our opinion, it is not a variation of truncus arteriosus and is best defined as aortic origin of the right pulmonary artery. Such a description distinguishes this anomaly from the Van Praagh type 3A truncus.

The development of aortic arches 4 and 6 varies in truncus arteriosus such that infants with hypoplasia or interruption of the aortic arch have associated large ductal connections between the truncus and the descending aorta, and infants in whom the arch is fully developed usually have absence of the ductus arteriosus.

The primary classification systems for truncus arteriosus have focused on the origins of the pulmonary arteries. The classification scheme of Collett and Edwards defines truncus arteriosus types by the presence of a main pulmonary trunk or the separation of the pulmonary arteries from the arterial trunk. From a surgical standpoint, however, the variations in the origin of the pulmonary arteries are often similar enough among the various types that separation by this classification scheme has not been as useful as the alternate scheme developed by Van Praagh. The Van Praagh classification system is described in Table 87.1. Most recently, a modified Van Praagh classification has been proposed by the Congenital Heart Surgery Nomenclature and Database project, classifying cases by the presence of confluent, or near confluent pulmonary arteries, truncus arteriosus with the absence of one pulmonary artery or truncus arteriosus in the presence of interrupted aortic arch or coarctation. The advantage of this system is that it is based on a hierarchical system and can be used interchangeably with the traditional classification systems.

Some authors have described “hemi-truncus” as a situation in which the right pulmonary artery arises from the ascending aorta and the left pulmonary artery from the right ventricle. This defect is not typically associated with a ventricular septal defect. In our opinion, it is not a variation of truncus arteriosus and is best defined as aortic origin of the right pulmonary artery. Such a description distinguishes this anomaly from the Van Praagh type 3A truncus.

The development of aortic arches 4 and 6 varies in truncus arteriosus such that infants with hypoplasia or interruption of the aortic arch have associated large ductal connections between the truncus and the descending aorta, and infants in whom the arch is fully developed usually have absence of the ductus arteriosus.

The primary classification systems for truncus arteriosus have focused on the origins of the pulmonary arteries. The classification scheme of Collett and Edwards defines truncus arteriosus types by the presence of a main pulmonary trunk or
progressive pulmonary overcirculation, which is not dissimilar to the situation seen in hypoplastic left heart syndrome.

**DIAGNOSIS AND INDICATIONS FOR SURGICAL INTERVENTION**

The diagnosis of truncus arteriosus can generally be made with accuracy from echocardiograms. Cardiac catheterization is indicated only when the patient presents late after birth and the issue of pulmonary vascular resistance is raised. Some children may have significant pulmonary arterial stenosis, which permits control of congestive heart failure early in life, and catheterization to define the level and degree of obstruction may be beneficial. In addition, abnormalities of coronary arteries and the severity of truncal valve abnormalities may occasionally prompt catheterization for greater characterization of the defects.

We have generally considered the presence of truncus arteriosus an indication for operation in a relatively urgent fashion. Because hemodynamics may be quite unstable in children with unrestricted pulmonary blood flow and because we have seen patients deteriorate rapidly while awaiting surgical intervention, we have elected to repair truncus arteriosus promptly after the diagnosis is made. This policy reflects the clear advantages of neonatal repair of truncus arteriosus. Review of series of truncus repairs reflects the trend toward earlier intervention. Whereas the first repairs of truncus arteriosus were performed in 1962 by Behrendt and associates, in 1967 McGoon first used a valved allograft for the repair. This operation was a refinement of the procedure described by Bastelli at the Mayo Clinic. The results of early repairs were quite poor, however, because of the development of pulmonary vascular obstructive disease. In most of these early repairs, the operation was undertaken after the patient reached 6 months of age, when pulmonary vascular resistance was already significantly elevated. In 1984, Ebert reported a series of 100 infants who underwent complete repair of truncus arteriosus at 6 months of age with an 11% mortality. This landmark report emphasized the improved results in early intervention in children with this lesion. In our experience, repair of truncus arteriosus has gradually improved as surgical techniques have evolved such that operative survivals of >95% are anticipated with neonatal repair in patients without associated valvar lesions. The late results of truncus arteriosus have been favorable, with little late mortality despite the need for reoperation to replace right ventricular outflow tract conduits.

**SURGICAL TECHNIQUE**

**Repair of Truncus Arteriosus**

The heart is exposed with a median sternotomy incision. The presence of thymic tissue is confirmed because many of these children have athyemia associated with DiGeorge syndrome. The clear presence of thymic tissue, therefore, may have implications for later management and prognosis. The heart is suspended in a pericardial cradle and the great vessels examined. If the patient is severely overcirculated with congestive heart failure, it may be advisable to promptly encircle one of the pulmonary arteries with a snare to limit the total pulmonary blood flow. On occasion, this can stabilize the patient while dissection is performed around the arch vessels.

The operation can be performed either with the patient on continuous cardiopulmonary bypass or by utilizing circulatory arrest. We have elected to use both of these techniques, and in simple truncus arteriosus, the complete operative repair can be performed during a single period of circulatory arrest of <40 minutes in most cases. The right and left pulmonary arteries are mobilized and encircled with tourniquets for control and the origins of the pulmonary arteries examined. In addition, on opening the pericardium, it is important to determine the location of the anterior descending coronary artery and confirm that it does not cross the right ventricular wall in the area of anticipated ventriculotomy. Heparin is administered and the aorta cannulated as distally as possible. Distal cannulation is particularly important because the pulmonary bifurcation may come off relatively distally and there is little room for cross-clamping of the aorta between the anticipated division of the pulmonary bifurcation and the distal aorta. Either the venae cavae are cannulated if continuous bypass is used, or a single right atrial cannula is used with circulatory arrest. If mobilization of the pulmonary artery confluence behind the aorta is considered to be too close to the anticipated cross-clamp application site, the brachiocephalic vessels are encircled with tourniquets and circulatory arrest is used, with clamping of the aorta more distally on the arch during the reconstruction of the back of the truncus arteriosus after excision of the pulmonary bifurcation. The infant is placed on cardiopulmonary bypass and the snare on the right and left pulmonary arteries tightened as shown in Figure 87.1 to prevent pulmonary overcirculation during cooling. The child is cooled to 18°C for circulatory arrest or 34 to 37°C for continuous bypass repair. In the presence of significant truncal valve insufficiency, venting of the left ventricle is important during cooling and may be accomplished by placing a vent through the right superior pulmonary vein across the mitral valve into the ventricle, or if truncal insufficiency is severe, by compressing the heart to maintain emptying of the ventricle during cooling.

The aorta is then cross-clamped and cardioplegic solution is administered into the truncal root with the pulmonary artery snare applied to force the cardioplegic solution into the coronary arteries. Alternatively, cardioplegia can be induced in a retrograde manner or the aorta opened and the coronaries directly cannulated. After cardioplegia is achieved, the snare is removed from the pulmonary arteries, and an incision is made near the takeoff of the pulmonary bifurcation anteriorly. Through this initial incision, the truncal valve is examined and the origin of the left coronary artery carefully identified. The left coronary can arise high from above the truncal sinuses and be intimately associated with the origin of the pulmonary bifurcation. Once the coronary arteries are identified, the pulmonary bifurcation is excised from the back of the truncus arteriosus. The aorta is then repaired using a

Fig. 87.1. Repair of simple truncus arteriosus. The infant is placed on cardiopulmonary bypass with either bivacal cannulation or single venous cannulation in the right atrium for circulatory arrest. The aorta is cannulated as distally as possible to allow cross-clamping proximal to the aortic cannulation site for the division of the pulmonary arteries from the truncal vessel. Snares are placed on the right and left pulmonary arteries to prevent pulmonary overcirculation during warming and to allow delivery of cardioplegic solution to the myocardium. After cardioplegia is achieved, the snares are released from the pulmonary arteries and the pulmonary bifurcation is excised from the back of the truncal artery, with care being taken to avoid the origin of the left coronary artery posteriorly, which can originate very close to the pulmonary bifurcation. An incision is made in the right ventricle, avoiding major epicardial coronary branches and the base of the truncal valve. PA, pulmonary artery; VSD, ventricular septal defect.

Fig. 87.2. The defect in the main trunk from excision of the pulmonary bifurcation is closed with a patch of pulmonary homograft material or pericardium with meticulous suture technique to ensure hemostasis. Cardioplegic solution is then administered to observe any leaking of the suture line because the area will be difficult to expose after complete repair. The ventricular septal defect (VSD) is exposed through the ventriculotomy incision. There is no muscle rim typically present at the superior margin of the VSD and, therefore, the patch is secured to the epicardial portion of the ventriculotomy incision superiorly.

after the repair of the truncus arteriosus is complete and the pulmonary bifurcation is mobilized to bring the bifurcation to the left for reconstruction, additional cardioplegic solution is injected into the aortic root to test the suture line of the truncal patch, and additional sutures are placed if necessary. Next, an incision is made in the right ventricle, avoiding major branches of the coronary arteries. This incision is made at the base of the truncal valve, and care must be taken not to carry the incision too far superiorly into the truncal valve annulus. The absence of infundibular septum in this area results in the possibility of damage to the truncal valve if the incision is started too far superiorly. The orientation of the incision is made so that the takeoff of the conduit from the right ventricle will be directed toward the pulmonary bifurcation.

As shown in Figure 87.2, the ventricular septal defect is exposed through the incision in the right ventricle. The defect is closed with a patch of polyester (Dacron) material using a running technique. Superiorly, the absence of the infundibular septum mandates that the patch be more ovoid in shape, and the patch is secured to the epicardial margin of the ventriculotomy incision superiorly to avoid interference with the truncal valve (Fig. 87.3). In the majority of cases, there is a bridge of muscle between the margin of the ventricular septal defect and the tricuspid valve septal leaflet, and in these patients, suturing in this area can be performed without risk to the conduction...
Fig. 87.3. The ventricular septal defect (VSD) is closed with an ovoid patch of polyethylene terephthalate (Dacron) material sewn to the superior margin of the ventriculotomy incision (inset). Typically, a rim of muscle is present inferiorly between the VSD and the tricuspid valve septal leaflet, and in these patients a running suture line can be created that avoids the conduction tissue. If the muscle bridge is not present, the inferior margin of the suture line is carried along the base of the septal tricuspid valve leaflet on the right ventricular aspect to avoid the conducting tissue.

Fig. 87.4. The pulmonary arteries are reconstructed with a pulmonary homograft. To prevent kinking of the homograft with distention, it is trimmed 2 to 3 mm distal to the commissural attachments of the pulmonary valve. To provide an adequate anastomosis and size match to the pulmonary bifurcation using a large pulmonary homograft of 12 to 18 mm in diameter, an incision is carried into the origin of the right pulmonary artery for a short distance and more significantly into the left pulmonary artery if additional opening is necessary. An anastomosis is then created with a running fine monofilament suture between the pulmonary homograft and the pulmonary bifurcation.

To accommodate such a large homograft, the pulmonary bifurcation is incised, with the incision slightly into the origin of the right pulmonary artery but more into the left pulmonary artery so that the conduit will lie toward the left. An anastomosis is then created between the homograft and the pulmonary bifurcation with a running monofilament suture (Fig. 87.4).

As noted in Figure 87.5, the homograft is then anastomosed to the superior margin of the ventricular incision to which the ventricular septal defect patch has been sewn. Approximately one-third of the circumference of the ventriculotomy incision is sutured in this manner. In some cases, the homograft will have an adequate amount of right ventricular muscle attached so that it can be trimmed to allow a very small margin of muscle at the suture line to the ventricle but with an adequate

tissue. In a minority of cases, there is absence of this muscle tissue, and suturing of the ventricular septal patch to the base of the septal leaflet of the tricuspid valve is necessary.

After closure of the ventricular septal defect is complete, the right ventricular outflow tract is reconstructed using a pulmonary or aortic homograft. Although in the past we elected to use larger pulmonary homografts to allow for the maximum possible growth of the infant before conduit change is necessary, more recently we have used aortic allografts preferentially, because the high pulmonary vascular resistance seen in the early postoperative period often causes dilation in the pulmonary allografts. Another advantage for the initial use of an aortic homograft is the curved nature of the ascending aorta that can be positioned to the left, curving around the enlarged truncal root in patients in whom the truncus is particularly enlarged.

The use of an aortic homograft in the initial repair of truncus arteriosus prevents pulmonary homograft dilation early. At the time of the conduit replacement after truncus repair which typically occurs between 3 and 6 years after the operation, a pulmonary homograft is preferentially selected since pulmonary vascular resistance is now low and placement of a large pulmonary homograft may obviate the need for additional conduit replacements in the future, and the development of pulmonary insufficiency in the homograft conduit can be treated later with a stent mounted on pulmonary valve with a percutaneous approach.

If a pulmonary homograft is used, it is important not to oversize the pulmonary homograft because even though it is desirable to have a larger homograft to allow for future growth and decrease the need for early reoperation, the capacitance of a large pulmonary homograft may equal the stroke volume of the right ventricle and limit the forward cardiac output in patients when there is severe oversizing of the homograft conduit. The conduit in such cases acts like an aneurysm of the right ventricle, decreasing overall right ventricular performance.

VSD patch

PTFE gusset

Fig. 87.5. The pulmonary homograft is then sewn proximally to the superior aspect of the ventriculotomy incision for approximately one-third of its circumference. As noted in the text, if adequate muscle is present on the pulmonary homograft, it can be sewn directly down to the right ventricular outflow tract. However, if inadequate tissue is present, the outflow tract is augmented with a gusset of polytetrafluoroethylene (PTFE) material, as shown in the inset, to create a gentle takeoff of the homograft from the right ventricular outflow tract to avoid compression. VSD, ventricular septal defect.

Alternative Repairs of Truncus Arteriosus

Several variations on repair of truncus arteriosus have been described, primarily to avoid the need for an allograft conduit.
from the right ventricle to the pulmonary arteries, which will commit most children to eventual conduit replacement. We have used conduit reconstruction in the majority of infants because the early morbidity and mortality after truncus arteriosus repair are commonly related to the occurrence of pulmonary vascular hypertensive crises and right ventricular dysfunction, and in this setting, the absence of a pulmonary valve exacerbates the hemodynamic instability. The presence of a competent valve in the right ventricular outflow tract seems to minimize the early hemodynamic instability in these patients, and replacement of the right ventricular outflow allograft is associated with a low morbidity and mortality.

In the interest of completeness, several alternative techniques are described here. The first alternative repair involves incision of the truncus arteriosus above the semilunar valve on the pulmonary arterial side of the common trunk (Fig. 87.7). Working through this incision, the surgeon can patch the origin of the pulmonary bifurcation from the arterial trunk with a piece of homologous pericardium or homograft material, with care being taken to avoid interference with the coronary ostium of the left coronary artery and allowing unobstructed flow from the truncal valve to the ascending aorta. An advantage of this technique is the lack of external bleeding with this suture line, which can be troublesome after patching of this area after division of the pulmonary bifurcation. A potential disadvantage, however, is that any dehiscence of this suture line will result in a significant left-to-right shunt. If this type of repair is performed, an incision is made in the right ventricle, and the ventricular septal defect is closed. The pulmonary bifurcation is then mobilized freely and either brought anterior to the ascending aorta or mobilized sufficiently to allow direct anastomosis to the superior margin of the right ventriculotomy. In situations in which the pulmonary bifurcation cannot be anastomosed directly to the right ventriculotomy without compression of the pulmonary bifurcation by the ascending aorta or if an anomalous anterior descending coronary artery crosses the outflow tract, it is possible to create a floor for the outflow tract reconstruction by the use of autologous tissue, such as the left atrial appendage. In Figure 87.8, the left atrial appendage is opened, creating a flap of tissue that is then brought over the outflow tract and secured to the superior margin of the ventricular incision and the pulmonary bifurcation. The base of the atrial appendage is oversewn. This creates an autologous connection between the right ventricle and the pulmonary bifurcation that has the potential for growth. The outflow tract is then augmented by an anteriorly placed patch of homologous pericardium or pulmonary homograft material. In this manner, a valveless connection is created between the right ventricle and the pulmonary bifurcation.

Another alternative is the use of a monocusp reconstruction of the right ventricular outflow tract, which has the potential advantage of early pulmonary valve competence during the initial period of hemodynamic instability postoperatively and the potential for later growth to decrease the need for conduit reconstruction later in life. In this technique (Fig. 87.9), a piece of homologous pericardium is used to create a single cusp, which is sewn to the wall of an outflow patch of pulmonary homograft, homologous pericardium, or PTFE material. This pericardial monocusp is created in a generous manner to allow it to close against the right ventricle (Fig. 87.10). The posterior floor of the reconstruction is performed as noted in Figure 87.8; however, the anterior reconstruction is completed with this monocusp outflow patch. The monocusp valve appears to function adequately for as long as several months and may decrease the incidence of late conduit changes, but it is more difficult to accomplish without at least some early postoperative pulmonary insufficiency.

**Repair of Truncus Arteriosus with Interrupted Aortic Arch**

When interrupted aortic arch is associated with truncus arteriosus, the operation is usually performed with the patient under circulatory arrest. Because of the instability of these infants, surgery in the first week of life is typical. After mobilization and snaring of the pulmonary arteries to prevent pulmonary overcirculation on bypass, cannulation of the main trunk and the right atrial appendage is performed. Because perfusion of both the brachiocephalic vessels and the distal aorta across the ductus arteriosus will be accomplished by a single cannulation, the arterial cannulation can be placed proximally in the main portion of the truncal vessel. Snares
are placed also on the brachiocephalic vessels originating from the ascending aorta. The infant is placed on bypass and cooled to a nasopharyngeal temperature of 18°C while snares on the right and left pulmonary arteries prevent pulmonary overcirculation and distal perfusion is provided across the ductus arteriosus. During cooling, the descending aorta and the left subclavian artery may be mobilized and a snare placed on the left subclavian artery if necessary. In some cases, aberrant origin of the right subclavian artery is present in this condition. In rare cases, it may be necessary to divide the right subclavian artery to gain adequate mobilization for repair, as in repair of interrupted aortic arch, but this is usually not necessary. Although several techniques are available for reconstruction of the aortic arch, we prefer to use a technique in which the arch is augmented with pulmonary homograft material to prevent tension on the anastomosis. After circulatory arrest is established and cardioplegia induced, which can be accomplished by snaring of the ductus arteriosus and the brachiocephalic vessels and infusion of cardioplegic solution through the aortic cannula in the proximal arterial trunk, the cannulae are removed from the heart. With the arch vessels snared, an incision is made on the lateral aspect of the ascending aorta beyond the origins of the pulmonary arteries and then carried inferiorly and across the pulmonary bifurcation (Fig. 87.11). Ductal tissue is excised and the ductus ligated on the pulmonary arterial end. In this manner, the pulmonary bifurcation is excised from the truncus. The pulmonary arteries are mobilized freely; then, all ductal tissue is excised from the descending aorta and an incision is made superiorly into the origin of the left subclavian artery. A side-to-side anastomosis is then created from the origin of the left carotid to the origin of the

Fig. 87.8. In situations in which a pulmonary homograft is not used for outflow reconstruction, autologous tissue may be used. In this alternative technique, the left atrial appendage is incised at its base and a flap of atrial appendage anastomosed to the pulmonary bifurcation superiorly and to the ventriculotomy incision inferiorly to bridge the ventriculotomy incision and the pulmonary bifurcation with autologous tissue. The base of the atrial appendage is then oversewn. It is important if this technique is used to open the atrial appendage to create a long bridge of tissue. The use of the unopened atrial appendage has been suggested; however, in our experience, sufficient tension may be present on this atrial appendage that with cardiac distention and contraction of the atrium, the bridge of tissue may compress the left coronary artery and cause myocardial ischemia. The repair is then completed with augmentation of the autologous floor of the outflow tract reconstruction with an anteriorly positioned patch of pericardium or homograft material.
left subclavian artery, providing a length of autologous tissue on the superior surface of the arch to allow for growth of the arch (Fig. 87.12). The ventriculotomy and closure of the ventricular septal defect are then performed in the usual manner, and the arch of the aorta is reconstructed with a patch of pulmonary homograft to provide unobstructed flow through the arch of the aorta and to decrease tension on the anastomosis to decrease the risk of bleeding or distal coarctation (Fig. 87.13). The pulmonary artery reconstruction is then performed as in simple truncus arteriosus.

Repair of Truncus Arteriosus with Truncal Valve Repair or Replacement

Newborns who have significant truncal valve stenosis and insufficiency represent a higher risk subset for neonatal repair. Fortunately, significant truncal...
Section III: Congenital Cardiac Surgery

Pulmonary artery

Fig. 87.11. Repair of interrupted aortic arch with truncus arteriosus. A vertical incision is made in the ascending aorta and brachiocephalic vessels onto the origin of the left carotid artery. This incision is placed medially and then carried transversely across the truncus to the base of the left pulmonary artery origin. The pulmonary bifurcation is then excised from the back of the truncus. The ductus arteriosus is ligated distal to the pulmonary bifurcation, and ductal tissue is excised from the descending aorta. An incision is then made vertically in the left subclavian artery and onto the descending aorta beyond any ductal tissue remnants. PDA, patent ductus arteriosus.

Fig. 87.12. The arch is reconstructed by direct anastomosis of the origins of the subclavian and carotid vessels with absorbable suture to create an autologous superior aspect to the arch reconstruction.

Valve stenosis is rare, and only in the most severe forms of truncal stenosis valve replacement is necessary at primary operation. Often the elimination of the large left-to-right shunt seen in these patients decreases the flow across the truncal valve, and what appears to be a significant level of stenosis preoperatively may be acceptable after the ventricular septal defect is closed and the truncal repair has been completed. Thus, primary valve replacement for repair of truncus arteriosus should be extremely rare.

A more common situation is the presence of significant truncal valve insufficiency in association with unrepaired truncus arteriosus with or without interrupted aortic arch. Over the last several years, an increasing experience has been reported of valve repair for truncal valve regurgitation at the initial repair of truncus arteriosus or as a secondary procedure. In patients in whom the truncal valve is quadricuspid and there is significant prolapse or abnormality of a single cusp, resection of the cusp and recreation of a trileaflet truncal valve may result in significant improvement in truncal valve insufficiency. In this repair, after division of the truncal root, an incision is made in the aortic wall immediately adjacent to the commissural attachment of the valve leaflet that is to be excised and the incision carried across the valve annulus obliquely. A second incision is made in the more anterior commissural attachment of this same valve cusp, and the cusp is excised with a portion of the truncal wall. Primary repair of the defect then results in a trileaflet valve, which may have less central insufficiency and a more normal distribution of forces on the valve sinuses, aiding closure of the valve centrally (Fig. 87.14A–C). In other cases, if the truncal valve leaflets are not obviously abnormal, or if there is an obvious area of truncal regurgitation at a commissural attachment, closure of the commissure between adjacent truncal valve leaflets with or without leaflet augmentation and annuloplasty may result in significant improvement in truncal insufficiency (Fig. 87.14D).

Often the valve leaflet that needs to be excised in patients with truncal regurgitation and quadraleaflet truncal valve is the leaflet adjacent to the left coronary ostium. In these cases, excision of the leaflet can be performed as described in Figure 87.14E and 87.14F. However, the left coronary artery needs to be mobilized with a button on the aortic wall prior to excision of the valve leaflet and then reimplemented into a suitable site in the truncal root as is often performed with the arterial switch procedure. With these techniques, any of the leaflets of the truncal valve can be excised, although excision of leaflets adjacent to the conduction tissue in the anterolateral aspect of the aorta can be associated with the development of heart block, and therefore, it is preferable to excise noncoronary leaflets or left-sided leaflets if possible.

In the situation of truncus repair with truncal valve replacement, the operation is typically performed with the patient on...
continuous cardiopulmonary bypass or with intermittent circulatory arrest. Bicaval cannulation is used and the aortic cannulation performed as distally as possible. The left heart is vented through the right superior pulmonary vein across the mitral valve to maintain decompression during cooling and rewarming. The aorta is clamped and cardioplegic solution administered directly into the truncal root if there is only modest truncal insufficiency or directly into the coronary arteries after the truncal vessel is opened if severe insufficiency is present. Alternatively, cardioplegia can be induced in a retrograde manner. In our experience, however, direct cannulation of the coronary ostia is possible in even very small neonates, permitting adequate distribution of cardioplegic solution. The truncus is divided transversely at the level of the takeoff of the pulmonary bifurcation and the bifurcation mobilized freely. An incision is then made vertically across the truncal valve annulus into the right ventricle, widely opening the right ventricular outflow tract (Fig. 87.15). The right and left coronary ostia are mobilized with a button of aortic wall for anastomosis to the reconstruction. The truncal valve is then excised as in Figure 87.16. The ventricular septal defect is readily apparent. We have generally preferred aortic allografts for truncal root replacement as in the early postoperative period high systemic pressures can lead to pulmonary homograft dilation and valvar insufficiency. When root replacement is required, the proximal anastomosis of the allograft is performed to the annulus of the truncal valve posteriorly. This suture line is created for approximately one-half to two-thirds of the circumference of the truncal valve annulus (Fig. 87.17). The ventricular septal defect is then closed with a patch of Dacron or PTFE material, baffling the left ventricular flow to the homograft valve. Thus, the superior margin of the ventricular septal defect patch is sewn to the base of the valve allograft anteriorly, reconstructing the left ventricular outflow tract. At suitable sites on the allograft, buttons of tissue are excised and the coronary arteries reimplanted as for the arterial switch operation for transposition of the great arteries (see Chapter 79). The distal anastomosis of the allograft to the ascending aorta is then completed. At this point, additional cardioplegic solution is injected into the aortic root to ensure that the suture lines are hemostatic and that no insufficiency of the allograft valve is present. The right ventricular reconstruction is then performed (Fig. 87.18), with an allograft valve from the right ventricular incision to the pulmonary bifurcation augmented with a gusset of PTFE material if necessary or by one of the other alternative techniques described previously. If truncal valve replacement is required later after initial repair, it is performed as in homograft root replacement (see Chapter 92).

A recent review of the Society of Thoracic Surgeons (STS) congenital heart surgery database showed that patients undergoing truncal valve surgery had a significantly higher mortality, particularly in the subset of patients who had associated interrupted aortic arch compared with patients undergoing isolated truncus arteriosus repair.

**POSTOPERATIVE MANAGEMENT**

The management of infants after repair of truncus arteriosus is primarily directed at minimizing pulmonary vascular resistance and right heart dysfunction. Sedation and occasionally paralysis with hyperventilation are standards of postoperative management. Low-dose inotropic support with phosphodiesterase inhibitors may be necessary to improve the right ventricular function in the early postoperative period. With these techniques, pulmonary hypertensive crises and acute right heart dysfunction have been relatively uncommon in our more recent series. However, significant
Fig. 87.14. Repair of truncal valve insufficiency. (A) The truncus is transected, and the leaflet to be excised is identified. Typically, a quadricuspid valve is present, and there may be a significant prolapse of one leaflet. An incision is made adjacent to the commissural attachment of the leaflet to be excised and is carried down across the truncal valve annulus obliquely. (B) A second incision is made anteriorly in a similar manner, and the valve leaflet along with a 1- to 2-mm section of the valve annulus is excised. (C) Primary closure of the valve annulus and the aortic wall then results in coaptation of the commissural attachments of the remaining truncal leaflets and decreases the magnitude of central insufficiency, improving the central coaptation between the remaining truncal valve leaflets. (D) In patients with truncal insufficiency in whom there is prolapse or dysplasia of a truncal valve leaflet resulting in localized regurgitation, closure of the commissural attachments between valve leaflets may be effective. The truncus is divided, and the truncal valve is examined from above. If areas of deficiency between valve leaflets at the commissures are identified, the commissure can be closed with interrupted or running sutures of monofilament PTFE material. We prefer PTFE suture, which seems to cut through the very delicate valve leaflet tissues less than other types of suture material. (E) In patients in whom the valve leaflet to be excised is associated with an adjacent coronary ostium, mobilization of the coronary ostium with excision of a button of aortic wall allows the valve leaflet and annulus to be excised as in panel B, permitting primary reconstruction of a trilobal valve. (F) The coronary button can then be reimplanted at a suitable site on the aortic wall either to a punch opening or to a medially based flap incision in the aortic wall.
Fig. 87.15. Repair of truncus arteriosus with truncal valve replacement. After circulatory arrest or with continuous bypass, the aorta is cross-clamped and cardioplegic solution is injected into the truncal root. The pulmonary arteries are snared to allow flow of cardioplegic solution into the coronary arteries if possible. If truncal insufficiency is severe, the truncus is opened superiorly as noted in this diagram and then cardioplegic solution is injected into the left and right coronary ostia under direct vision. The right and left coronary ostia are excised with a button of aortic wall, and a vertical incision is made down across the truncal valve annulus into the right ventricle. PA, pulmonary artery.

right ventricular dysfunction or unmanageable pulmonary hypertension with low cardiac output may result in severe hemodynamic instability and on rare occasion has been successfully managed with extracorporeal membrane oxygenation support for several days.

RESULTS
Although mortality rates for truncus arteriosus repair were as high as 60% to 70% until the early 1980s, the trend toward earlier repair and improvements in surgical and postoperative management techniques have resulted in a progressive improvement in the operative results such that survival rates of >95% are anticipated in simple truncus arteriosus. The association of severe truncal insufficiency or interrupted aortic arch is a relative risk factor for early mortality; however, good results have been achieved in these subsets of patients also. Patients who survive the perioperative interval have surprisingly good long-term results after repair of truncus arteriosus. Recent evaluation of the long-term results from San Francisco has shown a significant need for reoperation for conduit revision; however, the rates of late morbidity and mortality with this lesion are very low, and the long-term functional results are excellent. Durability of truncal valve repair has improved with contemporary techniques, although truncal valve surgery remains a significant risk factor for death.

CONCLUSION
Whereas truncus arteriosus has been associated with a very significant early and late mortality in the past, the repair of truncus arteriosus in the neonatal period has been associated with a progressive improvement in results. Although several innovative techniques of repair have been developed to obviate the need for use of allograft conduits for outflow tract reconstruction of the right ventricle, we believe that the presence of a competent pulmonary valve early after repair leads to improved postoperative hemodynamic stability. The low morbidity and mortality from late conduit revision have supported this approach. Nevertheless, the use of an allograft conduit in a neonate will lead to a virtually certain need for operative reintervention for conduit change; therefore, the use of autologous tissue in right ventricular outflow tract reconstruction has inherent appeal. Improvements in postoperative management of neonates after complex reconstructive surgery have resulted in significant improvement in the prognosis for children with truncus arteriosus complex, even those with significant additional abnormalities including truncal valve stenosis and regurgitation or interrupted aortic arch.

VSD patch

Fig. 87.17. The anterior circumference of the pulmonary homograft is secured with a polytetrafluoroethylene (Gore-Tex) or a polyethylene terephthalate (Dacron) patch sewn to the margins of the ventricular septal defect (VSD) up to the pulmonary homograft, reconstructing the left ventricular outflow tract. The coronary ostia are then reimplanted into the pulmonary homograft in the usual manner and the distal anastomosis to the ascending aorta created.

Fig. 87.18. The right ventricular outflow tract is reconstructed.
Truncus is a highly lethal defect that must be repaired in infancy. As these authors have described, Dr. Ebert presented the first large series of these patients who were operated on with an acceptable surgical mortality.

The best parts of this description are the emphases on safety during the initial repair. The importance of snaring the pulmonary artery if the patient is overcirculated and the possibilities of pulmonary overcirculation doing cardiopulmonary bypass are well described. In addition, the issues with the coronaries are also described. The left main coronary is often quite high and one must be careful to look for this when transecting the aorta and removing the pulmonary artery bifurcation.

We have differed from Dr. Spray and used pulmonary homograft early on. He has suggested aortic homograft because of the proper curve. He makes a good point but the early calcifications of these conduits are worrisome to us. Finally, I think there is a place for the percutaneous pulmonary valve in the reoperative situation if the conduit is big enough.

ILK
DOUBLE-OUTLET RIGHT VENTRICLE

Definition

Double-outlet right ventricle (DORV) refers to a heterogeneous group of cardiac malformations characterized by an abnormal ventriculoarterial connection in which both great arteries are related to the right ventricle. Although the term double-outlet right ventricle can be correctly applied to hearts with atrioventricular discordance (e.g., congenitally corrected transposition of the great arteries) or to hearts with univentricular atrioventricular connections (e.g., double-inlet left ventricle), for simplicity of discussion, only hearts with atrioventricular concordance and two adequate ventricles are discussed in this chapter.

The actual definition of what constitutes a DORV has been the source of controversy in the literature. Although some have required the presence of bilateral infundibula or atrioventricular valve-semilunar valve discontinuity (most commonly mitral-aortic discontinuity), these criteria are not essential in establishing the diagnosis of DORV. From a surgical perspective, it is most useful to adopt the "50% rule" in defining DORV. With this rule, a heart is termed DORV if >50% of both great arteries arise from the right ventricle. Usually, all of one great artery and ≥50% of the other great artery arise from the right ventricle in DORV.

Classification

A ventricular septal defect (VSD) is almost always present with DORV. Based on the work of Lev and colleagues, DORV is classified into four groups based on the relationship of the VSD to the great arteries (Table 88.1): subaortic, subpulmonary, doubly committed, and noncommitted (remote).

Subaortic Ventricular Septal Defect

DORV with subaortic VSD (Fig. 88.1A) is the most common group of DORV. It may or may not be associated with pulmonary stenosis. The presentation without pulmonary stenosis is similar to that of a child with a large VSD (heart failure). If there is pulmonary stenosis, it is usually infundibular, so the clinical presentation in this subgroup is similar to that of tetralogy of Fallot (cyanosis, hypercyanotic episodes). Accordingly, if a patient is not a candidate for complete repair at the time of presentation because of size, clinical condition, or other variables, palliative procedures in DORV with subaortic VSD without pulmonary stenosis would be pulmonary artery banding; in children with pulmonary stenosis, a systemic-to-pulmonary artery shunt would be appropriate.

Subpulmonary Ventricular Septal Defect

DORV with subpulmonary VSD (the Taussig-Bing anomaly) is the second most common group of DORV (Fig. 88.1B). Because of the location of the VSD, oxygenated left ventricular blood preferentially streams through the VSD into the pulmonary artery and desaturated right ventricular blood streams into the aorta as in transposition of the great arteries with VSD. These children present with cyanosis and heart failure. Associated coarctation of the aorta occurs commonly; aortic arch obstruction and subaortic stenosis can also be associated with the Taussig-Bing anomaly. Because DORV with subpulmonary VSD is prone to early development of pulmonary vascular obstructive disease, intervention in infancy is usually necessary. In addition to repair of the aortic coarctation and arch hypoplasia, if present, balloon atrial septostomy is commonly needed to improve mixing of oxygenated blood at the atrial level as in transposition of the great arteries. Although palliation can be accomplished with pulmonary artery banding, it is preferable to proceed with complete repair in infancy.

Doubly Committed Ventricular Septal Defect

In DORV with doubly committed VSD, the VSD is immediately beneath both the pulmonary artery and the aorta (Fig. 88.1C). Usually, the infundibular septum is absent or hypoplastic. As in DORV with subaortic VSD, there may be associated pulmonary stenosis. Thus, clinical presentation and surgical approach would be similar to that for DORV with subaortic VSD with or without pulmonary stenosis.

Noncommitted Ventricular Septal Defect

In the final group of DORV, the VSD is committed neither to the aorta nor to the pulmonary artery (Fig. 88.1D). The remote location of the VSD may be in the inlet septum as with atroventricular septal defects or a muscular VSD in the trabecular septum. Pulmonary stenosis may be present. The presentation and surgical palliation of DORV with noncommitted VSD would be similar to that for DORV with subaortic VSD with or without pulmonary stenosis.

Surgical Techniques

The goal of surgical repair in DORV is to achieve a biventricular repair utilizing the left ventricle as the systemic ventricle with unobstructed right and left ventricular outflow tracts. Usually, this can be accomplished within the first 6 to 12 months of life, thus obviating the need for palliative procedures. If it is anticipated that the final repair will require an extracardiac valved conduit or a complicated intraventricular tunnel, it is reasonable to delay correction to allow for growth by palliating, if necessary, with a pulmonary artery band or a systemic-to-pulmonary artery shunt. Also, in children who eventually will need a Fontan procedure, it is critical to protect the pulmonary vascular bed early on with appropriate palliation.

TGA, transposition of the great arteries; TOF, tetralogy of Fallot; VSD, ventricular septal defect.

Roughly 10% of children with DORV will have a restrictive VSD. By definition, this means that outflow from the left ventricle is obstructed, and therefore, early repair with enlargement of the VSD is mandated since spontaneous closure of the VSD, rather than being curative as in isolated VSD, would be fatal in DORV. Pulmonary artery banding is certainly not appropriate in patients with DORV and a restrictive VSD.

Intraventricular Tunnel Repair of Double-Outlet Right Ventricle with Subaortic Ventricular Septal Defect without Pulmonary Stenosis

Repair of DORV with a subaortic VSD is accomplished by creating an intraventricular tunnel channeling left ventricular blood through the VSD to the aorta (Fig. 88.2). This is facilitated by the use of a polyester (Dacron) or collagen-impregnated polyester tube graft corresponding to the size of the aorta. This is opened longitudinally so that about two-thirds of its circumference is available (Fig. 88.2A). The advantage of using a tube graft for the intraventricular tunnel is that the corrugations keep the required curve in the baffle to allow unobstructed left ventricular outflow. A flat Dacron or polytetrafluoroethylene (Gore-Tex) patch that one would use to close a simple VSD would be prone to kinking.

Fig. 88.2. Intraventricular tunnel repair of double-outlet right ventricle with subaortic ventricular septal defect (VSD) without pulmonary stenosis. (A) A (polyester) Dacron or Hemashield tube graft the size of the aorta is opened longitudinally for use as the patch. Suturing is started through the midportion of the graft and the base of the anteroseptal commissure of the tricuspid valve. (B) The VSD is exposed through a right ventriculotomy. The safe area for the enlargement of the VSD is shown with a dashed line. (C) The intraventricular tunnel is completed with pledgetted or continuous sutures. Care is taken to maintain orientation of the tube graft so one end is at the anterior-inferior margin of the VSD and the other end is anterior to the aortic valve. The arrow indicates flow of blood from the left ventricle through the enlarged VSD and tunnel to the aorta.

and would create obstruction unless the geometry and the size of the patch were exactly perfect.

After routine establishment of cardiopulmonary bypass with bicaval cannulation and cardioplegic arrest, the intracardiac anatomy is carefully inspected through a right atriotomy. The VSD is visualized through the tricuspid valve and its relationship to the aorta is confirmed. If there is any suspicion preoperatively or intraoperatively that the VSD is smaller than the aorta, it should be enlarged. This can be accomplished through the tricuspid valve or the right ventricle with either a transverse or a longitudinal right ventriculotomy. The VSD is enlarged superiorly and anteriorly (Fig. 88.2B), thus resecting some of the infundibular septum. Enlarging the VSD posteriorly and superiorly through the ventriculoinfundibular fold runs the risk of going outside the heart. The conduction tissue runs inferiorly and of course should be avoided (Fig. 88.1A).

Once the VSD is enlarged (if necessary), the Dacron tube graft is oriented so that the longitudinal axis of the graft corresponds to an imaginary line from the anterior-most portion of the aorta to the anterior-inferior limit of the VSD (Fig. 88.2C). It is helpful to place the first suture through the base of the tricuspid valve leaflet at the anteroseptal commissure, and then through the midportion of the tube graft (Fig. 88.2B). About one-third of the VSD sutures are placed along the posterior and inferior rim of the defect through the tricuspid valve, with care taken to avoid the conduction tissue, with several of these pledged sutures on the atrial side of the septal leaflet of the tricuspid valve. These sutures are passed through the Dacron tube graft, which is seated down and the sutures tied. The remainder of the circumference of the VSD is closed through the Dacron tube graft, which is seated down and the sutures tied. Repair of Double-Outlet Right Ventricle with Subaortic Ventricular Septal Defect and Pulmonary Stenosis

In the group of patients with DORV with subaortic VSD and pulmonary stenosis, it is useful to mark the planned right ventriculotomy incision with stay sutures before cardioplegic arrest after carefully identifying the course of the epicardial coronary arteries (Fig. 88.3A). The intraventricular tunnel repair of the VSD is identical to that used for patients with DORV and subaortic VSD without pulmonary stenosis (Fig. 88.3B). If a major coronary artery crosses the right ventricular outflow tract or if the pulmonary vascular resistance is elevated or if there is distal pulmonary arterial obstruction, a valved conduit should be used to establish right ventricle–pulmonary artery continuity. The pulmonary trunk is divided, with the proximal main pulmonary artery oversewn (Fig. 88.3B). The proximal portion...
Chapter 88: Double Outlet Ventricles

Fig. 88.3. Repair of double-outlet right ventricle with subaortic ventricular septal defect and pulmonary stenosis. (A) The site of the proposed right ventriculotomy is shown by a dashed line. Marking sutures are placed before cardioplegic arrest to aid with retraction and to properly orient the ventricular incision. (B) An intraventricular tunnel is fashioned as in Figure 88.2. The main pulmonary artery is divided and the cardiac end oversewn. (C) Right ventricle-to-pulmonary artery continuity is reestablished with a valved homograft conduit. About one-half of the circumference of the proximal homograft is sutured to the superior aspect of the right ventriculotomy. (D) Alternatively, a nonvalved transannular right ventricular outflow tract patch can be used to relieve the pulmonary stenosis.

of a valved homograft is sewn to the superior aspect of the right ventriculotomy. The homograft is trimmed to the proper length, and an end-to-end anastomosis between the distal homograft and the distal main pulmonary artery (or pulmonary bifurcation if the main pulmonary artery is small) is performed. Finally, the gap between the proximal right ventriculotomy and the proximal homograft is roofed with leftover homograft material or autologous pericardium (Fig. 88.3C). Alternatively, the native pulmonary trunk can be left intact, and the distal homograft conduit is sewn end-to-side to the junction of the native pulmonary trunk and pulmonary bifurcation allowing blood flow through both the stenotic native pulmonary valve and the new conduit.

Often it is possible to establish an adequate right ventricular outflow tract without a valved conduit as is done with repair of tetralogy of Fallot. In this case, after the division of obstructing right ventricular muscle bundles, a transannular outflow tract patch is created using autologous pericardium (Fig. 88.3D). If the pulmonary valve annulus is of good size, a nontransannular patch is adequate after a pulmonary valvotomy is performed. Otherwise, a transannular patch is necessary.

Sakamoto and colleagues have described an interesting transaortic approach for enlarging the VSD and tunneling left ventricular outflow through the VSD to the aorta in two patients with DORV with subaortic VSD and pulmonary stenosis.

Anatomic Repair of Double-Outlet Right Ventricle with Subpulmonary Ventricular Septal Defect

Currently, the preferred surgical repair of DORV with subpulmonary VSD (the Taussig–Bing anomaly) is the anatomic repair (the arterial switch operation). Since coarctation of the aorta is commonly seen in this group, these patients may have had prior coarctation repair with a pulmonary artery band, although simultaneous repair of the coarctation at the time of anatomic repair is now the accepted standard.

The VSD is closed either through a right atriotomy or through a right ventriculotomy channeling left ventricular blood into the pulmonary artery (Fig. 88.4A). The aorta is transected slightly higher than the pulmonary trunk (Fig. 88.4A). If present, the coarctation and associated aortic arch hypoplasia can be corrected at this time with a patch of homograft material using a brief period of profound hypothermia with circulatory arrest or regional low flow perfusion.

Particularly with side-by-side great arterial relationships, the circumflex coronary artery often arises with the right
Fig. 88.4. Anatomic repair of double-outlet right ventricle with subpulmonary ventricular septal defect (arterial switch operation). (A) The level of transection of the great arteries is shown with a dashed line. With a side-by-side relationship of the great arteries, the aorta should be divided higher than the main pulmonary artery. The ventricular septal defect is closed through a right ventriculotomy or right atriotomy, directing blood to the pulmonary artery. (B) The anterior descending coronary ostial button is transferred to an oval defect in the neoaorta. The right coronary-circumflex coronary ostial patch extends to the level of aortic transection as a U-shaped button. It is incorporated into the aortic suture line. The pulmonary bifurcation has been brought anterior to the distal aorta (the LeCompte maneuver). The incision along the undersurface of the right pulmonary artery (RPA) is indicated with a dashed line. (C) A large pericardial patch closes the U-shaped defect in the proximal neopulmonary artery and extends onto the undersurface of the RPA. Separate patches close the harvest site of the anterior descending coronary ostial button and the left lateral aspect of the pulmonary trunk. (D) With the same technique as in Figure 88.4C, the LeCompte maneuver can be avoided, leaving the pulmonary bifurcation posterior to the ascending aorta.

coronary artery from the right posterior-facing sinus, whereas the anterior descending coronary artery originates from the left posterior-facing sinus. In this situation, the anterior descending coronary artery is excised as a button and transferred to a defect created in the left anterior-facing sinus of the proximal pulmonary trunk (neoaorta; Fig. 88.4B). The right and circumflex coronary ostium is excised as a large U-shaped button. It is transferred above the right anterior-facing sinus of the proximal pulmonary trunk (neoaorta) and incorporated into the suture line between the proximal pulmonary trunk (neoaorta) and the distal ascending aorta (Fig. 88.4B). Positioning this coronary button more superiorly as it is transferred to the left avoids potential kinking of the circumflex coronary artery.

Reconstruction of the right ventricular outflow tract when the great arteries are side by side can cause compression of one of the coronary arteries or predispose to right ventricular outflow tract obstruction if performed exactly as one would with typical transposition of the great arteries, since there is so much offset between the “old” proximal ascending aorta (neopulmonary artery) and the distal pulmonary trunk. This potential problem can be addressed by opening the right lateral aspect of the distal pulmonary trunk onto the undersurface.
of the right pulmonary artery (Fig. 88.4B) after performing the LeCompte maneuver (bringing the pulmonary bifurcation anterior to the distal ascending aorta). The U-shaped defect in the "old" proximal ascending aorta at the site of the right and circumflex coronary ostial button is repaired with a patch of autologous pericardium or homograft material that is much wider distally. This increases the circumference of the proximal neopulmonary artery to accommodate for the typical size discrepancy between the smaller proximal aorta and the larger distal pulmonary trunk. This same patch is incorporated into the incision on the undersurface of the right pulmonary artery (Fig. 88.4C) to allow for a generous tension-free pulmonary arterial anastomosis and has the benefit of pulling the new pulmonary trunk right away from the right coronary artery. Both the old site of the anterior descending coronary artery button and the slight overhang on the left lateral aspect of the distal pulmonary trunk are closed with small pericardial or homograft patches. If the U-shaped patch filling the defect in the right posterior-facing sinus is broad enough distally, it accomplishes the same effect as a pantaloon patch for repairing both coronary button defects and is somewhat easier to do.

Alternatively, with side-by-side great arteries, pulmonary artery reconstruction can be performed using the same techniques outlined above without incorporating the LeCompte maneuver (Fig. 88.4D). To do this, it is very important to transect the aorta higher than the pulmonary trunk at the beginning of the repair (Fig. 88.4A).

**Intraventricular Repair of Double-Outlet Right Ventricle with Subpulmonary Ventricular Septal Defect**

In patients with DORV and subpulmonary VSD with side-by-side great arteries, an intraventricular tunnel repair is feasible. The subpulmonary VSD is exposed through a transverse right ventriculotomy (Fig. 88.5A). Often it is necessary to enlarge the VSD anteriorly and superiorly. The infundibular septum between the aorta and pulmonary artery is usually quite prominent and in fact can cause subaortic obstruction preoperatively. This is excised to provide an unimpeded channel from the left ventricle through the VSD to the aorta (Fig. 88.5B). Usual care must be taken to avoid injury to the conduction tissue (Fig. 88.1B). The intraventricular tunnel is now created using an opened Dacron or Hemashield tube graft as employed with DORV and subaortic VSD (Fig. 88.5C). Although the illustration in Figure 88.5C depicts interrupted pledgetted sutures, a continuous suture technique can also be used.

If the relationship of the great arteries is more anteroposterior than side by side, there is inadequate distance between the tricuspid valve and the pulmonary valve. The intraventricular tunnel will obstruct the subpulmonary region. Therefore, patients with DORV and subpulmonary VSD with anteroposterior great arteries should not undergo an intraventricular tunnel repair; anatomic repair with closure of the VSD to the pulmonary artery and an arterial switch operation are preferable.

**Damus–Kaye–Stansel Repair of Double-Outlet Right Ventricle with Subpulmonary Ventricular Septal Defect**

There is a subset of patients with DORV and subpulmonary VSD who have significant subaortic stenosis that may not lend itself to adequately successful resection. This would preclude an arterial switch operation, since postoperative right ventricular outflow tract obstruction would result. There are also a very small number of patients with coronary artery anatomy that makes it too risky to perform an arterial switch operation depending on the experience of the individual surgeon (e.g., intramural coronary artery or single coronary artery), although these situations have become less common as techniques dealing with these more challenging coronary abnormalities have evolved. In these situations, an arterial switch operation without coronary translocation (Damus–Kaye–Stansel procedure) is a feasible alternative.

With the Damus–Kaye–Stansel procedure, the subpulmonary VSD is closed either through the right atrium or through a right ventriculotomy incision to direct left ventricular blood through the pulmonary valve (Fig. 88.6A). The pulmonary trunk is transected just proximal to the pulmonary bifurcation. It is critical to avoid distortion of the proximal pulmonary trunk or ascending aorta, which may result in semilunar valve insufficiency. Before cardioplegic arrest, it is helpful to place a marking suture on the right medial aspect of the proximal pulmonary trunk at the planned site of transection. A corresponding marking suture is placed on the left medial aspect of the ascending aorta to define the proximal extent of the aortic incision and to ensure proper orientation of both great arteries. The aorta is opened along its left medial aspect from the previously placed marking suture distally for a length corresponding to the diameter of the pulmonary trunk. The incision on the aorta should start just above the commissural posts of the aortic valve. Attention should be given to carefully identify the coronary arteries and avoid any distortion. An end-to-side anastomosis between the proximal pulmonary trunk and the left medial aspect of the ascending aorta is performed using a continuous suture technique. It is surprising how often this anastomosis can be performed primarily without additional patch augmentation (Fig. 88.6A). However, in children with previous pulmonary artery banding, the level of transection of the pulmonary trunk is at the level of the band. After the scar tissue is excised from the band site, it is usually necessary to augment the end-to-side pulmonary aortic anastomosis with autologous pericardium or homograft material. Right ventricle-to-pulmonary artery continuity is now established with a homograft valved conduit (Fig. 88.6B).

Alternatively, the ascending aorta can be transected at the same level as the pulmonary trunk. A partial side-to-side anastomosis is constructed between the proximal ascending aorta and the proximal pulmonary trunk. The distal ascending aorta is anastomosed to this double-barreled arterial connection, commonly after patch enlargement of the ascending aorta and arch. The advantage of this double-barreled technique compared with the end-to-side anastomosis depicted in Figure 88.6 is less risk of semilunar valve distortion with subsequent insufficiency as well as the ease of enlarging the distal aorta.

With the Damus–Kaye–Stansel procedure, the aortic valve is still connected to the right ventricle. Since aortic pressure is always higher than right ventricular pressure throughout the cardiac cycle, the aortic valve remains closed. Right ventricular output is through the valved conduit into the lower pressure pulmonary arteries rather than through the aortic valve into the higher pressure systemic circulation. Obviously, any significant aortic valve insufficiency would be poorly tolerated, since the regurgitant blood would flow into the right ventricle, causing a left-to-right shunt that could be misdiagnosed as a residual VSD. In the case of significant aortic valve insufficiency, the aortic valve itself can be oversewn primarily without much difficulty. With current advances in the arterial switch procedure and the creation of intraventricular tunnels, it is uncommon to resort to a classical Damus–Kaye–Stansel procedure.
Repair of Double-Outlet Right Ventricle with Doubly Committed Ventricular Septal Defect

Surgical repair of the uncommon variant of DORV with doubly committed VSD is managed in much the same manner as described for DORV with subaortic VSD. The VSD is usually large, so channeling left ventricular blood to the aorta with an intraventricular tunnel does not present much difficulty. If there is pulmonary stenosis or if the VSD patch obstructs flow into the pulmonary artery, it may be necessary to perform a right ventricular outflow tract patch or to use a right ventricle-to-pulmonary artery valved conduit.

Repair of Double-Outlet Right Ventricle with Noncommitted Ventricular Septal Defect

A satisfactory biventricular repair of DORV with noncommitted VSD is more difficult because the remoteness of the VSD necessitates a complex intraventricular tunnel to direct blood from the left ventricle through the VSD to the aorta. If the VSD is in the inlet perimembranous location, the VSD must be carefully inspected for straddling tricuspid valve or even mitral valve tissue, which would preclude biventricular repair. If the VSD is small, it can be safely enlarged superiorly and anteriorly (Fig. 88.7A), since the conduction tissue in a perimembranous inlet VSD courses along the posterior and inferior rim of the defect on the left ventricular side of the septum similar to DORV with subaortic VSD (Fig. 88.1A). The intraventricular tunnel is then fashioned with a patch tailored from a Dacron or Hemashield tube graft (Figs 88.2A and 88.7B). The techniques and precautions described in the section on intraventricular tunnel repair of DORV with subaortic VSD are very much applicable to this repair of...
DORV with noncommitted perimembranous inlet VSD. Usually, even if there is no preexisting pulmonary stenosis, the large and bulky intraventricular patch creates some obstruction to the pulmonary valve so that a right ventricular outflow tract patch or a right ventricle-to-pulmonary artery valved conduit is necessary.

Sometimes, the noncommitted VSD is a muscular defect in the trabecular septum. If the VSD is small, it is enlarged anteriorly and inferiorly (Fig. 88.8A), since the conduction tissue courses on the superior posterior aspect of the defect (Fig. 88.1D). A suture line with the intraventricular tunnel repair as described above would not only place the conduction tissue at jeopardy as the patch is brought up to the aorta but also risks distortion of the tricuspid valve apparatus. For these reasons, in this situation the Dacron or Hemashield tube graft is left intact, with one end sutured around the VSD and the other end around the aortic valve (Fig. 88.8B). This large intraventricular tube is quite bulky and may obstruct right ventricular outflow, mandating the use of right ventricular outflow tract patch or right ventricle-to-pulmonary artery valved conduit. An obvious disadvantage to this intraventricular tube graft repair is the lack of potential for growth in the channel from the VSD to the aorta. Therefore, the tube graft must be of adult size at the time of the original repair or one must be resigned to reoperation to enlarge the tube as the child outgrows it.

An alternative approach to correction of DORV with noncommitted VSD has been described by Lacour-Gayet and colleagues wherein an intraventricular baffle is constructed to route the left ventricular outflow through the VSD (after surgical enlargement) to the pulmonary artery and then an arterial switch procedure is performed. An even more complex biventricular repair strategy is the use of multiple intraventricular patches to direct left ventricular outflow through the noncommitted VSD to the aorta.

There are situations in which a satisfactory biventricular repair cannot be safely accomplished with DORV and noncommitted VSD. Examples are multiple muscular VSDs, an inability to reliably channel the remote VSD to the aorta, or straddling atrioventricular valve tissue (although Serraf has described the innovative techniques to establish a biventricular repair with straddling atrioventricular valves). In these patients who are unsuitable for a biventricular repair, a modified Fontan procedure can be used effectively. Even though this will result in a physiologic univentricular repair, it is reasonable to enlarge a restrictive VSD
Fig. 88.7. Intraventricular tunnel repair of double-outlet right ventricle with noncommitted perimembranous inlet ventricular septal defect (VSD). (A) The VSD is exposed through a right ventriculotomy. The safe area for superior and anterior enlargement of the VSD is marked with a dashed line. (B) The intraventricular tunnel is created with an opened polyester (Dacron) tube graft, channeling left ventricular blood through the VSD to the aorta (arrow).

Complications and Postoperative Considerations

Many of the important complications after surgical repair of DORV are mechanical in nature and should be routinely sought out in the operating room after the patient is separated from cardiopulmonary bypass and addressed at that time if possible. With the routine use of intraoperative transesophageal echocardiography, many of these problems are recognized early allowing expeditious correction.

The same possible complications seen with closure of straightforward VSDs can occur during repair of DORV with VSD, particularly if it is necessary to enlarge the VSD during the correction. Surgically induced heart block can occur and underscores the importance of assiduously avoiding the area of the conduction tissue during repair (Fig. 88.1). Residual left-to-right shunting across the VSD patch or intraventricular baffle can severely compromise the patient’s hemodynamic status. In addition to intraoperative transesophageal echocardiography which will help precisely locate any residual leak, measurements of oxygen saturations across the right heart will help quantify the magnitude of the shunt. Certainly, any residual calculated $Q_s/Q_a$ ratio of 2:1 should be addressed in the operating room and probably a ratio of >1.5:1 should also be corrected.

The use of an intraventricular tunnel in the repair of most forms of DORV raises the possibility of left ventricular outflow tract obstruction, from either inadequate enlargement of a restrictive VSD or poor configuration of the intraventricular tunnel patch with resultant obstruction. Again, intraoperative echocardiography is helpful in identifying and localizing any narrowings. Careful simultaneous measurements in the operating room of left ventricular and aortic pressures will identify any residual left ventricular outflow tract gradient. If there is a significant residual gradient, it is helpful to inspect the left ventricular outflow tract through an aortotomy. Residual obstructing muscle often can be resected through the aortic valve. If the patch is the cause of obstruction, rather than replacing the entire intraventricular tunnel patch, it is possible to visualize the narrowed area through the
Double Outlet Ventricles

Aorta and relieve the obstruction through the right ventricle by incising the intraventricular tunnel patch at the site of narrowing and enlarging it with a separate patch of Dacron or pericardium. Although perhaps not aesthetically pleasing, this technique can be an easy solution to a potentially life-threatening complication.

Similarly, significant right ventricular outflow tract obstruction can occur after repair as a result of inadequate relief of preexisting pulmonary stenosis, obstructing muscle bundles, or obstruction from the intraventricular tunnel patch. Again, intraoperative pressure measurements and echocardiography help identify and locate the site of obstruction, which should be dealt with at the time of recognition if significant.

Myocardial dysfunction can be a significant problem postoperatively because of the complex and sometimes lengthy intraoperative repairs as well as the uniform presence of significant right ventricular hypertrophy and possibly even left ventricular hypertrophy in patients with a restrictive VSD. Naturally, diligent intraoperative myocardial protection is crucial. Postoperatively, in addition to inotropic support, fairly high right-sided filling pressures are often necessary to maintain adequate cardiac output because of the stiff, poorly compliant, hypertrophied right ventricle. In patients in whom it is anticipated that there will be postoperative right ventricular dysfunction due to existing right ventricular hypertrophy, extensive right ventricular incisions, or residual right ventricular outflow tract obstruction, it can be helpful to leave an interatrial communication (typically by not closing the patent foramen ovale) to allow right-to-left shunting. This strategy maintains systemic ventricular output at the expense of usually well-tolerated systemic arterial desaturation.

Particularly in children without pulmonary stenosis, pulmonary hypertension can be problematic in the early postoperative period and should be identified and treated with the usual measures of sedation, paralysis, pulmonary vasodilatation, and hyperventilation. In the past, when complete repair was delayed until later in life, pulmonary vascular obstructive disease was an important cause of postoperative mortality. Occasionally, delaying sternal closure until after the improvement of myocardial dysfunction and reduction of tissue edema can be life saving.

Finally, children undergoing the arterial switch repair of DORV with subpulmonary VSD can develop coronary ischemia even with technically adequate coronary transfer. Avoidance of ventricular distention and systemic hypertension in this situation is key.

**DOUBLE-OUTLET LEFT VENTRICLE**

**Definition**

Double-outlet left ventricle (DOLV) is a rare form of congenital heart disease in which >50% of both great arteries arise from the left ventricle. As with DORV, DOLV can be associated with atrioventricular
Section III: Congenital Cardiac Surgery

**Anatomy and Presentation**

A VSD is almost always present with DOLV and is usually subaortic in location, although it can be subpulmonic. There are no reports of DOLV with two well-developed ventricles in which the VSD is remote or absent. Pulmonary stenosis is present in most cases of DOLV and can be either valvular or subvalvular.

Children with DOLV with pulmonary stenosis will present with a clinical picture similar to that for tetralogy of Fallot with cyanosis. Palliation with a systemic-to-pulmonary shunt is very satisfactory. The uncommon patient with DOLV without pulmonary stenosis will present with symptoms of excessive pulmonary blood flow with heart failure, much like a patient with an unrestricted VSD. Interestingly, there may be some systemic desaturation due to the mixing of systemic and pulmonary venous return in the left ventricle. These children may be palliated early in life with a pulmonary artery band.

**Surgical Technique**

Complete surgical repair of DOLV is usually simpler than repair of DORV, since the aorta arises completely from the left ventricle, thus eliminating the need for a complex intraventricular tunnel. Furthermore, the VSD is unrestrictive, so there is no need to enlarge the VSD.

In patients with DOLV with pulmonary stenosis, the VSD is exposed through a right ventriculotomy (Fig. 88.9A). It is closed with a Dacron patch, with standard precautions taken to avoid injury to the conduction tissue, which lies in the usual location on the left ventricular side of the posterior-inferior portion of the defect (Fig. 88.9B). The proximal main pulmonary artery is divided and the cardiac end oversewn (Fig. 88.9A). Right ventricle-to-pulmonary artery continuity is established using a homograft valved conduit (Fig. 88.9C).

There are reports of total intracardiac repairs of DOLV without pulmonary stenosis in which the VSD is patched to direct right ventricular outflow through the VSD into the pulmonary artery. However, except in the most ideal situations, it is still probably easier to repair DOLV without pulmonary stenosis in the same manner as DOLV with pulmonary stenosis (i.e., simple patch closure of the VSD, oversew the proximal pulmonary artery, and establish right ventricle-to-pulmonary artery continuity with a homograft valved conduit; Fig. 88.9). In many cases with subaortic VSD and pulmonary outflow tract obstruction, the anatomic substrate for the pulmonary obstruction is typically subvalvular with only mild or no pulmonary valve stenosis. In these cases, after closing the subaortic VSD channeling left ventricular outflow to the aorta, the pulmonary root can be harvested with the valve intact (similar to the technique for a Ross procedure) and then translocated to the right ventricle. This obviates the need for a homograft valved conduit with its attendant requirement for eventual replacement.

**Complications and Postoperative Considerations**

As with surgical closure of a routine VSD, in repair of DOLV the risks of surgically induced heart block or residual left-to-right shunts exist, but there is nothing about DOLV that makes these complications more or less likely when the usual precautions and careful surgical techniques are used. Since all patients with DOLV have hypertrophied right ventricles, postoperative right ventricular dysfunction with a stiff, poorly compliant right ventricle...
can occur but is usually not problematic. Finally, as with any extracardiac valved conduit, improper technique can result in right ventricular outflow tract obstruction, which should be identified and corrected in the operating room.

**SUGGESTED READINGS**

The anatomic spectrum of DORV continues to require multiple operative approaches. In complex forms of these defects, surgical decision making can be difficult. The use of intraventricular tunnel repairs, often with the need for right ventricular outflow tract reconstruction with valved conduits, has led to a significant incidence of reoperation in these patients for conduit exchange. In addition, inadequate resection of septal muscle and enlargement of the VSD can result in progressive obstruction of the intraventricular tunnel and subaortic stenosis. The problems with these late defects have led some authors to suggest that in complex forms of DORV, conversion to a single-ventricle type of repair is preferable and may actually decrease the risk of late reoperation and complications.

A patient with subpulmonary VSD and DORV (the Taussig–Bing heart) commonly has associated coarctation of the aorta. Although repair of the coarctation and pulmonary artery banding can be performed for this condition, we perform primary complete repair in these infants. The division of the aorta at the time of the arterial switch procedure allows reconstruction of the arch by patch enlargement without difficulty and a low risk of recurrence of stenosis.

Even when complete correction requires the use of an extracardiac conduit, we primarily repair most patients with nonrestrictive pulmonary outflow tracts to prevent the complications of pulmonary artery banding, which may exacerbate myocardial hypertrophy and, in some cases with relatively restrictive VSDs, cause progressive subaortic obstruction. The progression of subaortic obstruction then drives more blood through the pulmonary artery band. These patients represent a very difficult subgroup at second-stage operation. Often they have been followed with a pulmonary artery band with good oxygen saturations and yet have had progressive subaortic obstruction. Thus, the actual $Q_a/Q_s$ ratio may not be restricted, and a significant left-to-right shunt may predispose the patient to develop pulmonary vascular disease. This is a particularly difficult situation in those patients who are being staged to single-ventricle correction. Bidirectional Glenn shunting or hemi-Fontan procedures should be performed early even if pulmonary artery banding is undertaken in infancy. Subjecting these patients to significant left-to-right shunts as subaortic stenosis develops in the face of a pulmonary band results in a very high risk of inadequate pulmonary circulation at the time of reoperation for Damus–Kaye–Stansel connection and bidirectional Glenn shunting. Therefore, a close follow-up is necessary after pulmonary artery banding to avoid this complication.

When a Damus–Kaye–Stansel operation is necessary because of subaortic obstruction, we augment the arch of the aorta as in the Norwood operation in most cases. Patients with significant subaortic obstruction. Thus, the actual $Q_a/Q_s$ ratio may not be restricted, and a significant left-to-right shunt may predispose the patient to develop pulmonary vascular disease. This is a particularly difficult situation in those patients who are being staged to single-ventricle correction. Bidirectional Glenn shunting or hemi-Fontan procedures should be performed early even if pulmonary artery banding is undertaken in infancy. Subjecting these patients to significant left-to-right shunts as subaortic stenosis develops in the face of a pulmonary band results in a very high risk of inadequate pulmonary circulation at the time of reoperation for Damus–Kaye–Stansel connection and bidirectional Glenn shunting. Therefore, a close follow-up is necessary after pulmonary artery banding to avoid this complication.

Therefore, a close follow-up is necessary after pulmonary artery banding to avoid this complication.
obstruction in infancy often have hypoplasia of the ascending aorta, and there is a significant size discrepancy between the ascending aorta and the proximal pulmonary artery. Therefore, direct connection of the pulmonary artery to the aorta, either primarily or with an augmentation hood, can result in kinking of the distalmost portion of the superior anastomosis with obstruction of the aorta, requiring additional augmentation or stenting. Creation of a long patch underneath the arch of the aorta prevents this kinking and augments the entire ascending aorta. A brief period of circulatory arrest is used for this portion of the operation.

Late restriction of the VSD when an intracardiac conduit is used is common enough that one should consider enlargement of virtually all VSDs in DORV at the time of complete repair. The exception may be isolated subaortic defects where there is a 50% override of the aorta and where the VSD is clearly as large as or larger than the aortic annulus.

Although intracardiac conduits can obstruct right ventricular outflow, it is also possible that the conduit attachments to the septal tricuspid leaflet can limit leaflet mobility and cause functional tricuspid stenosis.

Patients with DORV and uncommitted VSDs remain a difficult surgical challenge. Although resection of the anterior septum with inlet defects can occasionally permit an adequate left ventricular outflow without interfering with tricuspid valve function, in many cases complex intraventricular tunnels may be necessary, creating a virtual right-angled tunnel along the ventricular septum to the aorta.

In some cases with noncommitted VSD, the VSD is more directly related to the pulmonary artery than to the aorta. In these cases, in the absence of significant pulmonary stenosis, closure of the VSD to the pulmonary artery and arterial switch procedure is the best approach as is done in Taussig–Bing anomaly. In each case with noncommitted VSD, it is imperative to identify the relationship of the VSD to the great arteries and to conceptually craft a pathway from the VSD to the great vessels to decide when a two-ventricle repair can be accomplished. Very complex baffles with significant angulation are most likely to result in late stenosis; in such cases, the potential for obstruction is significant and, therefore in many cases, a single-ventricle-type repair might be the best approach.

There has been increasing interest in the use of three-dimensional (3-D) modeling systems using MRI data to help aid surgical planning in patients with DORV and noncommitted VSD. Although these modeling techniques do not account for the issue of straddling valves, which are best determined by echocardiography, creating 3-D models including creation of the 3-D printed casts of the cardiac anatomy can aid in designing the patches to prevent a pathway obstruction when an intraventricular tunnel is created.

The REV procedure described by LeCompte is a good alternative in patients who have significant amounts of infundibular muscle, which can interfere with the pathway from the VSD to aorta. Extensive resection of this muscle can create a more direct pathway from the left ventricle to aorta and prevent recurrent LV outflow tract obstruction following repair. DaSilva in Brazil has also described the technique of pulmonary artery translocation which can be used in some complex forms of DORV, moving the pulmonary root anterior to the aorta to the right ventricular outflow tract. Removing the pulmonary valve and root resects the subaortic and subpulmonary conus, which makes the VSD pathway to the aorta less obstructive.

DOLV remains an unusual condition. Although patch closure of the VSD is simple, overwashing of the pulmonary outflow and creation of a right ventricle-to-pulmonary artery conduit exposes the child to recurrent operation for conduit changes. As noted by Dr. Kanter, in some cases with unrestricted right ventricular outflow, the entire pulmonary valve and annulus can be excised from the ventricle and relocated onto the right ventricle with patch closure of the defect in the left ventricle. In this manner, a native valve can be reconstructed to the right ventricular outflow tract and potentially decrease the risk of late reoperation. Patients with significant pulmonary stenosis, however, are best treated with outflow reconstruction, either with a valved conduit or by direct reconstruction of the pulmonary confluence onto the right ventricle with the LeCompte maneuver and an anterior patch of pericardium or homograft material to create a nonvalved reconstruction. Coronary location often precludes primary outflow tract reconstruction with a transannular patch.

TLS
Transposition of the Great Arteries
Aaron W. Eckhauser and Thomas L. Spray

Complete transposition of the great arteries (TGA) is a congenital cardiac defect in which there is anatomic reversal of the relationship of the great arteries. The aorta arises entirely or largely from the right ventricle, and the pulmonary artery arises entirely or largely from the left ventricle (ventriculoarterial discordant connection). The lesion is incompatible with life without surgical intervention because in the resulting physiologic abnormality the pulmonary and systemic circulations exist in parallel instead of in series. Survival, therefore, depends on mixing between the pulmonary and systemic circulations. In spite of the severity of this cardiac defect, surgical therapy has become standardized such that anatomic and physiologic repair can be accomplished in the first few days of life in the majority of affected children.

TGA may coexist with other cardiac lesions, including coarctation of the aorta and patent ductus arteriosus. Transposition is associated with intact ventricular septum in approximately 50% of patients, ventricular septal defect (VSD) in 25%, and VSD with functional or anatomic left ventricular outflow tract obstruction (pulmonary stenosis) in 25%. Transposition with interruption of the aortic arch is a rare association.

ANATOMY

Complete TGA is characterized by atrioventricular concordance and ventriculoarterial discordance ([S,D,D] according to the Van Praagh classification system). There have been many interpretations and applications of the term transposition, but in this chapter, complete TGA is defined as atrial situs solitus, atrioventricular concordance, and ventriculoarterial discordance [S,D,D].

The morphogenesis of the abnormal relationship between the great arteries and the ventricles in TGA is controversial. In normal cardiac development, the subaortic conus is static, and dominant growth of the pulmonary conus forces the pulmonary valve anterior, superior, and to the left. Van Praagh suggested that in TGA the subaortic conus persists during normal looping of the ventricles, whereas the subpulmonary conus undergoes absorption. Differential growth of the subaortic conus in transposition, therefore, pushes the aorta anteriorly and disrupts the aortic-mitral valve continuity. If the subpulmonary conus fails to develop, the pulmonary artery will maintain a posterior location and pulmonary-mitral valve continuity will occur. Consequently, the aortic valve becomes anterior to the pulmonary valve, permitting both semilunar valves to connect with the distal great vessels without the rotation that is hypothesized to occur in normal cardiac development. Because canal development determines the rotation of the truncus arteriosus, the great arteries are similar in relationship at the semilunar valves as they are at the arch. Anatomic variations are often encountered, although the heart is left-sided with atrial situs solitus in 95% of patients. Left-to-right juxtaposition of the atrial appendages is a sign of other intracardiac anomalies. A true ostium secundum atrial septal defect is present in 10% to 20% of cases, but the majority of atrial communications are via a patent foramen ovale. Right aortic arch is present in 4% of patients with intact ventricular septum and up to 16% of those with VSD. Up to 50% of patients with TGA will have an associated VSD, many of which will spontaneously close. The VSDs are commonly perimembranous (conoven­tricular) in location, although they may be found anywhere in the ventricular septum. Pulmonary stenosis or atresia, overriding or straddling atrioventricular valves, coarctation of the aorta, and interruption of the aortic arch have all been noted in association with transposition and VSD.

The spatial relationship of the great vessels is quite variable, but the aorta is most frequently to the right and anterior to the pulmonary artery [S,D,D]. Less commonly, the aorta can be anterior and to the left with mirror-image branching ([L,L,L] or anterior and to the left with normal arch branching [S,D,L]). The sinuses of Valsalva and coronary artery ostia typically face the corresponding pulmonary arterial sinuses of Valsalva, permitting transfer of the coronary arteries in the arterial switch operation. Only a small number of patients who have a coronary artery that originates from a nonfacing coronary sinus pose a problem for arterial switch reconstruction.

The coronary anatomy can be described using a modified Leiden convention. In this description, the surgeon places themselves in the nonadjacent aortic sinus looking toward the pulmonary valve. The sinus to the surgeon’s right hand is labeled “1” and the sinus to the surgeon’s left hand is labeled “2” (Fig. 89.1). Coronary branching patterns can be described as normal, looping, or intramural. In the “normal” pattern, which accounts for 60% to 70% of cases, sinus 1 gives rise to the anterior descending and circumflex arteries. Sinus 2 gives rise to the right coronary artery. In this pattern, none of the major arterial branches crosses in front of or behind either of the major arterial trunks. The “looping” pattern, found in one-third of cases, results when one or more of the three major coronary arteries run in front of or behind the major arterial trunks. Posterior looping results when a coronary artery runs posterior to the pulmonary artery, most commonly the circumflex arising from sinus 2. Anterior looping results when one of the branches runs anterior to the aorta. This can occur when the left anterior descending artery arises from the right coronary artery in sinus 2 or a single coronary artery arises from either sinus 1 (right coronary artery crosses) or 2 (left main equivalent crosses). Branching patterns giving rise to double loops are not uncommon and account for 15% to 20% of cases. Finally, the “in­tramural” course occurs when a coronary artery appears to arise from one sinus, crosses through the media of the aortic wall behind the valve commissure, and
truly arises from the other adjacent aortic sinus. Occasionally, there is no true circumflex coronary artery, but separate branches arise from the left coronary to supply the corresponding portion of the left ventricle. Abnormal coronary branching patterns are more commonly seen in transposition with VSD than when an intact ventricular septum is present.

Important left ventricular outflow tract obstruction is unusual in association with TGA but has significant implications for management strategies. The most common type of left ventricular outflow tract obstruction is dynamic, resulting from leftward displacement of the hypertrophied muscular ventricular septum secondary to the development of higher right systemic ventricular pressure. The septum may then narrow the outflow tract, resulting in abnormal systolic anterior mitral leaflet motion and a situation similar to that noted in hypertrophic obstructive cardiomyopathy. Posterior malalignment of the ventricular septum may create a tunnel-like obstruction, and fibrous tags arising from the mitral apparatus or membranous septum can result in significant subvalvular obstruction, more commonly when a VSD is present. True valvar stenosis is uncommon, but a nonobstructive bicuspid pulmonary valve is not infrequently present. In rare cases, aortic arch obstruction with coarctation or true interruption of the aortic arch has been observed in patients with TGA, left ventricular outflow tract obstruction, and VSD.

**PATHOPHYSIOLOGY**

TGA {S,D,D} is a relatively common form of congenital heart disease, accounting for 9.9% of infants with congenital heart disease in a New England study and representing a frequency of 0.206 per 1000 live births. A distinct male predominance is noted, with a male-to-female ratio of 2:1, which increases to 3.3:1 when the ventricular septum is intact. In complex forms of transposition, a sexual predominance has not been noted. Untreated, 90% of children with D-TGA and an intact ventricular septum will die by 1 year of age.

The parallel relationship of the pulmonary and systemic circulations in TGA results in nonoxygenated venous blood passing through the right ventricle to the aorta, whereas the oxygenated pulmonary venous blood passes through the left ventricle back to the pulmonary artery. Mixing between the pulmonary and systemic circulations at the atrial, ventricular, or great vessel level through a patent foramen ovale or atrial septal defect, a VSD, or a patent ductus arteriosus is mandatory for survival. Patients with TGA and an intact ventricular septum survive initially because of aortopulmonary flow through a patent ductus arteriosus. After birth, both ventricles are relatively noncompliant, and infants with transposition often have increased pulmonary blood flow. This results in left atrial enlargement and functional incompetence of the foramen ovale with atrial level mixing of oxygenated and nonoxygenated blood. Inadequacy of mixing, however, will result in marginal tissue oxygenation that does not improve with oxygen administration. Atrial balloon septostomy results in improved admixture and improved tissue oxygen delivery.

Patients with TGA and significant VSD often have higher oxygen saturations by virtue of greater pulmonary blood flow and greater mixing at both the atrial and ventricular levels. In children with high pulmonary blood flow, pulmonary resistance may progressively increase during infancy. The early development of severe pulmonary vascular disease in children with TGA is exacerbated in patients with associated VSD. The rapid development of pulmonary obstructive disease may be related to hypoxemia, increased sympathetic activity, and excessive pulmonary blood flow.

Although neonatal pulmonary vascular resistance is elevated in infants with TGA, the resistance falls progressively during the neonatal period, coinciding with changes in the pulmonary and systemic ventricular compliance. In a normal infant, there is an increase in the left ventricular volume and pressure load and a decrease in the right ventricular volume and pressure load shortly after birth, resulting in a rapid increase in the left ventricular myocardial mass. Normal development of the left ventricle is lost in infants with D-TGA because the left ventricle ejects to the low-resistance pulmonary vascular bed. Thus, the left ventricle does not increase muscle mass relative to the right ventricle and within a few weeks loses the ability to maintain adequate cardiac output against significant afterload. This change occurs despite the fact that the left ventricle maintains a volume load in patients with transposition and intact ventricular septum. However, when a VSD or large patent ductus arteriosus is present, both volume and pressure overload of the left ventricle are maintained. In D-TGA with left ventricular outflow tract obstruction without a VSD, a ventricular pressure load is imposed without a significant volume load. These physiologic changes in the neonatal heart are important for the consideration of surgical approaches because after a few weeks of postuterine life, the left ventricle in D-TGA with intact ventricular septum takes on the characteristics and wall thickness of a pulmonary ventricle and may not be adequate to support the systemic circulation.
CLINICAL FEATURES
The most common clinical finding in an infant with TGA is cyanosis (arterial partial pressure of oxygen 25 to 40 mmHg), which varies in degree depending on associated anomalies. Typically, the cyanosis is more pronounced when the ventricular septum is intact and is often present at birth. The development of cyanosis later in infancy is usually associated with the presence of a significant VSD or left ventricular outflow tract obstruction. Congestive heart failure (CHF) may be the predominant clinical finding in patients with a large VSD or patent ductus arteriosus. Symptoms of cardiac failure, however, are rarely present in the first week of life but commonly appear by 1 month of age as pulmonary vascular resistance decreases and pulmonary blood flow becomes excessive, even in a patient with an intact ventricular septum.

MANAGEMENT
The widespread use of fetal ultrasound techniques has resulted in the common antenatal diagnosis of TGA. In fetuses with TGA and intact ventricular septum, the four-chamber view is normal. The parallel course of the aorta and pulmonary artery differentiates the fetus with TGA from those in which the arterial trunks are normally crossing. Color and pulsed wave Doppler showing inflow and outflow patterns of the left ventricular outflow tract coupled with a typical ejection pattern from the pulmonary artery further confirm the diagnosis of transposition. Postnatally, echocardiography has now generally supplanted cardiac catheterization in the majority of patients with simple complete transposition. Cardiac catheterization is now indicated only in infants in whom inadequate shunting is noted or if associated intracardiac or extracardiac abnormalities require clarification. Echocardiographic views confirming a posterior great vessel that divides into right and left pulmonary arteries and arises from the left ventricle in association with an anterior aorta arising from a right ventricle confirm the diagnosis of TGA. The intracavitary shunts can be determined by Doppler echocardiography, and several echo views can determine the size and location of VSDs with reference to the infundibular septum, the nature and size of atrial communications, the anatomy of the atrioventricular valves, and the presence and location of significant degrees of subpulmonary stenosis. In the majority of cases, the origins and anatomic distributions of the coronary arteries can be adequately visualized by echocardiography without the need for catheterization. Since virtually all coronary patterns can be dealt with surgically, preoperative identification of coronary anatomy is not necessary.

Cardiac catheterization is reserved for patients with significant clinical instability in order to improve the degree of intracavitary shunting by enlarging the interatrial septal communication. At catheterization, the left atrial pressure is usually greater than the right atrial pressure, and the pressure in the pulmonary (left) ventricle depends on the presence or absence of a VSD, the valvar or subvalvar stenosis, the age of the patient, and the magnitude of elevation of pulmonary vascular resistance.

The most important aspect of preoperative management of TGA is that oxygenated left atrial blood gets to the head. A PDA only helps to fill the left atrium, so atrial or ventricular level mixing is critical. If inadequate interatrial shunting results in clinical instability (acidemia, severe hypoxemia), the mainstay of management has been a Rashkind balloon atrial septostomy. A balloon-tipped catheter is passed through the systemic veins, through the right atrium and foramen ovale, and into the left atrium. The balloon is inflated and pulled vigorously across the atrial septum to tear the foramen ovale, improving admixture of pulmonary and systemic venous blood. This procedure may be performed in the intensive care unit with echocardiographic guidance in children who are clinically unstable. In patients with TGA and intact ventricular septum, atrial level mixing results in moderate hypoxemia but rarely CHF. Since an atrial septostomy decompresses the left ventricle, delayed repair may result in poor left ventricular performance. Prostaglandin E, is often administered to maintain duc tal patency and increase pulmonary blood flow helping to stabilize patients before early operative repair. In patients with atrial and ductal level shunting, mixing is improved with only mild hypoxemia but can be complicated by CHF and low diastolic pressures. Patients with PDA and restrictive atrial level shunting often develop pulmonary edema and metabolic acidosis. In patients with TGA and VSD, atrial, ventricular, and ductal shunting results in minimal hypoxemia but severe CHF once the pulmonary resistance falls. Therefore, patients who are good anatomic candidates for an arterial switch procedure who have acceptable arterial oxygen saturations are generally referred for early arterial switch without intervening atrial septostomy.

HISTORY OF SURGICAL REPAIR
Initial surgical therapy for TGA involved creation of an atrial septal defect using a closed technique to increase the mixing between the systemic venous and pulmonary venous circulations. This was first performed by Blalock and Hanlon in 1950. Although early mortality was high with this operative approach, successful creation of an atrial septal defect resulted in significant palliation in many of these children. Initial attempts to reverse the transposed vessels by both Mustard and Bailey were frustrated by an inability to maintain coronary perfusion and poor function of the anatomic left ventricle. Thus, initial surgical therapy was directed toward atrial transposition of the pulmonary and systemic venous returns. In 1952, Lillehei and Varco transferred the right-sided pulmonary veins to the right atrium and connected the inferior vena cava to the left atrium. A successful modification of this technique using an allograft to connect the inferior vena cava to the left atrium was described by Baffes in 1956.

Multiple attempts were made at both atrial and arterial repairs of TGA during the 1950s, and in 1954 Albert suggested the concept of switching the atrial septum so that caval return was directed to the left ventricle and the pulmonary venous return to the right. The atrial switch concept was first successfully accomplished by Senning in 1959 using an ingenious technique for relocating the walls of the right atrium and the atrial septum. Many of the early attempts at atrial repair were frustrated by the fact that the operation was performed on patients between 1 and 2 years of age and significant pulmonary vascular obstructive disease had already developed in many of these children. In 1964, Mustard described an alternate procedure for intratrial repair: excising the atrial septum and creating a large interatrial baffle of pericardium to redirect pulmonary and systemic venous blood resulting in a larger atrium than the Senning operation. Early results with the Mustard operation were markedly improved over the previously reported Senning repairs and reflected the significant population of patients in Toronto who had undergone successful Blalock–Hanlon atrial septectomies early in life.

A major development in the surgical treatment of TGA occurred in 1966 when Rashkind and Miller reported the use of a
balloon catheter technique to enlarge the atrial septal defect in patients with TGA, resulting in improved early physiologic stability and decreasing the need for operative atrial septectomy. During the 1960s, the Mustard operation became the most commonly performed procedure for transposition. As surgical techniques improved, it became clear that repair in the first few months of life could be accomplished with a low operative mortality and improved results compared with repair at a later age. In 1970, the Senning procedure reemerged as persistent problems with baffle obstruction and arrhythmias after the Mustard operation became well defined and the ability to use autologous tissue for the atrial reconstruction became a preferred approach.

The success with the atrial switch operations for TGA with intact septum did not translate to repair of transposition with a large VSD. Disappointing results with VSD closure and atrial repair in this group of patients continued to be a stimulus for the development of an arterial switch procedure, which was first successfully performed by Jatene and colleagues in 1975. Yacoub, shortly thereafter reported additional successful cases. The success of the arterial switch procedure with reimplantation of the coronary arteries in some patients with transposition and VSD led to reintroduction of this technique for patients with intact ventricular septum. Yacoub’s initial attempts in patients with TGA and an intact ventricular septum were unsuccessful in 1972. However, additional reports by 1976 suggested that such repair was possible in infancy. Early mortality with the arterial switch in infancy was related to the fact that the pulmonary left ventricle was not prepared to sustain systemic pressure. Therefore, initial approaches included pulmonary arterial banding (with or without a systemic-to-pulmonary shunt) and a single period of circulatory arrest, or circulatory arrest can be used for a brief period for atrial septal defect exposure and coronary transfer. After sternotomy, a portion of the anterior pericardium can be excised for use as an autologous patch for reconstruction of the anterior great vessel. The patch can be used either fresh or fixed in a glutaraldehyde solution to make for easier handling. Currently, we use pulmonary homograft patch material for pulmonary artery reconstruction. The ligamentum arteriosum or patent ductus arteriosus is dissected out, and the branches of the right and left pulmonary arteries are mobilized well out into the hilum of the lungs bilaterally. It is important to freely mobilize the

**OPERATIVE INTERVENTION: PALLIATIVE OPERATIONS**

The advent of the balloon atrial septostomy by Rashkind and Miller has essentially eliminated the need for the Blalock–Hanlon atrial septectomy. Infants with associated cardiac abnormalities and a thick atrial septum who are considered for later atrial baffle repair may benefit from the Blalock–Hanlon technique, although the safety of cardiopulmonary bypass has resulted in the common use of open atrial septectomy in such patients. Pulmonary arterial banding has been used for palliation with TGA and VSD in young infants who have intractable CHF until operative repair at 3 to 6 months of age. As the results with the arterial switch procedure and VSD closure in infancy have improved, banding in most instances is unnecessary because complete repair can be performed safely. Therefore, banding of the pulmonary artery has now been limited to very small neonates who might benefit from a delay in corrective surgery and those patients with transposition and an intact ventricular septum who present late for arterial switch repair and require “training” of the left ventricle to work at a higher pressure in order to become the systemic ventricle. For similar reasons, pulmonary arterial banding is used in patients with TGA who develop right ventricular dysfunction and failure after atrial baffle operations as a component of staged conversion to an arterial switch repair. Pulmonary arterial banding in TGA is a delicate procedure because limitation of pulmonary blood flow results in significant hypoxia and metabolic acidosis, and loose banding results in inadequate protection of the pulmonary vascular bed and poor development of the left (pulmonary) ventricle. Thus, in most situations in which preparation of the left ventricle is undertaken for conversion to an arterial switch procedure, banding must be associated with creation of an aortopulmonary shunt to maintain adequate pulmonary blood flow to prevent hypoxemia and ventricular dysfunction.

**SURGICAL CORRECTION**

Successful correction of TGA results in the rerouting of systemic venous blood to the pulmonary circulation and the pulmonary venous blood into the systemic arterial circulation. This may be accomplished at the atrial, ventricular, or great arterial level. The earliest repairs of TGA involve rerouting of the systemic and pulmonary venous returns at the atrial level, resulting in an adequate physiologic repair but not an anatomic repair because the morphologic right ventricle continues to be the systemic ventricle. Ventricular (Rastelli) and great arterial (arterial switch) repairs are more anatomic corrections resulting in the morphologic left ventricle as the systemic ventricle.

**Atrial Repair**

Despite the excellent results with atrial switch operations for TGA, anatomic correction has resulted in the arterial switch procedure becoming the standard surgical repair for TGA. Therefore, the Senning and Mustard operations will not be described in detail in this chapter.

**Arterial Repair**

The technique of the arterial switch operation involves transection of the great arteries, transfer of the coronary arteries, and repositioning of the great vessels. The procedure is performed through a median sternotomy with the use of cardiopulmonary bypass with mild or no hypothermia. In rare cases, the entire operation can be performed with a single period of circulatory arrest, or circulatory arrest can be used for a brief period for atrial septal defect exposure and coronary transfer. After sternotomy, a portion of the anterior pericardium can be excised for use as an autologous patch for reconstruction of the anterior great vessel. The patch can be used either fresh or fixed in a glutaraldehyde solution to make for easier handling. Currently, we use pulmonary homograft patch material for pulmonary artery reconstruction. The ligamentum arteriosum or patent ductus arteriosus is dissected out, and the branches of the right and left pulmonary arteries are mobilized well out into the hilum of the lungs bilaterally. It is important to freely mobilize the
pulmonary arterial branches out beyond the bifurcation to the lobar branches to permit safe anterior relocation of the pulmonary artery during the Lecompte maneuver without causing compression of the pulmonary arteries by the aorta. As noted in Figure 89.2, the aorta is cannulated as distally as possible to allow room for manipulation of the proximal aorta during the reconstruction. A cardioplegia needle is inserted into the aortic root, and bicaval cannulation is performed in most cases. In D-TGA, the aorta is anterior and to the right of the pulmonary artery, and the pulmonary artery is typically larger than the ascending aorta. After bypass is established, the ductus arteriosus is ligated but not divided. The aorta is clamped as close to the aortic cannula as possible, and cardioplegic solution is administered into the aortic root.

If a VSD is present, it can be approached either through the right atrium across the tricuspid valve or occasionally through the anterior great vessel or pulmonary artery (anterior muscular or conoseptal hypoplasia defects). In the majority of cases, however, we approach the VSD across the tricuspid valve. We prefer to address the VSD and atrial septal defect after the initial cross-clamping of the aorta so that additional doses of cardioplegic solution can be administered before aortic reconstruction. The VSD is closed in the usual manner across the tricuspid valve as described in Chapter 76. If an atrial septal defect is present, it is closed partially to allow for right-to-left shunting if necessary in the early postoperative period; if a patent foramen ovale is present, it is left unclosed. After the VSD is closed, if present, additional cardioplegic solution is injected into the aortic root, and then the aorta is transected above the level of the commissural attachments of the aortic valve and the pulmonary artery transected at the level of the bifurcation as noted in Figure 89.3. The ductus arteriosus is divided on the pulmonary arterial end, and the pulmonary arteries are freely mobilized from adjacent tissue. At this point, we perform the LeCompte maneuver, relocating the pulmonary bifurcation anterior to the aorta and then recross-clamp the aorta, keeping the pulmonary bifurcation cephalad and out of the operative field while coronary reconstruction is performed. The coronary ostia are examined carefully and excised from the anterior great vessel with a button of aortic wall extending down to the base of the sinuses of Valsalva, as noted in Figure 89.4 (inset A). The epicardial courses of the coronary arteries are then mobilized adequately to permit translocation of the coronary ostia to the posterior great vessel without kinking of the vessels, as noted in Figure 89.4. On occasion, small conal branches of the coronary arteries may need to be sacrificed to permit adequate mobilization. At a suitable site on the posterior great artery, a vertical incision is made with a medially based flap to allow takeoff of the coronary ostia without tension or kinking. Whereas generally the
sinuses of the aortic and pulmonary valves face each other, the commissural attachment of the pulmonary valve may be displaced superiorly or inferiorly and does not necessarily align directly with the commissural attachment of the aortic valve, as noted in Figure 89-4 (inset B). This fact must be taken into account when deciding about relocation of the coronary ostia. It is not uncommon for both coronary ostia to end up arising superior to the commissural attachments of the pulmonary valve or for both coronary ostia to be reimplanted to the same sinus of the pulmonary valve because of the variations in anatomy of the commissural attachments. It is generally preferable to reimplant the coronary arteries somewhat higher in the pulmonary artery than down into the sinuses of the pulmonary valve. This permits the coronary to come off of the neoaorta with less risk of kinking at the origin during distention of the aorta. As shown in Figure 89.5, the coronary ostia are then reimplanted into the medially based flap incisions. We prefer to use polypropylene suture for these anastomoses. On occasion, the placement of a vertically oriented suture line can result in kinking of the origin of the coronary artery, as noted in Figure 89.5D; in these cases, the rotation of the coronary buttons medially (Fig. 89.5E) can resolve the distortion.

Common variations in coronary translocation techniques are illustrated in Figures 89.6 and 89.7. As noted in Figure 89.6, when both coronaries come off a single sinus with the origin of the left coronary artery from an orifice near the commissural attachment of the aortic valve, it is possible to mobilize the commissure and excise the coronary arteries in the usual manner before translocation to the posterior great vessel. It is particularly important to note that the coronary artery may run intramurally in the aortic wall before exiting to the epicardial surface, and care must be taken not to cut across the coronary (Fig. 89.6B). An alternative technique for translocation that does not require separate coronary transfer is noted in Figure 89.7. The common coronary orifice or adjacent coronary orifices can be excised from the aortic wall as a single patch and then sewn side to side to the posterior great artery. The distal aorta can then be fashioned to create a flap over the origin of the coronary arteries, allowing unobstructed flow into the vessels (Fig. 89.7C). In the majority of cases, however, it is possible to transfer the coronary arteries directly to the posterior great vessel even when there is a single coronary from the right posterior-facing sinus, as noted in Figure 89.7D and 90.7E. Care must be taken, however, to position the coronary artery in such a manner that it does not kink one of the branches (Fig. 89.7E). Rotation of the coronary flap or translocation to a higher level on the pulmonary artery can adjust for many of the variations and possible kinking of the origins of the coronary arteries and allow coronary transfer in virtually all anatomic variations of TGA. In situations of single coronary ostium or side-by-side origin of the coronaries from the same sinus with very little distance between the orifices and intramural course, take down of the commissure, division of the coronary...
arteries, and rotation and reimplantation into the posterior great vessel may still leave an intramural course of the coronary that is prone to kinking and occlusion. The flap technique described earlier leaving the coronaries in situ may sometimes solve this potential problem; however, the Lecompte maneuver, bringing the pulmonary bifurcation anterior to the aorta, can compress the anteriorly located flap and limit the flow into the coronaries causing ischemia and potential late arrhythmias during exercise. One technique that has worked well for us in this situation is dividing the coronary arteries with reimplantation to the posterior great vessel and then performing an ostial coronary arterioplasty, cutting into the orifice of the intramural course of the coronary vessel and augmenting the origin with a small triangular patch of pulmonary homograft material or pericardium. This widely opens the orifice to the coronary artery and prevents kinking at the end proximal portion of the intramural course of the vessel (Fig. 89.7F and 90.7G).

Once coronary artery transfer has been completed, the distal aorta is then anastomosed to the neoaoorta using polypropylene suture. Because there is frequently a size discrepancy between the neoaoorta (to which the coronaries have been transferred) and the distal aorta, a vertical incision is used to make up the size discrepancy (Fig. 89.8). As noted in Figure 89.9, this incision can allow for adequate primary anastomosis in most circumstances even if there is a significant size discrepancy. The anteriorly placed vertical incision in the aorta has the additional advantage of pulling the aorta posteriorly, which helps to prevent compression of the pulmonary bifurcation that has now been anteriorly translocated. At this point, additional cardioplegic solution is injected into the aortic root (Fig. 89.10) to check for hemostasis of the suture lines, to ensure free perfusion of the coronary ostia without kinking, and to provide additional cardioplegia. Next, the defects in the anterior great vessel from which the coronaries have been excised are repaired with a generous portion of glutaraldehyde-fixed pericardium or pulmonary homograft material (Fig. 89.11). The patch is fashioned in a pantaloon shape and posteriorly is extended for 3 to 5 mm to allow for some extension and length of the pulmonary artery to the bifurcation. Anteriorly, native tissue is left in place and the patch trimmed appropriately to allow for an anterior portion of native tissue to be anastomosed to the pulmonary bifurcation in the hope of encouraging growth at this portion of the suture line. As noted in Figure 89.12, the anterior great vessel is then sutured to the pulmonary artery bifurcation, with care being taken to avoid tension on the pulmonary arteries, which may interfere with symmetric pulmonary blood flow. If necessary, an incision is carried out onto the origin of the pulmonary arteries to allow for an adequate size match and to prevent distortion of the origins of the pulmonary arteries. This anastomosis is occasionally completed with the aortic cross-clamp.
released and the heart reperfusing. After pulmonary artery reconstruction, the right atrium is closed, and the pulmonary origin of the ductus is oversewn, with care being taken not to interfere with the flow into the origin of the left pulmonary artery (Fig. 89.13).

When the great vessels are located side to side rather than anteroposteriorly, it is occasionally advisable to leave the pulmonary confluence posterior to the aorta, close the pulmonary bifurcation on the left, and incise the right pulmonary artery more rightward. This may facilitate reconstruction to the right ventricle after the arterial switch has been performed.

After completion of the repair, right atrial lines are placed for postoperative monitoring and the volume infusions and temporary pacemaker wires applied to the right atrium and the right ventricle. After the patient is weaned from cardiopulmonary bypass, a systemic pressure of no more than 60 to 70 mmHg is preferable to prevent distention of the newly systemic left ventricle.

### The Rastelli Operation

Infants with significant left ventricular outflow tract obstruction represent a small proportion of children with TGA. Left ventricular outflow tract obstruction in TGA is often dynamic in nature, so the relative contributions of the dynamic components of obstruction and the fixed components such as subvalvar fibrous rings and mitral valve leaflet tags are difficult to determine. At the time of arterial switch operation, some of the fixed obstruction can be resected across the pulmonary valve, but complete relief is not often possible. In the majority of cases, however, moderate relief of left ventricular outflow tract obstruction can be well tolerated because the pulmonary ventricle has been preconditioned to elevated intracavitary pressure.

When significant left ventricular outflow tract obstruction in association with TGA presents in infancy, creation of an interatrial communication and a systemic-to-pulmonary arterial shunt is often the best early approach, followed later by the Rastelli operation. In this situation, early complete repair is preferred, and we have generally elected to complete the operative procedure by the time the patient is 4 to 6 months of age even if a systemic-to-pulmonary artery shunt is initially performed.

In the Rastelli operation (Figs. 89.14 to 89.19), pulmonary venous blood is directed across the VSD to the aorta with an intracardiac baffle, and a valved conduit is used to reconstruct the right ventricular outflow tract to the distal pulmonary arteries. Figure 89.14 shows the transposed great arteries with the ascending aorta larger than the posteriorly located pulmonary artery because of significant pulmonary stenosis. A right ventriculotomy is created through an oblique incision heading leftward toward the pulmonary bifurcation. The VSD is easily exposed through this incision. As noted in Figure 89.15, the VSD is often somewhat smaller than the ascending aorta, and enlargement of the VSD is recommended to prevent late development of

---

Fig. 89.6. (A) In variations in which both coronary arteries come off a single sinus, the coronary ostia may have an intramural course. (B) Care must be taken not to transect the coronary artery during excision of the coronary button from the aortic wall (stippled area). (C) The aortic valve leaflet may need to be detached from the commissure to allow access to the coronary ostia for excision. (D) Separate excision of the two coronary ostia can be effective in most cases.
In some cases, excision of the single coronary ostium supplying both right and left circulations or side-by-side ostia from the same sinus are best translocated with a single coronary button excised from the sinus of the aortic valve. (B) The superior margin of the coronary button is anastomosed to the superior margin of the posterior great vessel. In this manner, there is no translocation of the coronary ostia posteriorly, but they are left in their normal anatomic relationships to prevent kinking of the arteries. (C) The aorta is then mobilized to create a flap of tissue sewn down over the coronary ostia, allowing unobstructed flow into the coronary vessels. (D) Translocation of a single coronary artery to the posterior great vessel can be effective in most cases. Care must be taken, however, to orient the artery such that kinking of the left coronary branch does not occur. (E) A more superior location of the coronary artery on the posterior great vessel generally relieves such kinking. (F) In situations with intramural coronaries with ostia that arise adjacent posteriorly from the aorta, the coronary buttons can be excised and the intramural course opened inside the aortic wall. The coronaries are then rotated and then reimplanted into the posterior great artery in the usual manner. (G) The narrow nature of the coronary arteries despite opening of the intramural course still often leaves stenosis, and therefore, incision of the coronary with patch augmentation with a small triangular patch of pulmonary homograft or pericardium material can ensure that there is no coronary inflow problem. This patch coronary ostioplasty must be done in a meticulous manner to prevent distortion and kinking of coronary flow.
obstruction across the intracardiac baffle, which becomes the outlet to the ascending aorta. Restriction of the VSD is one of the most common late problems after the Rastelli operation. In Figure 89.15 (inset A), the VSD is enlarged anteriorly and superiorly away from the area of the conducting tissue. The pathway of the conducting tissue along the right ventricular septum is noted in Figure 89.15B (stippled line), and the suture line for placement of the baffle from the left ventricle to the aorta is noted by the dashed line. In Figure 89.16, the creation of a conduit-like patch from either a polyester (Dacron) tube graft or a polytetrafluoroethylene (Gore-Tex) tube graft is described.

Alternately, a patulous rectangular patch of Dacron material can be used, allowing for a large amount of the material to bow into the right ventricle to permit an unobstructed connection from the VSD at the ascending aorta. We prefer to use Gore-Tex material for these connections because the rough surface of the Dacron patch material may cause hemolysis early postoperatively.

After the baffle is completed, the left ventricular output is directed across to the ascending aorta anteriorly (Fig. 89.17). The pulmonary artery is then divided and the pulmonary bifurcation incised for connection to a pulmonary homograft conduit of the largest size that will satisfactorily fit into the chest cavity (Fig. 89.18). Homograft material is preferred for reconstruction of the right ventricular outflow tract because it is compressible and typically will allow the conduit to sit in the left chest underneath the sternum without significant distortion. The pulmonary valve is oversewn to prevent antegrade flow out of the ventricle into a blind pouch, which could be a source of potential thrombi and thromboembolism. The stump of the pulmonary artery is also oversewn. The right ventricular outflow tract is then reconstructed with a pulmonary valved homograft with or without the use of a gusset, allowing a gentle takeoff from the right ventricle to the pulmonary outflow tract (Fig. 89.19).

Unusual cases of children with transposition and intact ventricular septum with significant left ventricular outflow tract obstruction may be treated by atrial baffle repair and connection of a conduit from the left ventricular cavity to the pulmonary bifurcation on the left.

Lecompte modified the Rastelli operation to decrease the risk of obstruction of the conduit from the left ventricle to the aorta by creation of the REV procedure. In this operation, resection of the subaortic conus is more extensive than in the Rastelli operation, and resection of muscle is carried to just below the pulmonary valve annulus superiorly (Fig. 89.20A and 89.20B). In addition, when tricuspid valve attachments to the ventricular septum are abnormal, a septal flap containing the important tricuspid valve attachments can be created and repositioned onto the ventricular septal patch after it is sewn in place. These more extensive resections of the ventricular septum create a more direct pathway from the left ventricle to the ascending aorta with a lower risk of recurrent stenosis. In addition, Lecompte suggested translocation of the pulmonary

---

Fig. 89.8. The pulmonary bifurcation is translocated anterior to the great artery in the Lecompte maneuver. To obtain an adequate size match between the distal ascending aorta and the proximal great artery to which the coronaries have been transferred, a vertical incision is used.

Fig. 89.9. The vertical incision in the distal aorta is shown, creating an adequate size match for the anastomosis (A), which is completed with a running absorbable suture (B).
bifurcation anteriorly in these patients with resection of a short portion of the ascending aorta to reposition the aorta more posteriorly and allow direct connection of the pulmonary bifurcation to the right ventricular outflow tract without the need for a homograft conduit, which would require later revision. A modification of the approach described by Lecompte resects a short segment of the aorta decreasing the length of the aorta and bringing it into a more posterior position. This short segment of aorta that is excised can then be used to reconstruct the pulmonary outflow tract using autologous tissue to allow for potential growth.

A variation on the REV procedure has been described by Nikaidoh and is useful for patients who have transposition-like forms of double-outlet right ventricle with VSD and small pulmonary valve annulus. In this approach, the pulmonary annulus can be incised across the conal muscle into the VSD and the aorta excised with mobilization of the coronary arteries as in the pulmonary autograft procedure for aortic valve replacement. The entire aortic root with the coronaries attached can then be positioned more posteriorly into the left ventricular outflow tract and secured to the pulmonary valve annulus posteriorly (Fig. 89.21A). The VSD is then closed anteriorly with a patch secured to the inferior border of the translocated aorta. In this manner, the outflow from the left ventricle becomes more directly related to the aorta without a complex intracardiac baffle and often without requiring enlargement of the VSD. The right ventricular outflow tract can then be reconstructed either with direct connection to the pulmonary bifurcation or with the use of a homograft valved conduit (Fig. 89.21B and 89.21C). In some cases, it is simpler to excise the coronary artery buttons and mobilize them to gain access to the subaortic area for excision of the aortic root before translocation of the aortic root posteriorly. The coronary buttons can then be reimplemented in a suitable orientation to the mobilized aorta, decreasing the potential risk of kinking along the epicardial course of the vessels.

An alternate approach to some of these patients may be pulmonary artery translocation. This operation has been described by DaSilva and takes the pulmonary valve from the left ventricle and transposes it to the right ventricle with patch closure of the pulmonary outflow tract. This removes the subaortic obstruction and can position the right ventricular outflow tract in a more anatomic location and provide more direct connection from the left ventricle to the ascending aorta.

SURGICAL RESULTS OF REPAIRS OF TRANSPPOSITION OF THE GREAT ARTERIES

The results of either a Mustard or a Senning atrial switch procedure have generally been good, with survival rates of 80% to 95% reported for complete repair in infancy in patients with intact ventricular septum. Atrial switch operations have been complicated by a high incidence of sinus node dysfunction or other atrial dysrhythmias, and the development of dynamic left ventricular outflow tract obstruction from systemic right ventricular pressure loading. The Senning operation has been associated with improved rates of sinus rhythm compared with the Mustard operation, although atrial arrhythmias are not uncommon with this approach. The incidence of late
deterioration in systemic right ventricular function is unknown but may become clinically significant in 10% of patients. Results with atrial correction appear to be improved with early repair before the development of significant pulmonary vascular obstructive disease, and age alone does not appear to be a significant independent predictor of operative risk.

Arterial switch operations have been associated with progressive improvement in operative and hospital mortality. Perhaps, the largest series of arterial repairs for transposition of the great vessels has been reported by the group at the Boston Children's Hospital, in which the 1-, 5-, and 8-year survival rates were 93%, 92%, and 91%, respectively. Additionally, they have shown that left ventricular size, mass, functional status, and contractility are normal on follow-up with no evidence of late deterioration. Follow-up studies of atrial and ventricular arrhythmias after the arterial switch operation have shown a 96% incidence of sinus rhythm on electrocardiography and 99% during Holter monitoring at a mean of 2.1 years postoperatively, which represents a marked improvement over the results with the atrial operations. The results of these careful studies have confirmed the superiority of the anatomic arterial switch procedure over atrial repairs. In spite of the excellent intermediate-term results with the arterial switch operation, late problems do occur in some of these children. Supravalvar pulmonary stenosis is the most frequent anatomic complication following the arterial switch, with a peak incidence during the first year in 2% to 30% of patients. Dilation of the aortic root and ascending aorta with progressive aortic insufficiency has been seen with increasing frequency in older patients after the arterial switch operation, perhaps reflecting the abnormal pulmonary arterial wall of the aortic root. In a large series out of Boston Children's Hospital, over half of patients developed aortic root dilation beyond three standard deviations after 10 years. Coronary arterial obstruction following arterial switch has also been reported in 2% to 7% of patients. Symptomatic patients with significant obstruction clearly require intervention, but there are little data regarding the rate of progression and timing of intervention on asymptomatic patients with mild-to-moderate obstruction. Overall though, most patients currently undergoing arterial switch operations can expect near normal developmental, neurologic, and cardiac function.

Fig. 89.12. The pulmonary bifurcation is then reconstructed onto the anterior great artery using running nonabsorbable suture. Incisions onto the right and left pulmonary arteries are made as necessary to create an adequate size match.

Fig. 89.13. After reconstruction, the origin of the ductus arteriosus is oversewn with absorbable suture, with care being taken not to narrow the takeoff of the left pulmonary artery (PA).

Fig. 89.14. The Rastelli operation. In transposition of the great arteries with significant left ventricular outflow tract obstruction, the aorta is larger than the posteriorly located pulmonary artery. The dashed lines show the direction for the ventriculotomy incision in the right ventricle avoiding major epicardial coronaries, and the location of the ventricular septal defect is noted.
As experience has been accumulated with patients after the arterial switch operation, it is apparent that the overall ventricular performance and the incidence of arrhythmias are significantly improved over atrial switch-type operations. Nevertheless, the neo-aortic root continues to initially have been a pulmonary root and root dilation over time has been seen as in patients after the Ross operation or after repair of hypoplastic left heart syndrome. While the need for reoperation for aortic insufficiency and root dilation appears to be quite low, continued monitoring of the patients over time will be necessary to determine whether the aortic valve will require reintervention in the future. In addition, there is a significant incidence of coronary artery stenosis and even asymptomatic coronary occlusion after the arterial switch operation, which may require additional interventions in the future. While it is clear that the arterial switch operation results in a significant improvement over the atrial switch-type repairs, continued longitudinal follow-up of patients will be necessary over a lifetime to determine the need for reintervention for various complications of this congenital anomaly.

Fig. 89.15. The ventricular septal defect and tricuspid valve attachments. (Inset A) Excision of the anterior superior margin of the ventricular septal defect away from the conducting tissue allows an unobstructed connection from the left ventricle to the aorta. (Inset B) In the "réparation à l'étage ventriculaire" (REV) procedure, the conal muscle beneath the aorta separating the aorta and pulmonary valves is also resected at the anterior left lateral margin of the ventricular septal defect away from the conducting tissue (stippled lines). The direction of the suture line for the ventricular septal defect patch to the aorta is shown by the dashed lines, avoiding the conduction tissue.
Fig. 89.16. A baffle created from a polytetrafluoroethylene (Gore-Tex) tube graft (inset) is used to create the connection from the left ventricle to the aorta.
**Fig. 89.17.** Completion of the baffle creates a conduit from the left ventricle to the aorta sown to the base of the septal tricuspid valve leaflet inferiorly. VSD, ventricular septal defect.

**Fig. 89.18.** After the intracardiac portion of the repair is completed, the pulmonary artery is transected and the pulmonary valve (inset A) and the main pulmonary artery (inset B) are oversewn to prevent stasis and bleeding. Alternatively, the pulmonary valve can be excised. The distal pulmonary artery is opened adequately for reconstruction with a pulmonary homograft.
Section III: Congenital Cardiac Surgery

**Fig. 89.19.** The right ventricular outflow tract is reconstructed using a pulmonary valved homograft to the pulmonary bifurcation augmented by a polytetrafluoroethylene (PTFE) gusset from the right ventricle (inset).

**Fig. 89.20.** (A) In the "réparation à l’étage ventriculaire" (REV) procedure, the aorta and the pulmonary artery are transected, and through an incision in the right ventricular outflow tract the infundibulum is widely excised to create an unobstructed pathway from the ventricular septal defect (VSD) to the aorta. A dilator can be passed across the outflow to guide resection of the VSD to avoid damage to the semilunar valve. (B) A generous patch of Dacron is used to close the VSD, directing the flow to the aorta. The resection of conal muscle provides a more direct connection of the ventricle to the aorta than in the standard Rastelli operation. The pulmonary artery is then reconnected to the right ventricular outflow tract after a Lecompte maneuver is performed, bringing the pulmonary arteries anterior to the aorta.
The Nikaidoh procedure involves excising the aortic root including the aortic valve from the ventricle by making an incision below the aortic valve annulus and mobilizing the entire root along with the attached coronary arteries. If exposure is difficult, the coronaries can be excised for reimplantation, much as in an arterial switch operation. Once the aortic root has been mobilized, the muscle between the pulmonary annulus and the ventricular septal defect (VSD) is divided, widely opening up the outflow from the left ventricle to the pulmonary valve annulus, and additional muscle resected if necessary. After infundibular muscle is resected, the aortic root is reimplanted into the left ventricular outflow tract at what was the previous pulmonary valve annulus. After the aortic root is translocated posteriorly, the anterior VSD is closed with a patch of Dacron or polytetrafluoroethylene material, which is secured anteriorly to the anterior portion of the aortic root, thus baffling the blood from the left ventricle to the aorta. (B and C) The right ventricular outflow tract reconstruction is created with an aortic or pulmonary homograft conduit.

**EDITOR’S COMMENTS**

Dr. Eckhauser and Spray have written a thorough description of the physiology and surgery for transposition of the great arteries. There has been a huge transformation of the procedure for this disease. I was involved very early on with the mustard and senning procedures which left the anatomic right ventricle as a systemic left ventricle. We learned the hard way how these ventricles often failed in the long run. The change to this procedure basically made these infants normal.

There is also no procedure that is technically more exciting in congenital heart disease. It is absolutely critical to get the coronaries right. There needs to be adequate mobilization and we have used marking ahead of time to determine the proper place to put these buttons while the heart is still full and beating. The differences are huge. This is a procedure that if done correctly should have virtually no mortality as long as there are no issues that causes kinking or compression of the coronary arteries. These authors have demonstrated different approaches for different coronary anatomy variations. The bottom line is that the vast majority of patients can have a switch successfully done.
Congenitally Corrected Transposition of the Great Arteries

Ergin Kocyildirim and Victor O. Morell

INTRODUCTION

Congenitally corrected transposition of the great arteries (ccTGA) is a complex cardiac lesion involving discordant atrioventricular (AV) and ventriculoarterial connections. The term congenitally corrected transposition was introduced by von Rokitansky in 1875. He described two patients in whom; the abnormal relationship of the great arteries was corrected functionally by the position of the ventricular septum. Cardell, Anderson et al., Lev and Rowlett, and Schiebler et al. reported extensive anatomical descriptions and clinical studies. Anderson et al. described the anatomy of the conduction system. Alternative terms used to describe ccTGA such as L-TGA, for situs solitus (S), L-loop (L), and the aorta left to the pulmonary artery, and [I,D,D] for situs inversus with mirror image anatomy. D-loop is for D-transposed great arteries, where L means left and D means right. ccTGA have become a universal terminology according to the Society of Thoracic Surgeons Congenital Heart Surgery Nomenclature and Database Project.

In this complex cardiac lesion, the right atrium is connected to the morphologic left ventricle, which is connected to the pulmonary artery and the morphologic left atrium is connected to a morphologic right ventricle, which is connected to the aorta (Fig. 90.1). As a result of the discordant connections at both levels, the blood flows in normal physiology. ccTGA represents the 1% of all congenital cardiac anomalies and about 94% of all cases are associated with other cardiac lesions, with the most common abnormalities involving the tricuspid valve (up to 91% of patients). Other associated defects are ventricular septal defects (VSDs), and pulmonary valve or subpulmonary stenosis resulting in left ventricular outflow tract obstruction (LVOTO). Also, dextrocardia is frequently associated with this cardiac defect. Most commonly, the associated lesions determine the severity of the symptoms and the surgical management strategy.

EMBRYOLOGY AND ANATOMY

During embryonic development, the primitive heart tube develops several curvatures. Corrected transposition in visceroastral situs solitus develops when the primitive heart tube loops to the left instead of the right, resulting in the absence of spiral rotation of the conotruncal septum. This causes the aorta to connect to the morphologic right ventricle and the pulmonary artery to connect to the morphologic left ventricle. The normal process of septation and valve formation is also affected and the ventricular morphology is maintained consistent within the ventricular chamber. The AV valve and conduction tissue correspond to the overall morphology of each ventricle. The process of malalignment leads to a VSD, which is a frequent associated anomaly (50% to 80% of all cases). The VSD is usually perimembranous and large but can be located anywhere in the septum.

When atrial situs inversus is present, a mirror-image relation exists and the aorta is almost always to the right of the pulmonary artery with dextrocardia. Malalignment of the atrial and ventricular septa is present, except where the pulmonary, mitral, and tricuspid valves meet and are joined by the right fibrous trigone. The atrial septal attachment to the fibrous skeleton lies to the right of the ventricular septal attachment. These changes result in the abnormally positioned AV node and His bundle. Abnormalities of the AV node, including dual AV node with the abnormal His bundle, are quite common and many of those ccTGA patients develop complete heart block spontaneously during intra- or extrauterine life. Tricuspid valve and VSD surgery may also precipitate the complete heart block.

The left ventricular outflow tract in this cardiac defect is located in the region between the septal leaflet of the mitral valve and the muscular ventricular septum. Anatomic obstruction is significant and hemodynamically important in about 50% of the patients.

Tricuspid valve anomalies are noted frequently. When Ebstein anomaly occurs in the presence of ccTGA, the tricuspid valve and the right atrial morphology are different. Unlike single Ebstein anomaly, the anterior leaflet is not sail-like and the atrialized part of the right ventricle is small.

In atrial situs solitus, the right-sided coronary artery, which feeds left ventricle, usually gives rise to the anterior descending and circumflex branches. The left-sided coronary artery supplies the right ventricle and becomes the posterior descending artery. The most common variation of the coronary artery distribution is the existence of a single coronary artery that arises from the right-facing sinus and divides into right and left main branches. In ccTGA, there is also a tendency toward early branching of the left main.

DIAGNOSIS

Patients with ccTGA may seek medical advice at any age, and their timing of presentation is usually dependent on the presence and severity of associated cardiac anomalies. Cyanosis could be the initial clinical presentation of a neonate or infant with severe pulmonary stenosis or pulmonary atresia requiring palliation with a systemic to pulmonary artery shunt. Not infrequently patients with pulmonary stenosis and a VSD have a nicely balanced circulation allowing for delayed surgical management during late infancy or early childhood.

Infants may experience congestive heart failure due to a large VSD, severe tricuspid regurgitation, aortic coarctation, or aortic arch abnormalities. Bradycardia can be the initial presenting symptom and it is most often caused by the spontaneous
The diagnosis of ccTGA is most often made by echocardiography. This study is useful to assess the ventricular morphology, mitral-pulmonary fibrous continuity, ventriculoarterial discordance, great vessels, and the associated cardiac lesions. Transeosophageal echocardiography is also a useful tool in making diagnosis in adults.

Cardiac catheterization is useful in assessing ventricular morphology, systemic AV valve regurgitation, systemic ventricular function, and the presence and significance of any associated cardiac anomalies. Coronary angiography is indicated and important in older patients.

**SURGICAL TREATMENT**

**Palliative Operations**

Patients in need of palliative surgery usually have either significant cyanosis or pulmonary overcirculation. In neonates and infants, significant pulmonary valve and/or subvalvar obstruction (LVOTO) in the presence of a VSD results in cyanosis. These patients can be initially managed with the placement of a modified Blalock–Taussig shunt.

Pulmonary artery banding could be utilized in neonates and infants with pulmonary overcirculation and failure to thrive secondary to the presence of a VSD. In these patients, the aim of the procedure is to reduce the distal pulmonary arterial pressure to <50% of the systemic pressure.

In patients who develop right ventricular failure after a classic repair pulmonary artery banding may be considered for LV retraining when a double-switch strategy is being considered. The ideal morphologic LV pressure after the banding should be approximately 75% of systemic. The development of morphologic LV dysfunction after the procedure is well recognized and could require postoperative inotropic support and/or loosening of the band.

**Definitive Operations**

The approaches to the surgical management of patients with ccTGA can be grouped into two options: physiologic (classic) or anatomic repairs. With a physiologic repair, the right ventricle remains the systemic ventricle and all other associated cardiac lesions are repaired. This approach is simpler but results in a RV-dependent systemic circulation, which has negative long-term implications, mainly RV failure and tricuspid regurgitation. After anatomic repair, the left ventricle becomes the systemic ventricle and the long-term outcomes are better. Nevertheless, the anatomic repair involves some form of a technically challenging double-switch procedure.

**Closure of Ventricular Septal Defects**

The majority of the VSDs in ccTGA are located in the perimembranous region. The presence of an overriding or straddling mitral valve usually signifies the presence of inlet extension. Most commonly, the surgical approach is via the right atrium with exposure of the VSD through the mitral valve. In selected cases, partial detachment of the septal leaflet of the mitral valve allows for better visualization of the defect. Transatrial approach is applicable to both physiologic and anatomic repairs. In patients requiring placement of a conduit between the morphologic LV and pulmonary arteries, the VSD could be easily closed through the ventriculotomy.

In the SLL type of L-TGA, it is important to realize that the conduction tissue runs in the subpulmonary infundibulum and along the anterior border of the defect. During VSD closure sutures must be placed on the left (systemic) side of the defect in order to avoid injury to the conduction system (Fig. 90.2). Frequently, the left-sided tricuspid valve has attachments to the posterior edge of the VSD and, therefore, the sutures need to be placed on the morphologic left ventricular side of the VSD.
The conduction system in patients with IDD type of L-TGA runs in the posterior edge of the defect. Therefore, VSD closure would require placement of all sutures along the pulmonary (left side) edge of the defect in order to avoid surgically induced complete heart block.

Also, a VSD could be closed through the aortic valve if the aortic root is large. Sutures are placed on the left (systemic) side of the VSD. Extra care must be taken not to interfere with the chordae or the tricuspid valve leaflets, which may cause AV valve insufficiency. In patients with L-TGA, VSD closure is associated with a significant risk of complete heart block, either from suture damage to the conducting bundle or from retraction on the anteriorly placed AV node and bundle.

**Repair of Left Ventricular Outflow Obstruction (Subpulmonary Obstruction)**

Thirty to 50% of patients with L-TGA present with some form of pulmonary or supravalvular obstruction. Direct relief of the LVOTO is usually not satisfactory because of the posterior position of the narrowed pulmonary outflow tract, which is wedged between the two AV valves. Accessory mitral valve chordal attachments to the subpulmonic area commonly contribute to the obstruction. Isolated valvular stenosis or discrete subvalvar membranes can be relieved by valvotomy and/or membrane resection. Another complicating factor is the presence of the abnormal conduction system in close proximity to the pulmonary valve in this patient population.

During a "physiologic repair," the surgical management of LVOTO commonly involves the placement of an extra-anatomic conduit between the morphologic left ventricle and the pulmonary arteries (Fig. 90.3). The conduit takeoff from the LV is in a more apical position due to the location of the papillary muscles and coronary arteries. These conduits commonly sit retrosternally, an important fact to remember at the time of reoperation. Valved conduits are most

**Fig. 90.2.** Ventricular septal defect (VSD) closure via a right atriotomy. (A) The VSD is visualized through the right-sided mitral valve. The conduction tissue (yellow) is anterior and cephalad to the pulmonary valve and descends along the anterior margin of the VSD. (B-D) The VSD is closed with a prosthetic patch. Note that the sutures along the superior and anterior VSD border are placed on the morphologic right ventricular side of the septum to avoid the conduction tissue. Ao, aorta; LV, left ventricle; MV, mitral valve; PA, pulmonary artery; RV, right ventricle.
Fig. 90.3. "Classic repair" in congenitally corrected transposition of the great arteries (ccTGA) with ventricular septal defect (VSD) and pulmonary stenosis (PS). (A) The VSD is closed leaving the right ventricle (RV) as the systemic ventricle. (B) A left ventriculotomy is performed avoiding injury to the coronary arteries and the left ventricle (LV) papillary muscles. (C) An LV to pulmonary artery (PA) conduit is placed.

frequently used but a nonvalved synthetic tube can also be used when the pulmonary resistance is low and the distal pulmonary tree is adequate in size.

**SURGICAL MANAGEMENT OF TRICUSPID VALVE INSUFFICIENCY**

The tricuspid valve could be normal, but frequently there is Ebsteinoid-like displacement of the septal leaflet down into the body of the RV without atrialization of the RV free wall. Also, dilatation of the RV and tricuspid annulus contributes to the development of regurgitation, even in morphologically normal valves. Surgical exposure of the tricuspid valve is often challenging because of the abnormal location of the valve within the ventricle often requiring a trans-septal approach. Exposure of the valve via a left atriotomy through a left thoracotomy incision has also been advocated. Although we have successfully repaired a few of these valves, the more "standard" management remains valve replacement.

**ANATOMIC REPAIR**

Anatomic repairs reestablish the LV as the systemic ventricle. To achieve a complete anatomic repair, the systemic and pulmonary venous returns also need to be redirected or switch, thus the term "double-switch operation." Three surgical options exist as follows:

1. Rastelli procedure + atrial switch (most common).
2. Arterial switch procedure + atrial switch.
3. Aortic translocation procedure + atrial switch.

It is important to realize that these procedures are technically demanding and are usually associated with a prolonged cross-clamp time. We perform "double-switch" operations under standard bicaval cardiopulmonary bypass with moderate hypothermia and cold blood cardioplegia.

The Rastelli procedure with an atrial switch can be performed in children with significant LVOTO or pulmonary atresia. Kawata et al. described this approach which aims to divert the morphologic left ventricle outflow through the VSD to the aorta in combination with an atrial level switch procedure. After an infundibular incision, the interventricular tunnel is created with a prosthetic patch, funneling the left ventricular blood into the aorta. A conduit is used to establish right ventricle to pulmonary artery continuity (Fig. 90.4).

Another alternative is the REV (Réparation à l’Étage Ventriculaire) procedure, which involves the enlargement of the VSD to create a more direct communication between the left ventricle and the aorta. A direct anastomosis between the right ventricle and the pulmonary artery is created.

The concept of combining the arterial and atrial switch procedures for the management cc-TGA was introduced by Ilbawi in 1990. Currently, it is most frequently utilized in the presence of an unrestrictive VSD without significant pulmonary or subpulmonary obstruction. Patients with mild-to-moderate subpulmonary obstruction secondary to resectable accessory AV valve tissue are also candidates. A significant number of these patients might have undergone pulmonary artery banding to manage pulmonary overcirculation or for LV retraining. Also, this approach should be considered in children with important tricuspid insufficiency and/or RV dysfunction.

The technical aspects of the arterial switch in ccTGA are quite similar to the "usual" d-TGA technique (Fig. 90.5). Both great vessels are transected and the coronary buttons harvested from the native aorta. After the LeCompte maneuver, the distal aorta is anastomosed to the neo-aortic root and the coronary arteries are reimplanted. The neopulmonary root is reconstructed with native pericardium and the pulmonary artery anastomosis is performed. VSD closure is performed through the right atrium or via the transected "native" aorta.

The aortic translocation procedure in combination with an atrial switch, first described in 2005 by Morell and colleagues, is applicable to patients with LVOTO and a VSD. This technique consists of harvesting the aortic root from the right ventricle,
Section III: Congenital Cardiac Surgery

Fig. 90.4. Rastelli procedure in congenitally corrected transposition of the great arteries (ccTGA). (A and B) Via a distal right ventriculotomy, an intraventricular tunnel is created with a prosthetic patch, leaving the left ventricle (LV) as the systemic ventricle. (C and D) A right ventricle (RV) to pulmonary artery (PA) conduit is then placed and an atrial switch procedure is performed. (Blue arrow means venous blood; red arrow means arterial blood.)

Fig. 90.5. Arterial switch procedure in congenitally corrected transposition of the great arteries (ccTGA). (A) The ascending aorta and main pulmonary artery are transected and the coronary buttons are harvested. The proximal coronary arteries are extensively mobilized to achieve tension-free coronary artery reimplantation. (B) The coronary buttons are reimplanted to the neoaorta. (C) The neopulmonary artery is reconstructed with autologous pericardium. (D) The pulmonary artery anastomosis is performed; note that the LeCompte maneuver was utilized.
usually removing one (left main coronary button most commonly) or both coronary buttons from the aorta because of the side-by-side relationship of the great vessels. Then, the main pulmonary artery is transected proximally and the LVOTO is relieved by dividing the outlet septum and the hypoplastic pulmonary valve annulus. The aortic root is translocated and sutured to the pulmonary annulus, positioning the aorta closer to the LV, the VSD is then closed. The coronary buttons are reimplanted and the RVOT is reconstructed with or without a conduit (Fig. 90.6). This technique creates better alignment of the right and left ventricular outflow tracts and is especially useful for patients with an inlet VSD, hypoplastic RV, or straddling AV valves.

There are several options available for the “atrial switch” component of the operation. We have utilized three techniques, namely, (1) the Mustard, (2) the Senning, and (3) the hemi-Mustard/Bidirectional Glenn. The Senning procedure, with pericardial patch augmentation of the pulmonary venous baffle, is our preferred option (Fig. 90.7). In the presence of dextrocardia, which is associated with a smaller right atrial mass, we tend to favor the Mustard or hemi-Mustard.

RESULTS

Physiologic (Classic) Repair

The long-term outcomes of patients with ccTGA who have undergone a physiologic surgical repair are unsatisfactory. The published reports reveal 20-year-survival and surgical reintervention rates that approximate 50%. As expected, systemic right ventricular dysfunction and/or tricuspid valve insufficiency are predictors of poor outcomes. In these patients, the incidence of right ventricular dysfunction starts to become noticeable during their second decade of life; by 45 years of age, 32% to 56% of patients have developed ventricular dysfunction.

Systemic AV valve (tricuspid) regurgitation tends to be universally present in patients with systemic RV dysfunction and congestive heart failure. Do these patients develop TR because of systemic ventricular dysfunction, or does the TR hasten the development of it? To date, there is no clear answer. Hraska and associates found that in patients with ccTGA undergoing “classic repairs,” the poorest outcome was seen in those undergoing tricuspid valve replacement. In this study, Ebsteinoid malformation of the TV was not only a risk factor for late development of TR but was also an independent preoperative predictor of mortality. These findings are consistent with other published reports.

Anatomic Repair

The poor outcomes associated with the “classic repair” have led us to explore anatomic repairs. It is fair to say that “double-switch” procedure is considered the preferred surgical therapy for the management of ccTGA, especially in the presence of tricuspid valve anomalies or insufficiency and right ventricular dysfunction. In 1997, Karl et al. showed that the initial risk of the double-switch repair was similar to that of classical repairs. Duncan et al. showed that the double-switch operation could be performed with excellent hospital and long-term survival.

In 2009 Ly et al. achieved successful double-switch operation in 20 patients with ccTGA, 17 of whom had pulmonary artery banding procedure. The mean time elapsing from first banding to final repair was 14 months. Actuarial survival at 10 years was 100%, and the freedom from reoperation at 5 and 10 years was 93% and 77%, respectively.

In 2012, Hiramatsu and associates published the largest surgical series on the double-switch operation in 90 patients (72 “Rastelli/REV” and 18 arterial switches). The overall in-hospital mortality was 10%, with a 20-year-survival rate of approximately 80%. The freedom from reoperation was 77.6% in the Rastelli/REV group versus 94.1% in the arterial switch group. The freedom from arrhythmia was statistically higher in the arterial switch group (78.6%
with intracardiac anatomy not suitable for procedure. The actuarial survival at 22 years was 79%, which was no different than vs. 57.1%). The ratio of NYHA class I to II at outpatient clinic was exactly the same in both groups (86%).

The overall experience with the aortic translocation/atrial switch procedure is limited; the hospital mortality appears to be similar to the other surgical alternatives, but there are truly no long-term data available. Aortic translocation should be considered an alternative approach for patients with intracardiac anatomy not suitable for the Rastelli.

Fontan Procedure
Shin’oka et al. reported on 38 patients with ccTGA that were managed with a Fontan procedure. The actuarial survival at 22 years was 79%, which was no different than patients managed with anatomic repairs. Furthermore, there were fewer reoperations in patients who underwent a Fontan procedure than those undergoing a biventricular repair. The Fontan procedure is certainly an acceptable option for patients with unfavorable anatomy for a biventricular repair.

Left Ventricular Training
The success of the double-switch procedure depends on the ability of the left ventricle to support the systemic circulation. In patients with ccTGA, this usually requires the placement of a pulmonary artery band in order to retrain the LV, by inducing left ventricular hypertrophy. Left ventricular retraining frequently requires a minimum period of 6 to 12 months. Bove et al. noted that older patients are less likely to achieve satisfactory left ventricular retraining. Brawn and associates do not recommend retraining for patients older than 15 years of age. However, the upper age limit is not yet defined. Pulmonary artery banding has been identified as a risk factor for the development of pulmonary root dilatation and neoaortic valve regurgitation.

CONCLUSION
Patients with ccTGA represent a rare but complex group for whom the surgical correction remains a challenge. “Overall” patient outcomes appear to be improved with surgical management that reestablishes a left ventricular-dependent systemic circulation.

SUGGESTED READINGS

Lev M, Rowlatt UF. The pathologic anatomy of mixed levocardia. A review of thirteen cases of atrial or ventricular inversion with or without corrected transposition. Am J Cardiol 1961;8:216-263.

ccTGA, or (S,L,L) transposition, continues to present a challenge for surgical intervention. The tenuous nature of the conducting tissue in this condition has resulted in a significant incidence of late complete AV block with or without surgical intervention. Despite attention to the surgical details of VSD closure, AV block continues to be a late problem requiring pacemaker insertion in up to one-third of cases. In addition, even with direct intracardiac repair, patients are left with a systemic morphologic right ventricle with often an abnormal AV valve and, in addition, frequently a conduit from the morphologic left ventricle to the pulmonary arteries that will require replacement. Thus, the incidence of late reoperation is high and the problem of late systemic ventricular dysfunction significant. Valve reparative procedures on the left side of the heart to the abnormal anatomic tricuspid valve have not been particularly successful, and valve replacement has been associated with late ventricular function deterioration and the complications of prosthetic heart valve insertion. Even conversion to the single-ventricle type of morphology in patients with significant pulmonary stenosis has not been associated with improved long-term results because left AV valve regurgitation may compromise ventricular performance after conversion to single-ventricle physiology. The suboptimal late results have led some authors to suggest the use of a double-switch procedure for selected patients with (S,L,L) anatomy. As described in this chapter, the double-switch procedure creates a Senning or Mustard baffle at the atrial level associated with closure of the VSD to the pulmonary artery and an arterial switch procedure at the level of the great vessels. In this case, the anatomic left ventricle becomes the systemic ventricle, and ventricular inflow is switched at the atrial level. The abnormal tricuspid valve is then associated with the pulmonary ventricle, which is presumably at a lower pressure, and therefore the regurgitation is better tolerated. The use of this technique has been increasing, and the follow-up results for these patients suggest improved outcomes compared with alternative “physiologic” repairs. As nicely summarized by the authors of this chapter, there are now several series with significant numbers of patients being reported with intermediate short-term follow-ups of up to 5 years with a low incidence of atrial arrhythmias but with the need for reoperation in a significant number of the patients. Overall mortality, however, has been quite low. The known
problems of atrial arrhythmias from atrial baffles and the need for conduit revision with these repairs may very well limit the long-term durability of the operation even though ventricular function may be preserved. The operation may also be used for patients with right ventricular dysfunction and tricuspid regurgitation who present later in life either without prior palliative procedures or with prior palliative shunts or bands. Some patients who have had late ventricular deterioration after complete intracardiac repairs despite good anatomic results have had sufficient cardiac dysfunction to require cardiac transplantation for corrected transposition.

The authors of this chapter have described the use of pulmonary artery banding in patients with congenitally corrected transposition of the great arteries to prepare the left ventricle for a double-switch operation. This approach has been used in patients with tricuspid regurgitation to shift the ventricular septum to the right ventricular side, which can significantly decrease the amount of tricuspid regurgitation and to even preserve ventricular function. In patients with corrected transposition and unrestricted pulmonary blood flow, pulmonary banding early in life may be a long-term palliative approach. The technical aspects of pulmonary artery banding are not complex; but in this patient population, the procedure can be associated with extreme ventricular dysfunction with even minor changes in band tightness. Pulmonary banding in this patient population becomes one of the more challenging operations in the armamentarium of the congenital heart surgeon. Generally, pulmonary banding has to be done with continuous monitoring by transesophageal echocardiography to watch the shift of the septum. Even when the band appears to be in perfect position, the ventricles can rapidly deteriorate in function resulting in hypotension and cyanosis. Generally, the band has to be tightened and then released somewhat to allow the ventricle to slowly adapt to increasing pressure. These patients may be extremely ill in the postoperative Cardiac Intensive Care Unit requiring inotropic support and ventilation and sedation for several days to adjust to the acute afterload on the ventricle. Some of these patients may benefit from remotely adjustable pulmonary arterial bands, which can be gradually tightened using remote devices. The use of these adjustable bands may allow the ventricle to more gradually adapt to the increasing pressure. The primary difficulty in banding the pulmonary artery and preparing the left ventricle for the double-switch procedure as noted by the authors is the fact that there is no clear cut-off of age range when this is likely to be successful. The reported series of ventricular retraining and subsequent switch procedures have been associated with a significant operative mortality and morbidity, but in some cases can result in a good anatomic repair and preclude the need for cardiac transplantation.

TLS
PULMONARY STENOSIS

Pulmonary stenosis at the valvar level has been reported to account for 8% to 10% of all congenital heart defects. Although critical pulmonary stenosis may present in the newborn period and require early intervention, most of these lesions are less severe and present after the neonatal period. The pulmonary valve is usually stenotic and dome shaped with fused leaflet tissue and a small central orifice. The right ventricle is usually normal in size, but secondary hypertrophy of the ventricle and infundibulum may occur. The etiology is not known and is probably multifactorial. There is a reported increased incidence of 2% to 4% in siblings of patients with this defect. Treatment of this congenital defect with either balloon valvotomy or surgical valvotomy is associated with low morbidity and mortality and excellent long-term outcomes.

Diagnostic Considerations

Infants with critical pulmonary stenosis may present in the newborn period with severe cyanosis and heart failure. The clinical manifestations are relative to the severity of the stenosis and the patency of a foramen ovale or an atrial septal defect (ASD). In most children with pulmonary valve stenosis and intact ventricular septum, symptoms develop more slowly. Most patients are initially identified by a harsh systolic ejection murmur and a thrill over the pulmonic region on physical examination. An electrocardiogram usually reveals right-axis deviation, prominent P waves, and right ventricular (RV) hypertrophy. A chest radiograph may show prominent pulmonary artery shadows secondary to poststenotic dilation. The heart shadow is normal except in severe cases with congestive failure. Subsequent studies should include echocardiography to establish the severity of the lesion and identify associated abnormalities. Doppler evaluation allows estimation of the gradient across the valve and RV outflow tract. Finally, cardiac catheterization may be performed for additional diagnostic information, hemodynamic data, and for possible therapeutic intervention with balloon valvotomy.

Surgical Treatment and Techniques

Patients with pulmonary valve stenosis and intact ventricular septum require intervention for symptomatic lesions and for significant transvalvular pressure gradients. Historically, surgery was the mainstay of therapy for isolated pulmonary valvar stenosis. Currently, however, catheterization with balloon valvotomy has replaced surgery as the cornerstone of initial treatment. In cases of recurrent stenosis, repeat balloon valvotomy may be attempted before surgical therapy. The incidence of pulmonary insufficiency after balloon valvotomy is high (80%), but it is often clinically mild and well tolerated in most patients. Failed balloon valvotomy can be an indication for urgent surgical intervention. Surgical pulmonary valvotomy may be performed as an open technique using cardiopulmonary bypass or more rarely through a closed transventricular approach. Operative mortality is minimal except in cases of critical stenosis with associated RV hypoplasia and congestive heart failure. The results of treatment are directly related to the size of the RV chamber and the age of the patient at presentation.

Open Pulmonary Valvotomy Using Cardiopulmonary Bypass

Exposure for open pulmonary valvotomy is obtained through a median sternotomy. After heparinization, an aortic cannula is placed in the ascending aorta, and bicaval cannulation is performed. Snares are placed around the inferior and superior venae cavae. A catheter is placed in the ascending aorta for the antegrade delivery of cold blood cardioplegia. A patent ductus arteriosus must be ligated or snared at the initiation of cardiopulmonary bypass. An aortic cross-clamp is applied, and cardioplegia is delivered antegrade to achieve myocardial arrest. The snares are secured around the venous cannulae. The procedure may also be performed without a cross-clamp and cardioplegic arrest if there is no atrial or ventricular communication present.

A longitudinal pulmonary arteriotomy is performed above the level of the valve commissures. The stenotic valve is inspected, and the fused commissures are identified and carefully incised with a no. 11 scalpel blade. The incisions should extend to the annulus (Fig. 91.1A, and 91.1B). Any valvar adhesions to the pulmonary arterial wall are sharply incised. A partial valvotomy may be performed to remove thickened valve tissue or dense scarring on the leaflets. Dysplastic portions of the valve may require excision. The infundibulum is then inspected through the valve for any residual subvalvar stenosis. Sharp infundibular resection through the valve should be performed if necessary. Rarely, a ventriculotomy is required with an infundibular or transannular patch closure. If a small annulus is present, a Hagar dilator may be used to size the valve annulus. The need for a transannular patch can be determined based on this measurement. If there is supravalvar hypoplasia, a pericardial patch is used to close the incision in the pulmonary artery from the annulus to the base of the left pulmonary artery. The arte­riotomy is otherwise closed with a running polypropylene (prolene) suture.

If there is evidence of an ASD or patent foramen ovale, a right atriotomy is performed and the atrial septum is inspected. Closure of a patent foramen ovale or ASD is performed using primary closure or pericardial patch closure with a running prolene suture technique. The tricuspid valve (TV) leaflets are retracted to expose the infundibular outflow tract. Infundibular resection may be performed through the TV to relieve any remaining stenosis. The TV is tested for competence before closure. The atriotomy is then closed.
valvotomy may be performed using a closed approach. Echocardiography is used to assess pulmonary bypass. A wet pump should be partially open. Measurements of pressure prolene suture.

A technique that avoids the use of cardiopulmonary bypass. If the right ventricle is hypoplastic, a patent foramen ovale is left partially open. Measurements of pressure in the right ventricle and the main pulmonary artery will document any residual gradient and should be performed before decannulation. Intraoperative transesophageal echocardiography is used to assess any residual gradient or pulmonary valve insufficiency. There is often a small residual gradient across the valve postoperatively, which may regress with time.

Off-Pump Transventricular Pulmonary Valvotomy

If a restrictive patent foramen ovale is present or the atrial septum is intact, pulmonary valvotomy may be performed using a closed technique that avoids the use of cardiopulmonary bypass. A wet pump should be available on standby for possible use if necessary. A median sternotomy is used, and a purse string of 4-0 prolene suture is placed on the anterior aspect of the right ventricle just below the infundibulum. A 14-gauge angiocatheter with a pressure transducer is first introduced through the right ventricle into the pulmonary artery. Hegar dilators of progressively larger sizes (up to 7 or 8 mm) are then introduced across the valve. If the membrane does not dilate easily, a long vascular clamp can be passed through the purse string and right ventricle to disrupt the valve membrane. We now prefer the use of a balloon dilation catheter and right ventricle to disrupt the valve membrane. A needle pressure transducer is then used to assess the remaining gradient across the valve. After adequate dilation is achieved, the purse string is tied and an additional reinforcing suture is placed in the ventricular epicardium.

Perioperative Management

Most patients with pulmonary stenosis are operated on electively with routine preoperative and postoperative care. Neonates with critical stenosis should be stabilized in the intensive care unit and operated on as soon as possible. Acidosis, electrolyte abnormalities, and congestive heart failure are corrected preoperatively.

These patients may also have stenosis in the infundibular region secondary to RV myocardial hypertrophy. Inotropes must be used with caution in the preoperative and postoperative periods because increased contractility may cause increased dynamic obstruction across the pulmonary outflow tract and further compromise pulmonary blood flow.

Postoperative Care and Surgical Complications

Postoperative care for patients after surgical pulmonary valvotomy should focus on adequate RV filling pressures and reduced pulmonary artery pressures. Pulmonary vasodilators may be used in the early postoperative period to increase pulmonary flow and reduce RV afterload. Inotropic support may be useful for the first few days.

Transcardiac monitoring catheters may be placed in the right atrium or through the right ventricle into the pulmonary artery to continuously monitor hemodynamic data postoperatively. These are generally discontinued within the first 48 hours.

Pulmonary insufficiency may result from either open or closed valvotomy. Most patients will tolerate this residual valve incompetence with little difficulty. RV dysfunction may be present in the early postoperative period. This is usually transient, but may require moderate inotropic support during the early postoperative recovery.

Infants with critical pulmonary stenosis and an adequate-sized pulmonary valve annulus are often treated with balloon valvuloplasty rather than surgical intervention. However, patients with severely dysplastic pulmonary valves or significant RV outflow tract obstruction with dynamic infundibular obstruction may still come to surgical intervention and require open valvotomy or a transannular patch. If the obstruction is adequately relieved, any residual infundibular hypertrophy will regress over time. Most patients recover without complications, and long-term outcomes are excellent for both balloon valvotomy and surgical valvotomy.

PULMONARY ATRESIA WITH INTACT SEPTUM

Pulmonary atresia with intact septum (PA/IVS) is a rare defect that represents between 1% and 3% of all congenital heart defects. The exact cause or event that leads to pulmonary atresia is unknown. The lesion is sporadic, and no significant familial pattern has been identified. By definition, there is no communication between the right ventricle and the pulmonary arteries. Consequently, a patent ductus arteriosus is essential for early survival with this defect. The confluence of the branch pulmonary arteries with the main pulmonary artery is usually normal and the main pulmonary artery then tapers to an atretic pulmonary valve. The atresia of the pulmonary valve may vary significantly from a thick muscular obstruction without significant valve tissue to a thin plate-like fused trileaflet valve with well-developed sinuses and commissures. There are usually varying degrees of hypoplasia of the right ventricle and the TV, and RV-to-coronary artery fistulas may be present. Morphologically and functionally, the hypoplasia of the TV usually varies directly with the hypoplasia of the right ventricle. The TV is almost always abnormal with dysplastic leaflets, shortened chordae, and restricted leaflet motion. An Ebstein-like malformation may be present in up to 10% of patients and is usually associated with severe tricuspid
regurgitation. Coronary artery fistulas are present in 45% of cases and are more common in patients with severely hypoplastic right ventricles and small competent TVs. Of note, aortopulmonary collaterals are rarely found in patients with this defect. Without early surgical intervention, children with PA/IVS have an extremely high mortality rate. The natural history of this defect is associated with 50% mortality at 2 weeks and 85% mortality at 6 months.

**Diagnostic Considerations**

Diagnosis of this lesion is usually made in neonates and is prompted by the presence of hypoxia in varying degrees in the newborn period. Physical examination findings are often remarkable for prominent cervical venous pulsations and hepatic enlargement. A significant murmur is indicative of tricuspid regurgitation or may be related to the patent ductus arteriosus. An electrocardiogram shows progressive evidence of right atrial enlargement with peaked right atrial P waves. A chest radiograph is unremarkable at birth but may later reveal an increased cardiac shadow secondary to right atrial and left ventricular enlargement. The diagnosis of pulmonary atresia with intact ventricular septum is usually made by two-dimensional echocardiography. Ventricular cavity sizes, valve dimensions and function, and the nature of the pulmonary artery obstruction can be determined by echocardiography. Cardiac catheterization is used for a definitive diagnosis and further evaluation. Information determined during right and left heart catheterization should include the size and competency of the TV, the functional status of the ventricles, the degree of RV hypoplasia, the degree of infundibular hypoplasia, the presence or absence of coronary sinusoids and their communications with the anatomy of the coronary arteries, and the size of the pulmonary arteries. In addition to an injection of contrast medium into the right ventricle, selective coronary angiograms are required to assess the native coronary anatomy, particularly in the severely hypoplastic RV group. Newborns with hypoxemia and poor perfusion in spite of medical management should be assessed for the presence of a restrictive ASD, which can be enlarged by balloon septostomy at the time of catheterization. If the ductus arteriosus is closed or restrictive, prostaglandin E1 (PGE1) is infused to open the ductus. In the current era, a role is developing for stenting of the ductus arteriosus at the time of catheterization as an initial palliative intervention.

**Anatomic Considerations**

Our initial management of patients with PA/IVS is based largely on an anatomic classification, which specifically defines the degree of RV hypoplasia and the TV annular size measured as a Z-score. This classification not only allows initial management strategies but also has predictive value for the possible use of the right ventricle in subsequent definitive biventricular repair. The Z-score is determined by comparing the diameter of the TV (as measured by echocardiography) to the “expected” size and calculating the difference in standard deviations. This allows for a quantitative assessment of the degree of hypoplasia of the TV, which in most patients varies directly with the degree of hypoplasia of the RV. We and others have found that the degree of RV hypoplasia and the TV Z-score correlate with short- and long-term outcomes of surgical management of PA/IVS.

In this classification, newborns with PA/IVS are initially separated into three groups of mild, moderate, and severe RV hypoplasia. In patients with mild RV hypoplasia, the TV and RV cavity are approximately two-thirds or greater of calculated normal size and the RV outflow tract is well developed. This usually correlates with a Z-score for the TV of 0 to -2. In patients with moderate RV hypoplasia, the TV and the RV cavity are approximately one-half of calculated normal size (with a range of one-third to two-thirds normal), and the outflow tract is developed enough to allow an effective pulmonary valvotomy. This usually correlates with a Z-score for the TV of -2 to -4. In patients with severe RV hypoplasia, the TV and RV cavity are one-third or less of calculated normal size and the outflow tract is severely hypoplastic or obliterated and is often not amenable to an effective pulmonary valvotomy. This usually correlates with a Z-score for the TV of -4 to -6.

Our approach is not based on a single anatomic finding but instead assesses the overall RV morphology and the degree of both TV and RV hypoplasia.

The TV is often anatomically and functionally abnormal in patients with PA/IVS. Therefore, a TV Z-score or valve diameter alone may not adequately predict the likelihood of achieving a biventricular repair. Similarly, some patients with only moderate RV hypoplasia may have a severe tricuspid malformation and ultimately undergo a single-ventricle approach with a Glenn or Fontan procedure. In addition, the compliance of the abnormal right ventricles with significant ventricular hypertrophy and small cavity size may limit the possibility of a complete two-ventricle repair even in those with only moderate hypoplasia.

A fourth subgroup of patients may present with marked cardiomegaly caused by right atrial enlargement, severe tricuspid regurgitation, and an Ebstein’s anomaly of the TV. Dilation and dysfunction of the right atrium (RA), RV, and ventricular septal wall in these patients often compromise left ventricular function and lead to biventricular failure. These patients may have significant compromise of the left ventricle by the dilated right ventricle, and the inefficient flow of blood in and out of the right ventricle compromises overall systemic blood flow. The creation of an aortopulmonary shunt may stabilize pulmonary blood flow in these patients, but the effect of the dilated right ventricle on systemic cardiac output may remain. Patch closure of the TV is usually not suitable for these patients, because there will be no outflow of the coronary sinus return, and often sinusoidal connections and Thebesian vessels into the right ventricle cannot then be decompressed. Surgical intervention in these patients is associated with >50% mortality. In these patients, the best approach may be early cardiac transplantation.

During the initial evaluation of patients with PA/IVS, particular attention must be paid to the anatomy of the coronary circulation. Abnormalities of the coronary circulation are often found in the severely hypoplastic group and may dictate which surgical management option is indicated. During fetal development, RV hypertension may cause intramyocardial sinusoids to develop. These sinusoids often communicate by fistulas with the coronary artery circulation. The morphology of these sinusoids and their specific communications are extremely variable. Proximal coronary artery stenosis or obstruction may develop in a native coronary artery supplied by these intramyocardial sinusoids. If the distal coronary artery flow is dependent on these sinusoids for adequate myocardial perfusion, they are termed RV-dependent coronary circulations (RVDCCs). Decompression of the right ventricle in these patients is contraindicated as it may lead to acute myocardial ischemia and death. A limited experience has shown that a shunt from the aorta to the right ventricle may be beneficial in these patients to augment myocardial perfusion and coronary blood flow.

**Initial Surgical Treatment and Techniques**

Most infants with PA/IVS will require surgical management early in life to survive.
Treatment with intravenous PGE, will maintain pulmonary flow through the patent ductus arteriosus and allows time for evaluation and interventional decision making. Recently, some neonates have been successfully palliated with stenting of the ductus arteriosus at the time of catheterization. This has allowed delay of surgical intervention in those neonates who would otherwise be treated with a central shunt as an initial palliation. The efficacy of this catheter-based therapy appears promising for some neonates with PA/IVS, but the indications remain to be defined. Once the anatomy and morphology of these lesions have been identified at cardiac catheterization, classification is determined, and an appropriate operative strategy is planned. Delay in surgical treatment is often hazardous and may reduce survival. The primary goals of initial therapy should be to minimize early mortality and maximize the potential for a biventricular repair later in life. The choice of surgical approach is based on the anatomic classification previously described (Table 91.1).

Initial Procedures for Neonates with Mild Right Ventricular Hypoplasia

Neonates with mild RV hypoplasia (the right ventricle approximates two-thirds of normal or greater) and a tricuspid Z-score of 0 to −2 are best treated with a pulmonary valvotomy, ligation of the patent ductus arteriosus, and creation of a central systemic-to-pulmonary artery shunt. Occasionally, there are patients in which a pulmonary valvotomy alone will be adequate to restore pulmonary blood flow. These are rare and this surgical strategy should be performed with caution. Most of these patients will require a shunt as an additional source of pulmonary blood flow. Neonates with moderate RV hypoplasia and a tricuspid Z-score of −2 to −4 are treated with a pulmonary valvotomy, patch augmentation of the pulmonary outflow tract, insertion of a central shunt, and ligation of the patent ductus arteriosus. Pulmonary valvotomy with patch augmentation of the pulmonary outflow tract relieves RV hypertension, reduces tricuspid regurgitation, and promotes growth of both the RV cavity and TV. Neonates with severe RV hypoplasia and a tricuspid Z-score of −4 to −6 are usually treated with a shunt only. If there is no RVDCC and no pulmonary valvotomy is performed, then the TV can be made incompetent to decompress the RV using an open or closed tricuspid valvotomy technique. Catheter balloon disruption of the TV has also been described.

### Off-Pump Transventricular Pulmonary Valvotomy

Closed pulmonary valvotomy may be performed on patients with mild-to-moderate RV hypoplasia who have an adequately developed RV outflow tract below the obstructed pulmonary valve. This should be performed with wet-pump standby in case there is hemodynamic instability during the procedure. The technique is performed as previously described. Many of these patients can now be effectively treated with perforation of the membrane using radiofrequency ablation catheters and subsequent balloon catheter dilation valvotomy. This approach may obviate the need for initial surgical intervention in this group of patients.

### Aorta-to-Pulmonary Artery Shunt

A median sternotomy is used in performing a central shunt. The shunt insertion is performed by connecting either the innominate artery to the right pulmonary artery or the ascending aorta to the main pulmonary artery using a polytetrafluoroethylene (Gore-Tex) graft. A 3.0-mm shunt is used for neonates ≤3.0 kg, a 3.5-mm shunt in those >3.0 kg, and 4.0-mm shunt in those >4.0 kg. Cardiopulmonary bypass is usually not necessary but immediately available during the procedure. Partial occluding thin-bladed vascular C-clamps of appropriate sizes are applied to either the innominate artery or the aorta and to the pulmonary artery. Care must be taken to avoid occluding or compromising flow in the patent ductus. The arteriotomies are performed with a no. 11 scalpel blade and fine vascular scissors. The proximal anastomosis is performed on the anterior aspect of the aorta or the innominate artery in an end-to-side manner using a running 7-0 prolene suture technique. A similar anastomosis is performed to the anterior aspect of the main pulmonary artery or the right pulmonary artery. We prefer to leave the proximal clamp on during the distal anastomosis and avoid clamping the graft or allowing blood in it before flow is established. This reduces the risk of thrombus formation in the graft prior to release of the clamps. The graft is flushed with heparinized saline prior to completion of the distal anastomosis. The clamps are released slowly to deair the graft, and flow is established through the shunt. The ductus arteriosus is ligated after completion of the central shunt procedure.

### Moderate Procedures for Neonates with Moderate Right Ventricular Hypoplasia

Neonates with moderate RV hypoplasia are best treated with ligation of the patent ductus arteriosus, insertion of a central shunt, a pulmonary valvotomy, and patch augmentation of the pulmonary outflow tract. The transannular patch and pulmonary valvotomy may be performed with cardiopulmonary bypass and cardioplegic arrest. This allows a motionless bloodless field to perform an effective valvotomy, resect obstructing infundibular myocardium, and ensure an adequate patch augmentation. Incision of the RV outflow tract in pulmonary atresia must be performed carefully to avoid injury to the base of the aortic valve leaflet. Thus, the use of cardioplegia and cardiopulmonary bypass may allow more accurate placement of the valvotomy incision.

In select patients, we have also successfully used a closed off-pump technique to perform a pulmonary valvotomy and place...
a transannular outflow tract patch of pericardium without the use of either cardioplegic arrest or cardiopulmonary bypass.

**Off-Pump Pulmonary Valvotomy with Transannular Right Ventricular Outflow Tract Patch**

In neonates with moderate RV hypoplasia, the infundibulum may be long and narrow but reaches the pulmonary valve membrane. In these patients, a pulmonary valvotomy and a pericardial transannular patch may be performed without using cardiopulmonary bypass.

A median sternotomy incision is used. Wet-pump bypass is available with the lines on the field in case bypass is necessary. A pediatric cross-clamp is placed immediately beneath the bifurcation of the pulmonary artery. The ductus is kept patent to provide pulmonary blood flow. A vertical incision is made in the main pulmonary artery down to the atretic pulmonary valve and RV junction. A partial-thickness myocardial incision is made over the right ventricle to bring the incision over the RV cavity. Part of the muscle is resected to a depth of 1 to 2 mm to thin out the right ventricle. An elliptical pericardial patch is now sutured to the pulmonary artery incision with a running 5-0 or 6-0 prolene suture down to the RV junction. The suture line is continued onto the myocardium to the edges of the RV incision, leaving the sutures loose inferiorly. A no. 12 blade scalpel is then used to incise the pulmonary valve membrane and to cut through the remaining myocardium into the RV cavity under the pericardial patch. The sutures are pulled up to control bleeding and the cross-clamp on the pulmonary artery is removed.

If the RV pressure is not adequately reduced to between one-half and one-third of systemic pressure, a rhizotomy knife is introduced through a purse string in the pericardial patch, and the RV muscle is further incised until an adequate outflow tract has been created to adequately reduce the RV pressure (Fig. 91.2A–91.2C).

**Initial Procedures for Neonates with Severe Right Ventricular Hypoplasia**

Neonates with severe RV hypoplasia (less than one-third normal) can be difficult to manage. If there is a restrictive atrial communication, then balloon atrial septostomy may be performed at the time of catheterization. The ductus is kept patent with PGE, and may also be stented at the time of initial catheterization. At the time of surgery, simple pulmonary valvotomy is usually not effective in relieving RV hypertension and establishing antegrade flow to the pulmonary arteries. An extensive myomectomy and pericardial outflow tract patch may be performed using cardiopulmonary bypass. A Gore-Tex central shunt is inserted from the aorta to the main pulmonary artery, and the ductus arteriosus is ligated. If there are no sinusoids or if the sinusoids are tortuous and narrow and the native coronary circulation is normal, the right ventricle may be decompressed by incising the TV under direct vision using cardiopulmonary bypass and cardioplegic arrest or using a closed technique as described. It should be noted that patients who undergo tricuspid valvotomy decompression of the right ventricle should not have a concomitant pulmonary valvotomy with associated pulmonary insufficiency. This will allow the shunt flow to be directed retrograde across the outflow tract to the right ventricle and then into the right atrium, resulting in a significant steal of blood away from the pulmonary vascular bed. Repeat cardiac catheterization within 3 months is performed in this group of patients.

**Closed Tricuspid Valvotomy**

Closed tricuspid valvotomy is used in patients with severe RV hypoplasia where the possibility of a subsequent biventricular repair is minimal. Preoperative catheterization must determine the absence of sinusoids or an RVDCC before decompression of the right ventricle. As noted previously, RVDCC is one in which the native coronary circulation has proximal stenoses and the sinusoids...
have broad-based communications with the RV cavity and the coronary circulation.

The closed tricuspid valvotomy is performed through a median sternotomy. The pericardium is opened, and a purse-string suture is placed around the right atrial appendage. An instrument is made using a rhizotomy knife with a small, curved blade passed through a segment of red rubber tubing (Fig. 91.3A and 91.3B). A pressure-measuring needle is placed into the tubing and connected to a transducer monitor. The tubing is then introduced into the right atrium via the right atrial appendage and passed into the right ventricle while the pressure is monitored. The knife blade is then exposed in the right ventricle and the TV is cut anteriorly. Care is taken to avoid incising the area of the conduction system. When the RV pressure has fallen to one-half systemic pressure or less, the knife is retracted into the tubing, which is then removed from the right atrium. The purse-string suture is tied to achieve hemostasis. We have found in patients without a pulmonary valvotomy that decompression of the right ventricle with a tricuspid valvotomy results in regression of the narrow tortuous types of sinusoids and has not resulted in myocardial ischemia if the native coronary circulation is intact.

### Definitive Surgical Treatment and Techniques

Cardiac catheterization is repeated when the patient is 3 to 6 months of age, depending on the anatomy and echocardiographic findings. Further procedures will be based on the anatomic findings at catheterization. These patients are again divided into those with mild, moderate, or severe RV hypoplasia (Table 91.2).

#### Definitive Procedures for Patients with Mild Right Ventricular Hypoplasia

Some patients with mild hypoplasia treated initially by pulmonary valvotomy may not require subsequent surgery unless the obstruction to the outflow tract has recurred. Relief of obstruction with pulmonary regurgitation and an open atrial communication can produce a large right-to-left shunt resulting in hypoplasia of the TV annulus while the right ventricle develops well due to the regurgitation. This can lead to a discrepancy in the size of the TV and the RV cavity. In a patient with mild RV hypoplasia, definitive repair consists of primary or patch closure of the ASD with a fenestration or an adjustable snare, enlargement of the RV cavity and RV outflow tract by myocardial resection, and pericardial patch augmentation of the RV outflow tract. A monocusp transannular patch with an autologous pericardial valve or a homograft or tissue valve is inserted in the pulmonary outflow tract, depending on the size of the child.

### Enlargement of the Right Ventricular Cavity and Right Ventricular Outflow Tract

The RV cavity is enlarged by sharp resection of trabecular myocardium. The procedure is performed using cardiopulmonary bypass.

with bicaval cannulation and both antegrade and retrograde blood cardioplegia. The right atrium is opened obliquely and the TV is inspected. The annulus is measured and compared with normal values, and its competence is tested with cold saline. An incision is made longitudinally from the main pulmonary artery, through the annulus. If the outflow tract is hypoplastic, the incision is extended to the RV cavity. Obstructive hypertrophied muscle in the outflow tract is resected. Care is taken to work between the papillary muscles of the TV, which must be preserved. A glutaraldehyde-treated pericardial outflow patch is then placed on the transannular incision. If the RV cavity is adequate and the TV is competent, a pulmonary valve may not be required. In infants, we generally prefer a pericardial monocusp valve. In older children, we have used a pulmonary homograft or porcine valve within the RV outflow tract.

Adjustable Atrial Septal Defect

If the ASD is large, it is closed with a pericardial patch, leaving an open defect adjacent to the right superior pulmonary vein for the adjustable snare. If the defect is small with firm edges, it may be closed with the purse string of the “adjustable atrial septal defect.” The adjustable ASD is performed by placing a no. 1 prolene suture as a purse string around the tissue edges of the existing septal defect. A pericardial pledget is used to avoid tearing of the tissue edges. The no. 1 prolene is secured to the edges of the defect with 5-0 prolene interrupted sutures. Both ends of the no. 1 prolene are then brought out through the interatrial groove. An 8-F polyethylene tube is measured so that the end will lie under the linea alba closure. The prolene sutures are passed through the lumen of this tube to create a snare to control the size of the atrial communication. The end of the tubing is sutured to the atrial wall with a single prolene suture. The size of the ASD is adjusted by tightening or loosening the snare. retracting the prolene sutures in the snare results in closure of the ASD, and pushing on the prolene opens the communication. The prolene is then fixed to the tube with several medium hemoclips. The end of the snare is left under the linea alba in the subxiphoid region, where it can be retrieved under local anesthesia postoperatively for subsequent adjustment. The same technique can be used to create an adjustable defect in a patch repair using pericardium. The defect in the suture line is left on the right side adjacent to the right superior pulmonary vein, where it is encircled by the no. 1 prolene snare as described. The ASD is left open until the patient is weaned from bypass. The ASD is then slowly closed using the snare while the right atrial pressure and the arterial oxygen saturations are monitored. A right atrial pressure of about 10 to 12 mmHg with an oxygen saturation of $\geq 88\%$ on 100% fraction of inspired oxygen (FiO$_2$) is the goal. This adjustment of the ASD snare may be facilitated by using transesophageal echo visualization as well (Fig. 91.4A and 91.4B).

Definitive Procedures for Patients with Moderate Right Ventricular Hypoplasia

In a patient with moderate RV hypoplasia, definitive repair is dictated by the previous growth and development of the right ventricle and the TV. If the right ventricle and TV diameter are one-half to two-thirds of normal size, repair consists of partial closure of the ASD with an adjustable snare, enlargement of the RV cavity by myocardial resection, and insertion of a valved connection between the right ventricle and the pulmonary artery. A monocusp transannular patch from native pericardium may be used in younger patients. If the right ventricle and TV diameter is one-third to one-half of normal, repair consists of partial closure of the ASD with an adjustable snare, enlargement of the RV cavity, creation of a bidirectional cavopulmonary Glenn shunt, and insertion of a valved connection between the right ventricle and pulmonary artery. The Glenn shunt reduces the volume load on the small right ventricle and provides an obligatory source of pulmonary blood flow.

![Fig. 91.4](image-url)
from approximately one-third of the systemic venous return. This has been termed the “one and one-half ventricle repair” or “partial biventricular repair.” The ASD is adjustable to create a gradient between the right atrium and left atrium to encourage forward flow through the RV, which will enhance the development of the TV and the right ventricle. Either a two-ventricle repair (with takedown of the Glenn shunt) or a completion of the Fontan reconstruction will follow based on the subsequent growth and development of both the right ventricle and TV.

Tissue Valve Insertion
A transannular incision is made vertically across the pulmonary outflow tract and extended onto the left pulmonary artery and down into the right ventricle. Any residual membrane in the region of the annulus is resected, as well as obstructive muscle in the outflow tract. The distance between the RV outflow tract and the pulmonary artery bifurcation is assessed. If it is short, a stented bioprosthetic porcine valve can be placed under a pericardial or Gore-Tex patch within the RV outflow tract (Fig. 91.5A and 91.5B). A running 3-0 prolene suture is used to insert the valve, which is also sutured to the patch anteriorly. The pericardium is treated with glutaraldehyde for 3 minutes and rinsed with saline. If the distance between the RV outflow tract and the pulmonary artery bifurcation is adequate, an appropriately sized pulmonary homograft may be used. A running suture of 4-0 prolene is used distally just below the pulmonary artery bifurcation. Proximally, the homograft is sutured to the RV outflow tract just below the pulmonary valve annulus with a running suture of 3-0 prolene (Fig. 91.6A and 91.6B). A hood of pericardium or Gore-Tex may be used to complete the reconstruction.

Transannular Pericardial Patch with Monocusp Valve
The technique of a transannular pericardial patch with a monocusp valve is not only used for neonates and infants but can also be used for older children. It is best used for patients with mild or moderate RV hypoplasia with normal pulmonary artery size because the valve will remain competent for a shorter period of time than a tissue valve. It has the advantage, however, of not causing obstruction even when the valve has become incompetent. Insertion of a transannular patch with a monocusp valve is performed through median sternotomy using cardipulmonary bypass and bicaval cannulation. After harvesting, the pericardium is treated with glutaraldehyde for 5 minutes and then rinsed in saline. Both the transannular patch and the monocusp valve leaflet are outlined on the harvested pericardium using a sterile marking pen. Sizing of the monocusp valve is made using a metal dilator approximately 20% larger than the “normal” diameter for the pulmonary annulus. The width of the monocusp leaflet at its base should be approximately one-half of the circumference of the dilator. It should also correspond with the width and shape of the inferior end of the transannular patch. The superior edge of the monocusp valve leaflet should be attached to the edges of the incised pulmonary artery 5 to 10 mm distal to the area of the true valve annulus. The monocusp valve is attached to the edges of the pulmonary artery and the right ventricle using the same suture that attaches the edges of the transannular
patch (Fig. 91.7A and 91.7B). A strip of treated pericardium may also be used to reinforce the suture line in the myocardial edges and promote hemostasis.

Definitive Procedures for Patients with Severe Right Ventricular Hypoplasia

In a patient with severe RV hypoplasia (one-third of normal size or less) and a Z-score of −4 to −6, a biventricular repair is usually not possible. Most of these patients will undergo insertion of a central shunt in the neonatal period with or without decompression of the right ventricle depending on whether or not there is an RVDCC. Tortuous sinusoidal connections without coronary stenoses do not usually denote an RVDCC. Decompression of the right ventricle at the time of the bidirectional Glenn shunt will usually result in closure of these sinusoids as opposed to the broad-based fistulous connections. In some cases, the large fistulous connections can be identified on the epicardial surface of the heart and can be suture ligated at the time of the bidirectional Glenn shunt, allowing RV decompression at that site. RV decompression can be performed via the right atrium using the closed technique described previously to incise the anterior leaflet of the TV.

If there is an RVDCC, a bidirectional Glenn shunt is performed at 3 to 4 months of age without RV decompression and without cardiopulmonary bypass. Any additional source of pulmonary blood flow such as a previously placed central shunt is reduced to give an estimated combined $Q_a:Q_s$, ratio of 1:1 from the Glenn shunt and the systemic-to-pulmonary artery shunt. At 2 to 3 years of age, the Fontan procedure is completed with a fenestration or an adjustable ASD. During this final procedure, the atrial septum is excised and the coronary sinus is unroofed. If there are signs of myocardial ischemia, either preoperatively or intraoperatively, the RVDCC may be improved by creating an aorta-to-right ventricle shunt at the time of the Glenn shunt or the Fontan procedure. Early bidirectional Glenn shunting or augmentation of RV flow with an aorta-to-right ventricle connection and an early Fontan procedure results in improved oxygenation of the coronary flow from the RV in these patients with RVDCC.

However, these patients may continue to have problems with ventricular dysfunction and myocardial ischemia, and may have acute myocardial infarction early in life, causing ventricular dysfunction or early death. Thus, in some patients with significant ventricular dysfunction in association with RVDCC, early shunting for stabilization followed by orthotopic cardiac transplantation should be considered.

Bidirectional Cavopulmonary Glenn Shunt

A median sternotomy incision is used for the Glenn shunt. Care should be taken in dissecting out the superior vena cava (SVC) and the right pulmonary artery to stay in the perivascular plane and avoid disrupting lymphatic tissue, which could result in a chylothorax. Injury to the phrenic nerve as it courses along the pericardium on the lateral aspect of the SVC must also be avoided. The pulmonary artery pressure is measured on both sides. The azygos vein is ligated and divided.

A left SVC may be present and is usually found anterior to the left pulmonary artery. Care must be taken not to mistake a left upper-lobe pulmonary vein for a systemic vein. The SVC is then clamped just above the right atrium, and the proximal pressure is monitored. If the pressure does not rise above a mean of 30 mmHg, then a left SVC should be suspected. If there is a left SVC with a venous communication to the right SVC, the pressure will usually not rise above 30 mmHg and bypass or a temporary shunt is not necessary.

If the proximal pressure in the clamped SVC is $\geq 30$ mmHg, a temporary shunt should be used. The use of bypass is avoided if at all possible, particularly if there are ventricular sinusoids. The SVC is dissected from surrounding tissue starting at its right atrial junction and extending to the confluence of the innominate vein. The right pulmonary artery is identified and dissected circumferentially from surrounding tissue both medially and laterally to the site of primary branching. A purse-string suture of 5-0 prolene is placed in the SVC at the junction of the innominate vein. A second purse string is placed in the right atrial appendage. The patient is heparinized, and a temporary bypass shunt is created using two modified aortic cannulas and a Y-connector with a chapeau attachment. The SVC is cannulated with one modified aortic cannula at the junction of the innominate vein. The distal end of this cannula should be beveled so that the opening is as large as possible relative to the venous cannulation site and should face superiorly toward the right internal jugular vein. The second cannula is placed in the right atrial appendage. The circuit is connected after air is completely evacuated from the cannulas and the clamps are removed. A needle can be placed in the chapeau attachment to facilitate the removal of air. Flow should be visualized in
the shunt after removal of the clamps. The cannulas are then supported by towels in a medial position that allows exposure of the SVC and right pulmonary artery.

The SVC is then clamped at its junction with the right atrium and at its junction with the innominate vein. The pressure may be measured in the proximal SVC with the first clamp in place to ensure proper functioning of the shunt. Methylene blue is used to mark the anterior aspect of the SVC and the superior aspect of the PA to ensure proper alignment of the subsequent cavopulmonary anastomosis. The azygos vein is ligated and divided. The SVC is divided at the atrial junction, with care being taken to leave an adequate cuff of tissue with the clamp to allow subsequent closure of this SVC stump. Attention to the rhythm at this point helps to avoid clamp injury to the sinoatrial node.

The SVC orifice is identified from within the right atrium. It is important that this orifice be widely open and not restrictive. The right pulmonary artery is incised adjacent to the opening in the SVC stump. The posterior wall of the anastomosis is achieved by suturing the adjacent pulmonary artery and right atrium together with 5-0 prolene. Anteriorly, the connection may be bridged with a pericardial patch if needed to assure a patent unrestricted opening.

Any previously placed systemic-to-pulmonary artery shunt is now reduced in size to give an estimated combined $Q_s:Q_a$ ratio of 1:1 from the systemic-to-pulmonary artery shunt and the Glenn shunt. The change in arterial systolic blood pressure, with the shunt open versus closed, should be no more than 5 to 7 mmHg.

The SVC and pulmonary artery pressures are measured, as well as the arterial oxygen saturations on 100% oxygen. The heparinization is not reversed. If a jugular vein line has been inserted, it is used for measuring the pulmonary artery pressure and for the infusion of pulmonary vasodilators, if necessary. The line is removed within 24 hours to avoid venous thrombosis.

A Gore-Tex membrane is left as a pericardial substitute to facilitate reoperation for the Fontan procedure.

**Lateral Tunnel Fontan with Adjustable Atrial Septal Defect**

A Fontan procedure is usually performed as a second-stage operation after the creation of a cavopulmonary Glenn shunt. A median sternotomy is performed, and bicaval venous cannulation is used for total cardiopulmonary bypass. Note that the SVC cannula is placed above the previous Glenn shunt anastomosis. Systemic hypothermia to 28°C is used in addition to cold blood cardioplegia.

A right atriotomy is performed just anterior to the lineal terminalis, and the edges are retracted with stay sutures. The coronary sinus is identified and cannulated with a retrograde cardioplegia catheter. A prolene purse string is placed at the opening of the coronary sinus to secure the catheter and achieve more efficient delivery of the cardioplegia. The atrial septum is excised. The SVC orifice is identified from within the right atrium. It is important that this orifice be widely open and not restrictive. The right pulmonary artery is incised adjacent to the opening in the SVC stump. The posterior wall of the anastomosis is achieved by suturing the adjacent pulmonary artery and right atrium together with 5-0 prolene.

After the right atrium-to-pulmonary artery anastomosis has been completed, the lateral tunnel is constructed. A rectangular Gore-Tex patch is cut from 0.8-mm-thick Gore-Tex vascular patch material. The length is carefully measured from the orifice of the inferior vena cava (IVC) to the SVC orifice. The width is left about two-thirds of the length to be trimmed after completion of the posterior suture line.

A running 4-0 prolene suture with an RB1 needle is used for the posterior suture line, which is begun posteriorly at the IVC orifice. The suture line is carried superiorly to the site of the adjustable ASD orifice, where it ends. This site is chosen because there is a natural recess close to the right superior pulmonary vein at the superior and lateral end of the fossa ovalis. A second 4-0 prolene suture line is begun at the superior end of the ASD and carried superiorly around the SVC orifice. The ASD is sized according to the age of the patient and made large in diameter so that it may be reduced in size if necessary after the patient is taken off bypass. As a rule of thumb, the defect size is 4 mm for 2-year-olds and 6 mm for 4-year-olds and above. The patch is trimmed appropriately as the suture line advances. Before the anterior suture line is completed, the snare control is placed for the adjustable ASD. A no. 1 prolene suture is brought through a pericardial pledget, through the interatrial septum at the lower border of the ASD, and through the edge of the Gore-Tex patch. It is then brought back through the upper edge of the Gore-Tex patch and out through the interatrial septum and through the pericardial pledget. An 8-F polyethylene tube is cut to the appropriate length to reach the linea alba, and the prolene sutures are brought through this snare. The no. 1 prolene is sutured to the edge of the Gore-Tex patch with a 5-0 prolene suture, the polyethylene tubing is sutured to the lateral wall with 2-0 chromic catgut, and the prolene is fixed to

---

Fig. 91.8. (A) A bidirectional Glenn shunt is performed using a superior vena cava-to-right atrium shunt. This technique avoids the use of cardiopulmonary bypass. (B) The cannulas are placed in the superior vena cava and the right atrium (as shown), allowing continuous flow of venous return to the right atrium during creation of the cavopulmonary anastomosis.
the tubing with a medium hemoclip. These three points of fixation prevent inadvertent closure of the ASD by tension on the prolene. The patch is now trimmed to create a wide-open connection and to reach just anterior to the linea terminalis. The anterior part of the suture line is completed using full-thickness sutures to avoid a suture line leak. The right atrial incision is then closed with 4-0 prolene (Fig. 91.9A and 91.9B).

The coronary sinus cannula and the purse-string suture are removed, and the right atrium is closed in a two-layer fashion with a running prolene suture. Transthoracic lines are generally placed in the left and right atria. If an internal jugular line is not inserted, then the right atrial line can be inserted to measure the pressure in the pulmonary system via the Fontan tunnel or the Glenn shunt. Air is evacuated from all structures. The patient is warmed to normothermia and subsequently weaned from cardiopulmonary bypass. The adjustable ASD snare is adjusted to achieve arterial saturations of 80% to 85% while an attempt is made to maintain pressure in the lateral tunnel Fontan at or below 15 mmHg. Adjustment of the ASD can be facilitated by visualization intraoperatively with transesophageal echocardiography.

For Fontan operations in these patients, some have preferred the use of the fenestrated lateral tunnel Fontan with a fixed 4-mm fenestration by a punch technique rather than use of an adjustable defect. While this does not allow postoperative adjustment of the shunt, it does simplify the operative procedure and has been shown to be effective. In most of these cases, the fixed defect will ultimately close spontaneously.

Extracardiac Fontan with Adjustable Fenestration

The extracardiac Fontan is performed through a median sternotomy using cardiopulmonary bypass and bicaval cannulation. The procedure can be completed in most patients without the need for cardioplegic arrest of the heart. A clamp is placed on the IVC near its junction to the right atrium. The IVC is then divided between the snared venous cannula and the clamp. The atrium is repaired and the clamp is removed. The open end of the IVC is anastomosed end-to-end to a Gore-Tex conduit (16 to 20 mm in diameter) using a running Gore-Tex suture. The proximal anastomosis is performed end-to-side between the Gore-Tex conduit and the inferior aspect of the right pulmonary artery. The clamps are released and flow is established between the IVC and the pulmonary arteries. A direct anastomosis can be made between the conduit and the atrial wall to allow shunting through the fenestration (Fig. 91.10A and 91.10B).

To insert an adjustable ASD, a partial occluding vascular C-clamp is placed on the Gore-Tex graft. A direct anastomosis is performed between the extracardiac conduit and the right atrium. A snare is inserted to control the opening and closing of this "atrial septal defect." An alternate method uses a conduit for the defect. With this technique, a short segment of 8.0-mm Gore-Tex graft is anastomosed end-to-side to the middle of the larger conduit. A similar technique is used to create an opening in the right atrium, and the other end of the 8.0-mm graft is anastomosed end-to-side to this site. A snare is inserted around the smaller conduit. A distinct drawback to the extracardiac Fontan is the need for anticoagulation with warfarin postoperatively for 6 months to 1 year, with subsequent conversion to aspirin therapy.
Section III: Congenital Cardiac Surgery

**Aorta-to-Right Ventricle Shunt**

The aorta-to-right ventricle shunt is performed through a median sternotomy using cardiopulmonary bypass and bicaval cannulation. Cardioplegic arrest of the heart may or may not be necessary. The shunt is created using a 5.0-mm ringed Gore-Tex graft. A partial occluding clamp is placed on the anterior wall of the ascending aorta. An aortotomy is created, and an end-to-side anastomosis is performed between the graft and the ascending aorta using a running polypropylene suture. A ventriculotomy is made in the infundibular portion of the right ventricle, and the distal end of the graft is anastomosed to this site using a running polypropylene suture.

**Postoperative Care and Surgical Complications after the Fontan Procedure**

Early management after the Fontan procedure is focused on optimizing cardiac output and reducing the systemic venous pressure. The adjustable ASD or fenestration is useful because it allows as much as one-third of the systemic venous return to traverse the ASD to the left atrium, thus lowering the systemic venous pressure while increasing the cardiac output. A Fontan pressure of $\leq 15$ mmHg is ideally achieved by adjustment of the fenestration.

The pulmonary vascular resistance may be reduced significantly with the use of inhaled nitric oxide. This drug has an advantage over other pulmonary vasodilators because its effect is confined to the pulmonary vascular bed, and the systemic vascular resistance is not reduced. Methe moglobin levels should be monitored carefully with the use of nitric oxide.

Inotropes are routinely used, starting with 5 µg/kg per minute of dopamine and dobutamine. If the systemic vascular resistance is low, dopamine or epinephrine in higher doses is infused via the left atrial line. If these medications are not effective, milrinone or isoproterenol (Isuprel) may be added.

If the hemodynamics are optimal with minimal support, early extubation is attempted. In more critical cases, the patients are sedated and paralyzed for 12 hours before being weaned from the ventilator. If the systemic venous pressure has been high early in the postoperative course, the patient is diuresed before extubation. The patient must be actively monitored for the development of pleural and pericardial effusions, which must be drained immediately. If the venous pressure or the left atrial pressure is high,
Echocardiography is performed to assess ventricular and valvular function and to exclude the presence of any obstruction within the systemic venous pathway or pulmonary arteries. Rarely, recatheterization may be necessary for postoperative assessment.

The ASD may require adjustment early postoperatively. In most cases, it is left partially open. In some patients, as the left ventricular function improves, the right-to-left shunt increases, resulting in a decrease in the arterial oxygen saturation. The snare can be exposed under local anesthesia behind the linea alba in the subxiphoid region and is further tightened using medium hemoclips. Betadine is used to irrigate the wound and is injected into the polyethylene snare. The ASD can also be opened further by pushing on the prolene sutures, but this is not as reliable as the ability to close the ASD. The use of an adjustable ASD at complete repair permits right-to-left shunting in those cases in which early ventricular compliance limits forward flow into the pulmonary vascular bed and helps to stabilize these patients in the critical early postoperative period.

At 6 to 12 weeks, an echocardiogram and arterial oxygen saturation measurement are used to assess the size of the defect. If it is small, it is left to close spontaneously. If it is still large, the defect is closed in the catheterization laboratory with a balloon, and if the venous pressures are acceptable, the snare is exposed again behind the linea alba and the defect is closed completely. This allows delayed closure of the ASD without surgical or catheter device intervention.

**SUMMARY**

In neonates with pulmonary atresia and intact septum, we have found that the surgical classification of RV and tricuspid hypoplasia into mild (more than two-thirds of normal with a tricuspid Z-score of 0 to −2), moderate (one-third to two-thirds of normal with a tricuspid Z-score of −2 to −4), and severe (less than one-third of normal with a tricuspid Z-score of −4 to −6) has been useful in selecting a surgical approach.

A similar classification is used in older children, and patients are stratified into those who will benefit from an attempt to achieve a biventricular repair and those who are best suited to a single ventricle strategy and a Fontan procedure. With this approach, the surgical mortality and morbidity can be reduced.

**RESULTS OF SURGICAL TREATMENT**

Historically, the surgical treatment of PA/IVS was associated with very high morbidity and mortality. Previous extensive reviews of the clinical and pathologic aspects of this defect have allowed for a greater understanding of the disease and the development of surgical therapy. With increasing surgical experience, a more standardized approach has evolved and outcomes from many institutions have steadily improved. The role of catheter-based interventions in these patients, including balloon valvotomy and stenting of the RVOT and the ductus arteriosus, is evolving and remains to be clearly defined.

In the CHSS multi-institutional study, 408 neonates with PA/IVS were studied from 33 institutions. Overall survival was 77% at 1 month, 70% at 6 months, 60% at 5 years, and 58% at 15 years. Prevalence of end states at 15 years was as follows: successful biventricular repair, 33%; Fontan repair, 29%; one-and-a-half ventricle repair, 5%; heart transplant, 2%; death before reaching definitive repair, 38%; and alive without definitive repair, 2%. They concluded that 85% of all neonates with PA/IVS are likely to reach a definitive surgical repair, with a double-ventricle repair achieved in an estimated 50% and a Fontan repair achieved in 35% in the current era.

**FUTURE CONSIDERATIONS**

Transcatheter therapy in patients with PA/IVS is becoming a more common approach to initial interventions in neonates. These techniques include radiofrequency ablation valvotomy, PDA stenting, RVOT stenting, and device closure of ASD. As experience increases, these techniques are gaining wider acceptance as alternatives to or complements to surgery in treatment options. A major area of controversy regarding pulmonary atresia and intact ventricular septum is the use of radiofrequency ablation and perforation of the RV outflow tract with balloon dilation in preference to surgical intervention in these neonates. Although the early experience is relatively good with radiofrequency ablation and perforation of the RV outflow tract with balloon dilation (followed by ductal stenting if necessary to maintain pulmonary blood flow), the disadvantage of this technique is the fact that in patients with severely hypoplastic RV outflow tract there is not complete relief of the gradient. Residual obstruction may limit RV growth, and a more radical relief of RV outflow tract obstruction and even division of hypertrophied muscle bundles in the cavity of the right ventricle may permit better growth. The technique can be very effective, however, in patients who have a plate-like pulmonary valve atresia with a reasonable-sized pulmonary annulus and relatively well-developed right ventricle. In these cases, balloon dilation while maintaining the patient on prostaglandin and then gradually letting the ductus arteriosus close can permit total interventional repair with closure of the ASD with an occluder device at a later time. Hybrid therapies, including a Blalock–Taussig shunt and RV outflow reconstruction with later occlusion of the Blalock–Taussig shunt and atrial septum in the catheterization lab, have also been used with good success in selected patients. A comparison of these relatively noninvasive approaches with surgical approaches in all patients with pulmonary atresia and intact septum has not been performed, and therefore the selection criteria for these various interventions are controversial. Various hybrid approaches may emerge combining both surgical and catheter-based interventions. In some studies, however, catheter-based interventions in neonates have rarely avoided surgical interventions.

In utero perforation and dilatation of the RV in mid-gestational fetuses with PA/IVS has been reported in a limited experience. The overall effect of this type of fetal intervention on subsequent growth and development of the right ventricle and its clinical impact on outcomes in patients with PA/IVS also remains to be defined.

**Editor's Comments**

Infants with critical pulmonary stenosis and an adequate-sized pulmonary valve annulus are now treated with balloon valvuloplasty rather than surgical intervention. However, patients with severely dysplastic pulmonary valves or significant RV outflow tract obstruction with dynamic infundibular obstruction may still come to surgical intervention and require valvectomy or outflow patching. Transventricular dilation of a stenotic pulmonary valve is rarely necessary but may be applied to certain patients with pulmonary valve atresia.

It is interesting that surgical or transcatheter relief of critical pulmonary stenosis in infants has been associated with a significant incidence of pulmonary insufficiency. As these children have been followed over time, a small percentage have developed right ventricular dilatation sufficient to require valve insertion in the pulmonary outflow tract. It is interesting that the incidence of RV dilation meeting criteria for valve replacement appears to be lower in these patients than in patients who have undergone tetralogy of Fallot repair and who have similar degrees of pulmonary insufficiency. This may suggest that the infundibular incision and resection of muscle in tetralogy of Fallot patients may aggravate the RV dilation and dysfunction in this subset.

The classification scheme described in this chapter relating the relative size of the right ventricle to the surgical approach taken has several advantages. A more classic technique used by the Congenital Heart Surgeons Society has related tricuspid valve diameter (or Z-value) to the optimal technique of repair. Because the tricuspid valve size depends on RV size, these two approaches would seem to be similar. It should also be noted, however, that the tricuspid valve is often abnormal in pulmonary atresia, and therefore, tricuspid valve diameter alone may not accurately reflect tricuspid valve function. Thus, some patients with a moderate-sized right ventricle may be limited in long-term repair by abnormal tricuspid valve inflow and require a Glenn shunt and outflow reconstruction or the Fontan operation. In addition, the compliance of abnormal right ventricles with significant ventricular hypertrophy and small size may limit the utility of complete two-ventricle repair in those with moderate hypoplasia. The use of an adjustable atrial septal defect at complete repair as pioneered by Dr. Laks has permitted right-to-left shunting in those cases in which early ventricular compliance limits forward flow into the pulmonary vascular bed and may help to stabilize these patients in the critical early postoperative period.

Decompression of the right ventricle by tricuspid valve incision remains somewhat controversial. Although in the majority of patients tricuspid valve incision/avulsion is well tolerated, patients who have had valvotomies with associated pulmonary insufficiency may not tolerate decompression of the right ventricle well, because the shunt flow may be directed retrograde across the outflow tract to the right ventricle and then into the right atrium, resulting in a steal of blood away from the pulmonary vascular bed. Whereas decompression of the ventricle may result in resolution of some sinusoidal connections to the coronary arteries, in many cases it is not necessary to decompress the ventricle, and late results have not yet shown a significant effect of decompression on arrhythmias or ventricular dysfunction. As noted in this chapter, decomposition of a ventricle that has RV-dependent coronary circulation to greater than one coronary system is contraindicated, and these patients have a significant risk of morbidity and mortality from coronary ischemia regardless of the operative approach taken. Thus, in some cases, early bidirectional Glenn shunting or augmentation of RV flow with an aorta-to-right ventricle connection and an early Fontan procedure may result in improved oxygenation of the
septal defects, atrial septal defects, and atrioventricular septal defects. Rarely, the coronary sinus may also be unroofed in association with this entity. It is said that arrhythmias, including sinus node dysfunction, atrioventricular block, supraventricular tachycardia, and bundle-branch block, are more common under the circumstance of an absent right SVC. During cardiopulmonary bypass, the isolated left SVC must be cannulated directly for the management of venous return if the atrium must be opened.

**Left Superior Caval Vein Draining Directly into the Left Atrium**

A left SVC may drain directly into the left atrium. Drainage of the vena cava to the left atrium (either the left or the right SVC) was found in <0.2% of the patients in the CHP Cardiology Patient Database. Forty percent of these were patients with atrial isomerism, and 15% were also associated with an atrioventricular septal defect. When the left SVC connects directly to the left atrium, it is usually in association with abnormalities of lateralization with either right or left atrial isomerism. It is slightly more common for the SVC to drain directly into the left atrium in cases of right isomerism. In addition, the left SVC may drain directly into the left atrium without other serious cardiac malformations, causing right-to-left shunting. When this becomes hemodynamically significant, correction of the shunt may require interatrial baffling of the orifice of the left SVC to the systemic atrium or translocation of the left SVC to the right atrium or right SVC. It should be recalled that, in left isomerism, a solitary left SVC may drain directly to the systemic or right-sided atrium or through the coronary sinus.

Left superior caval drainage into the left-sided atrium must be surgically addressed when the systemic and pulmonary venous circulations are to be separated. This is most commonly encountered during the palliation or repair of various forms of the functionally univentricular heart. Under those circumstances, the left SVC may be directly connected to the left pulmonary artery (left bidirectional Glenn anastomosis) as part of a staged or total cavopulmonary connection. Interatrial tunneling of the venous return from the atrial orifice of the left SVC to the right (systemic) atrium may compromise or complicate the intracardiac repair of many defects, especially atrioventricular septal defects. Removal of the left SVC from the left atrium and direct attachment to the right-sided atrium or right SVC may be more efficacious. Cryopreserved homograft tissue may also be used as a patch or conduit to help achieve this extracardiac correction. Another option, in the presence of normal pulmonary hemodynamics, is to attach the left SVC directly to the left pulmonary artery, even when a biventricular repair is contemplated. This will correct the right-to-left shunt and still provide decompression of the left superior caval system.

**Presence of a Levoatrial Cardinal Vein**

The levoatrial cardinal vein is occasionally confused with the persistence of the left SVC. However, it differs from a left SVC in several ways. The levoatrial cardinal vein is thought to result from the persistence of anatomic channels that connect the capillary plexus of the embryonic foregut to the cardinal veins. It is usually found with a normally present left innominate vein. It ascends from the left atrium or a confluence of pulmonary veins dorsal to the left pulmonary artery, passing between the left pulmonary artery and the left bronchus (Fig. 76.3). When this vein receives pulmonary venous return, the passage of the levoatrial cardinal vein between these two large and potentially fixed structures causes obstruction to the anomalously draining pulmonary venous return.

The levoatrial cardinal vein is most usually recognized in association with left atrioventricular valve stenosis or atresia and with a restrictive or absent interatrial opening. It may provide the only exit for pulmonary venous blood that arrives through normally connected pulmonary veins into the left-sided atrium in patients with left ventricular inflow obstruction. It provides an exit into the systemic venous circulation. An analysis of the CHP Cardiology Patient Database found that 0.04% of the patients had a levoatrial cardinal vein. Fifty percent of the patients had either right or left isomerism, and a small proportion of the patients had other associated anomalies, including double-outlet right ventricle, tetralogy of Fallot, ventricular septal defect, and atrioventricular septal defect.

The levoatrial cardinal vein has little surgical significance. It does not provide a useful venous pathway beyond the early neonatal period, and even then it is too small or obstructive. However, it must be recognized and closed during corrective surgery that demands a separation of the systemic and pulmonary venous circulations. For example, persistence of this vein following a bidirectional Glenn anastomosis would provide an unacceptable collateral route of decompression for the superior venous circulation.

**Right Superior Caval Vein to the Left (Pulmonary) Atrium**

A right SVC that connects directly to the left atrium has been reported as an isolated anomaly and may cause a right-to-left shunt of approximately 30%. In this situation, the right SVC passes medially and dorsally to the aortic root, connecting to the cephalic portion of the left atrium. It may receive one or more pulmonary veins (Fig. 76.4).

coronary flow from the right ventricle. However, these patients continue to have problems with ventricular dysfunction and may have acute myocardial infarction early in life, causing ventricular dysfunction or early death. Thus, in patients with significant ventricular dysfunction in association with RV-dependent coronary circulation, early shunting for stabilization followed by orthotopic cardiac transplantation has been advocated by some centers, and we have performed this procedure in several infants.

For the majority of patients with RV-dependent coronary circulation placement of an aortopulmonary shunt initially followed by bidirectional Glenn shunt and early Fontan procedure seems to be acceptable and the mortality rates do not appear to be higher than the mortality rates with primary cardiac transplantation. Most of the mortality in these patients occurs in the first 3 to 4 months after birth from myocardial ischemia and acute myocardial infarction. Patients who survive to the bidirectional Glenn procedure appear to have relatively good longer term outcomes with the Fontan procedure, and the late mortality rate is relatively low despite the abnormal coronary circulation. The effectiveness of augmenting flow into the right ventricle with aortopulmonary shunts in these patients is not established and often the right ventricle is very small and placement of shunt into the ventricular body difficult. In most cases, we have avoided aortic to right ventricular shunts.

A major area of controversy regarding pulmonary atresia and intact ventricular septum is the use of radiofrequency ablation and perforation of the right ventricular outflow tract with balloon dilation in preference to surgical intervention in these neonates. Although the experience of the Toronto Hospital for Sick Children is relatively good with radiofrequency ablation and perforation of the right ventricular outflow tract with balloon dilation (followed by ductal stenting if necessary to maintain pulmonary blood flow), the disadvantage of this technique is the fact that in patients with severely hypoplastic right ventricular outflow tract, there is no complete relief of the gradient. Residual obstruction may limit right ventricular growth, and a more radical relief of RV outflow tract obstruction and even division of hypertrophied muscle bundles in the cavity of the right ventricle may permit better growth. The technique can be very effective, however, in patients who have a plate-like pulmonary valve atresia with a reasonable-sized pulmonary annulus and relatively well-developed right ventricle. In these cases, balloon dilation while maintaining the patient on prostaglandin and then gradually letting the ductus arteriosus close can permit total intervention repair with closure of the atrial septal defect with an occluder device at a later time. Hybrid therapies, including a Blalock–Taussig shunt and RV outflow reconstruction with later occlusion of the Blalock–Taussig shunt and atrial septum in the catheterization lab, have also been used with good success in selected patients. A comparison of these relatively noninvasive approaches with surgical approaches in all patients with pulmonary atresia and intact septum has not been performed, and therefore the selection criteria for these various interventions are controversial.

The increasingly aggressive use of RV outflow tract ablation and stenting in patients who have moderate tricuspid diameter and RV hypoplasia has dramatically decreased the number of patients who come to surgical intervention for pulmonary atresia with intact ventricular septum. In our center, it is extremely uncommon to be referred to as a patient for RV outflow tract augmentation or for aortopulmonary shunting unless the patient has such a hypoplastic tricuspid valve and right ventricle that eventual Fontan operation is the ultimate goal. To date, there have not been good studies comparing the interventional catheterization approaches for this lesion with conventional surgical therapies. Nevertheless, the majority of patients seem to come to an eventual two ventricle repair after the catheter-based approaches with the occasional need for augmentation of pulmonary blood flow with a shunt or with stenting of the ductus arteriosus.

When outflow tract patches are required, we have elected to use cardiopulmonary bypass in most cases, because it makes the operation simpler. Incision of the RV outflow tract in pulmonary atresia must be done carefully, because even a slight deviation of the incision can cut into the base of the aortic valve leaflet or compromise the left coronary artery. Thus, the use of cardioplegia and cardiopulmonary bypass has resulted in more accurate placement of the incision. In addition, we have elected to place the shunts through a median sternotomy incision rather than a thoracotomy in the majority of patients so that the ductus arteriosus can be ligated at the time of shunt placement. If ductal patency remains, pulmonary overcirculation can occur; therefore, closure of the ductus in the operating room with maintenance of distal saturations is a good sign that the shunt is adequate in size. In addition, competitive flow from the ductus, which may compromise shunt patency in the early postoperative period, is eliminated and retrograde flow into the RV is minimized.

A particularly difficult group of patients are those with pulmonary atresia and Ebstein malformation of the tricuspid valve with severe tricuspid insufficiency. These patients may have significant compromise of the left ventricle by the dilated right ventricle, and the inefficient flow of blood in and out of the right ventricle compromises the overall systemic blood flow. The creation of an aortopulmonary shunt may stabilize pulmonary blood flow in these patients, but the effect of the dilated right ventricle on systemic output remains problematic. Patch closure of the tricuspid valve is not suitable for these patients, because there will be no outflow of the coronary sinus return, and often sinusoidal connections and Thebesian vessels into the ventricle cannot then be decompressed. In these rare instances, the best approach would appear to be early cardiac transplantation. Sano and his colleagues in Okayama, Japan, have suggested either radical plication or complete excision of the right ventricular free wall (with closure of the tricuspid valve orifice) in patients with Ebstein malformation and pulmonary atresia to eliminate the effect of the right ventricle on left ventricular function. These very radical approaches seem to have been successful in a small number of cases and should be considered in patients with pulmonary atresia with

(continued)
severe Ebstein malformation because patch closure of the tricuspid valve will, as mentioned, often not relieve the dilation of the right ventricle and the secondary effects on left ventricular function. Patch closure of the TV with a small punch hole in the patch may also be considered.

When valve insertion is required, homograft valves can often be used. If the homograft valve is too long from the pulmonary bifurcation to the normal annulus level, it is possible in most circumstances to use a pulmonary homograft and cut the valve just at the commissural attachments, sewing the distal end of the homograft to the pulmonary bifurcation and sewing the proximal homograft in the RV outflow tract to the infundibular septum. In this situation, the pulmonary valve is positioned more inferiorly in the right ventricle but maintains a normal anatomic outflow tract.

When monocusp outflow tract reconstruction is used, we have elected to use either a PTFE patch with a pericardial monocusp fashioned in the operating room or homograft tissue with a contained monocusp, PTFE pericardial membrane, or native pericardium. For Fontan operations, we have preferred the use of the fenestrated lateral tunnel or extracardiac conduit Fontan with a fixed 4-mm fenestration rather than the adjustable ASD used by the authors. In most cases, the fenestration will close spontaneously. The approach to the Fontan operation and hemi-Fontan versus bidirectional Glenn shunt will be commented upon in a later chapter.  

TLS
Pulmonary atresia with ventricular septal defect (VSD) and major aortopulmonary collaterals is a complex lesion in which great morphologic variability exists regarding the sources of pulmonary blood flow. The anatomy of the true central pulmonary arteries is also highly variable ranging from normal in size to complete absence. Major aortopulmonary collateral arteries (MAPCAs), probably derived embryologically from the splanchnic vascular plexus, are extremely variable in their size, number, course, origin, arborization, and histopathologic makeup. A very uncommon segment of the lung may be supplied solely from the true pulmonary arteries, solely from the aortopulmonary collaterals, or from both, sometimes with connections between the two sources occurring at central or peripheral points and at single or multiple sites. In contrast, the intracardiac morphology of this lesion is relatively straightforward, often with a single anteriorly malaligned VSD, well-developed right and left ventricles, and normal atrioventricular and ventriculoarterial connections. Very uncommonly MAPCAs are present in a similar manner in other lesions like single ventricles, double outlet right ventricle, and transposition complexes.

The ultimate goal of surgical therapy in this lesion is to reconstruct completely separated, in-series pulmonary and systemic circulations. The traditional surgical management strategy for achieving this goal is to embark on a staged reconstruction to centralize the multifocal pulmonary blood supply, recruiting as many lung segments as possible, and then close the VSD and provide egress from the right ventricle to the “unifocalized” pulmonary arterial system. In the past, this has always required multiple operations.

The most important physiologic factor signifying a favorable outcome for these patients after complete repair is the postrepair peak right ventricular pressure. This should be as low as possible. The peak right ventricular pressure depends greatly on the number of lung segments that are unifocalized and on the status of the pulmonary microvasculature in those segments. Another important factor is that the reconstruction must achieve unobstructed delivery of blood from the right ventricle to the pulmonary microvasculature. A number of impediments to achieving this ideal outcome exist. Lung segments can be lost for several reasons. The natural history of these MAPCAs often follows a course of progressive stenosis and occlusion, sometimes making the segment of lung supplied by that collateral inaccessible at the time of unifocalization. Even if accessible, a longstanding severe stenosis of the collateral can lead to distal arterial hypoplasia and underdevelopment of preacinar and acinar vessels and alveoli. In addition, iatrogenic occlusion can occur when these collaterals are unifocalized in stages using nonviable conduits, sometimes resulting in loss of these segments. Finally, MAPCAs without obstruction can rapidly lead to pulmonary vascular obstructive disease in their supplied segments. Similarly, staged unifocalization necessitating the use of modified Blalock–Taussig or central shunts may result in pulmonary vascular obstructive disease.

**THE THERAPEUTIC GOALS AND PATIENT SELECTION**

It seems logical that the longer the microvasculature of a given lung segment is left to the hemodynamic vagaries of a MAPCA, the more likely it is that it will either develop pulmonary vascular obstructive disease or involute. Only the “perfectly stenosed” MAPCA may allow normal distal development. Furthermore, stenoses in MAPCAs are well known to progress with time, suggesting that even a “perfectly stenosed” vessel is not likely to remain that way. Extending this logic, it seems clear that the sooner these hemodynamic vagaries can be removed, the greater the likelihood that the largest number of healthy lung segments can be incorporated into the unifocalized pulmonary circuit. The pulmonary microvasculature taken in aggregate is healthiest at birth and declines thereafter. From these arguments, it seems intuitive that one-stage complete unifocalization and repair early in life gives the greatest chance of achieving a healthy and complete pulmonary vascular bed.

We have prospectively applied a complex surgical management protocol that reflects these goals and principles. The first priority is to completely unifocalize the pulmonary arterial and MAPCA complex via a median sternotomy incision. This removes the MAPCAs from the abnormal physiologic milieu as early as possible. Whenever possible, we also perform intracardiac repair at the first operation. If simultaneous intracardiac repair is not considered advisable because of the concern about unacceptable peak right ventricular pressures, a polytetrafluoroethylene (PTFE) shunt is constructed between the ascending aorta and the fully reconstructed single-compartment pulmonary arterial system. Based on experience with more than 550 patients, this approach of one-stage complete bilateral unifocalization was performed in about 85% of all patients. In 56%, intracardiac repair was also performed. In 29%, a central shunt was created; intracardiac repair was achieved within 2 years in the great majority of patients in whom shunts were created. The remaining 15% of patients typically fall into two general categories. In one group, centrally confluent true pulmonary arteries were present in association with a relatively complete arborization pattern to most or all lung segments. The source of pulmonary blood flow is via MAPCAs that share dual-supply vascular distribution with the true pulmonary arteries. In this anatomic variant, we construct a neonatal...
Fig. 92.1. Technique of aortopulmonary window. (A) The main pulmonary artery is divided as proximally as possible and spatulated with a longitudinal incision. (B) It is important to carefully apply the clamp such that the sequestered portion of the aorta is somewhat posterior to the direct lateral aspect of the aortic circumference. (C) Aortotomy is made, and the anastomotic site is enlarged by excising an aortic wall button. Anastomosis is performed with continuous 7-0 monofilament absorbable suture.

aortopulmonary window by removing the blind end of the main pulmonary artery from the infundibulum and anastomose it to the ascending aorta, and we concurrently ligate important MAPCAs (Fig. 92.1). If the patients are selected properly, the central source of pulmonary blood flow will distribute to all lung segments. Patients are then evaluated for intracardiac repair at 3 to 6 months of age. In the second group, true pulmonary arteries may or may not be present. The important factor is that the majority of MAPCAs have multiple stenoses at the segmental and subsegmental branches. In our opinion, these patients are best managed by sequential staged thoracotomies at intervals of 3 to 6 months.

Regardless of which approach is taken, creative surgical techniques are used to achieve native tissue-to-tissue continuity. Allograft patch material is often necessary, but we use it noncircumferentially so that the growth potential of the native tissue is preserved. We limit the use of circumferential nonviable conduits to the central mediastinum.

Ideal age of repair of this lesion based on our extensive experience seems to be between 3 and 6 months in most patients. Our current approach involves the following. If the patient is well balanced physiologically, we prefer to perform this procedure when the patient is between 3 and 6 months of age. However, if the patient is severely cyanotic or has significant pulmonary overcirculation, repair is feasible at an even earlier age. The advantages of early one-stage repair are numerous. Early normalization of cardiovascular physiology and correction of cyanosis is achieved. Protection against pulmonary hypertension, related to high flow either through collaterals or through systemic shunts, is accomplished. The number of operations is reduced. The use of nonviable material in the periphery of the lung is completely eliminated in the great majority of cases. With this approach, the number of patients who can be completely repaired is substantially enhanced.

**TECHNIQUE: ONE-STAGE COMPLETE UNIFOCALIZATION AND INTRACARDIAC REPAIR**

Surgical access to the mediastinum is via a generous midline incision and a median sternotomy (Fig. 92.2). A subtotal thymectomy is performed and the pericardium is harvested and preserved in glutaraldehyde solution. The primary dissection is in the central mediastinum around the tracheobronchial tree, subcarinal space,
Chapter 92: Pulmonary Atresia with Ventricular Septal Defect and Major Aortopulmonary Collaterals

Fig. 92.2. (A) An extended midline incision and sternotomy are performed to facilitate generous sternal retraction. (B) The pulmonary blood supply. The pulmonary arteries are small: the right pulmonary artery (RPA) supplies only the right lower lobe, and the left pulmonary artery (LPA) supplies only the upper lobe. The collaterals supply the remainder of the lung segments. (C) View from the surgeon’s side after harvest of the pericardial patch. The pericardial edges are suspended with silk stay sutures and held with hemostats to facilitate hilar dissection. AA, ascending aorta; AO, aorta; DA, descending aorta; LC, left collateral; LL, left lung; MPA, main pulmonary artery; RA, right atrium; RC, right collateral; RL, right lung; RV, right ventricle; SVC, superior vena cava.

and the space between the superior vena cava and the aorta. The native pulmonary arteries, if present, are dissected out (Fig. 92.3A). Most collaterals from the upper descending aorta can be identified and dissected in the subcarinal space (between the tracheobronchial angle and the roof of the left atrium) by an approach between the right superior vena cava and the aorta (Fig. 92.3B). The floor of the pericardial reflection in the transverse sinus is opened, and the posterior mediastinal soft tissues are dissected using cautery. The descending aorta is then exposed in the posterior mediastinum, and all the collaterals from it are identified, dissected, mobilized, and controlled. The subcarinal approach is an important maneuver not only to gain access to collaterals, which typically arise from this location, but also to provide the most direct avenue for collateral rerouting for direct tissue-to-tissue anastomosis, which would otherwise be impossible. In addition, in some cases collaterals arising from the aortic arch or the neck vessels are exposed and dissected in the superior mediastinum along the trachea or through the pleural cavities. Avenues for collateral rerouting are also developed by opening the pleura on both sides posterior to the phrenic nerves in the hilar regions (Fig. 92.4). If the collaterals need only to be ligated and not unifocalized, then the mediastinal dissection can be minimized by the pleural approach. In such cases, the right pleura is widely opened anterior to the phrenic nerve, the right lung is lifted out of the pleural cavity, and the right-sided collaterals are identified and dissected. Similarly, the left pleura is opened and the left-sided collaterals are identified and dissected. The pleural approach is also useful to quickly gain control of all the collaterals in unstable patients before or immediately after cardiopulmonary bypass is instituted.

In stable patients, as many collaterals as possible are permanently ligated at their origin, mobilized, and unifocalized without cardiopulmonary bypass (Fig. 92.3C and 92.3D). When the patient’s oxygenation reaches a compromising level, cardiopulmonary bypass is instituted, and the remainder of the collaterals is unifocalized at mild-to-moderate hypothermia with the heart beating. A calcium-supplemented blood prime is used in the cardiopulmonary bypass pump circuit to maintain normal cardiac function. During
the unifocalization process, the emphasis is on avoiding synthetic or allograft conduits in the periphery and on achieving unifocalization by native tissue-to-tissue anastomosis. One or more of the following techniques of unifocalization are generally used in these patients:

1. Side-to-side anastomosis of the collateral to the central pulmonary arteries, thereby augmenting the hypoplastic central pulmonary arteries
2. Side-to-side anastomosis of collateral to collateral or of collateral to peripheral native pulmonary artery
3. End-to-side anastomosis of collateral to collateral or of collateral to native pulmonary artery
4. End-to-end or end-to-side anastomosis of collateral to central conduit
5. Allograft patch augmentation of stenotic distal segments of the collaterals

---

**Fig. 92.3.** (A) The pericardium is incised over the right pulmonary artery. (B) The right pulmonary artery (RPA) is mobilized extensively all the way into the hilum. Transverse sinus dissection is performed in the area shown by the dashed line. (C) The right collateral (RC) is identified and mobilized. (D) The aortic end is occluded with a large hemoclip, and the collateral is transected. As much length of the collateral as possible is taken to facilitate tissue-to-tissue reconstruction of the neopulmonary arteries. DA, descending aorta.

---

**Fig. 92.4.** The pericardium and parietal pleura on both sides are incised longitudinally above and below the pericardium (the phrenic nerve is left on a strip of tissue with careful attention not to injure the nerve during the entire procedure). This facilitates hilar dissection for isolating, rerouting, and unifocalizing the collaterals. P, phrenic nerve. * indicates the extent of incision.
6. Allograft patch augmentation of the reconstructed neocentral pulmonary arteries

These anastomoses are achieved directly by bringing collaterals through the transverse sinus or below the lung hilum or occasionally above the hilum, using as much of the collateral length as possible. Collateral length is given the highest priority to achieve tissue-to-tissue anastomosis. For example, if a discrete stenosis is present in the midportion of a collateral, the entire collateral would still be used. The stenosis is managed by side-to-side reconstruction at the necessary level or, if that is not possible, by patching. Some times even collaterals that had a dual supply to a lung segment along with true pulmonary artery supply are unifocalized to build up the size of the reconstructed pulmonary arteries. However, particularly difficult aspects of unifocalization are occasionally completed after cardioplegia is induced and aortic cross-clamping at moderate hypothermia. The important concepts necessary to achieve this type of unifocalization are flexibility regarding reconstruction, aggressive mobilization, maximizing the length of the MAPCAs, and creative rerouting (Figs. 92.5–92.8).

Fig. 92.5. (A) The right pulmonary artery (RPA) is opened. This arteriotomy is later extended to augment the RPA. (B) An arteriotomy is then made in the posterior wall of the RPA. (C) The end of the collateral vessel is splayed open. LPA, left pulmonary artery; MPA, main pulmonary artery; RC, right collateral.

Fig. 92.6. (A) The collateral is anastomosed to the right pulmonary artery (RPA) posteriorly using 7-0 absorbable monofilament suture. The site of the anastomosis varies depending on the position and course of the collateral. (B) The unifocalized collateral through the RPA. The opening should be unobstructed, wide, and without any kinks. (C) The appearance of the right-sided pulmonary arteries after unifocalization. LPA, left pulmonary artery; MPA, main pulmonary artery; RC, right collateral.
After unifoimalization is completed, the new single-compartment pulmonary arterial system is assessed for suitability for VSD closure (see section "Criteria for Closure of the Ventricular Septal Defect"). If VSD closure is indicated, a longitudinal ventriculotomy is made in the right ventricular infundibulum and the hypertrophied muscle bundles are resected (Figs. 92.9–92.12). The VSD is closed with a glutaraldehyde-fixed autologous pericardial patch or a polyester (Dacron) patch using continuous nonabsorbable monofilament running suture and sometimes reinforced with interrupted pledged mattress sutures. The right atrium is opened to inspect the atrial septum. An atrial septal defect or patent foramen ovale, if present, is partially closed to leave a small unidirectional interatrial communication as a “pop-off” valve for venous blood in case of postoperative right ventricular dysfunction. In some cases with intact atrial septum, a small one-way interatrial communication is created. At this stage, rewarming is started.

An allograft valved conduit is tailored and used to connect the right ventricle to the reconstructed neopulmonary arterial system (Fig. 92.10). The distal conduit is anastomosed to the reconstructed pulmonary arteries. If needed, a distal tongue of tissue is shaped to augment the reconstructed central branch pulmonary arteries.

In a total of >2000 unifoimalized collaterals, only a small number have been reconstructed with circumferential nonvi- able conduit (expanded PTFE; Fig. 92.13). In patients with absent or stringlike true pulmonary arteries, sometimes a second, nonvalved allograft conduit may be necessary to reconstruct the central left and right pulmonary arteries. In such patients, in whom growth potential is an issue, the hilar regions are reconstructed only with native tissue using the techniques described, and this second conduit serves as the main left and right pulmonary arteries only with the conduit limited to the pericardial cavity (Fig. 92.14). In patients with adequate collateral length, the collaterals alone are used to reconstruct the central main, right, and left pulmonary arteries, without the need for a second conduit (Fig. 92.13). The proximal right ventricle-to-conduit anastomosis is performed with a running nonabsorbable monofilament suture. A pressure-monitoring catheter is placed through the right atrium into the right ventricle or pulmonary arteries across the tricuspid valve. The right ventriculotomy is then closed with a pericardial or an allograft patch shaped like a hood, extending from the proximal conduit onto the right ventricle.

After separation from cardiopulmonary bypass, aortic, right ventricular or pulmonary arterial, and atrial pressures are measured continuously. A transesophageal echocardiogram is performed to ensure that there are no significant residual defects.

Bilateral pleural and mediastinal tube drains are placed and the sternum is closed. If bleeding or ventilation is an issue, we electively leave the sternum open and close the chest wound with a silicone rubber
Chapter 92: Pulmonary Atresia with Ventricular Septal Defect and Major Aortopulmonary Collaterals

**Fig. 92.8.** (A) The transected left collateral (LC) is routed into the central mediastinum through the transverse sinus. (B) The collateral is then unifocalized to the left pulmonary artery (LPA) using the technique described for the right side. (C) The appearance of the pulmonary arteries after the unifocalization is completed. AA, ascending aorta; MPA, main pulmonary artery.

(Silastic) patch. Secondary sternal closure is performed on the second or third postoperative day.

**CRITERIA FOR CLOSURE OF THE VENTRICULAR SEPTAL DEFECT**

Once the complete unifocalization has been performed, while the patient is still on cardiopulmonary bypass, the total resistance of the pulmonary vascular bed is assessed in some patients by an intraoperative pulmonary flow study. The pulmonary vascular bed is cannulated and perfused using a calibrated pump head from the cardiopulmonary bypass machine, with gradually increasing flow leading up to the equivalent of at least 3 L/m² cardiac output. At the same time, a pressure catheter is placed in the pulmonary artery system and the left atrium is vigorously vented. If the mean pulmonary artery pressure is ≤25 mmHg, the decision is made to close the VSD. If the mean pulmonary pressure is >25 mmHg, a central shunt is created.

**POSTOPERATIVE MANAGEMENT**

The significant postoperative events are phrenic nerve palsy, severe episodic

**Fig. 92.9.** (A) The hypoplastic main pulmonary artery is disconnected from the heart and (B and C) opened into both branch pulmonary arteries all the way into the hilum. LPA, left pulmonary artery; RPA, right pulmonary artery.
bronchospasm, pulmonary parenchymal reperfusion injury, and pulmonary hemorrhage. Rarely, splanchnic end-organ injury has occurred.

With proper attention to the phrenic nerve, we have minimized this complication. Severe bronchospasm is probably caused by the extensive dissection and disruption of lymphatics and blood vessels around the tracheobronchial tree. It is also possible that the autonomic nerve balance is affected because of the dissection. Another important observation is the development of reperfusion injury of the lung. This is generally limited to the segments that are severely underperfused before unifocalization. The splanchnic end-organ injury is manifested in the form of acute hepatic insufficiency and rarely bowel necrosis. Aggressive monitoring of serum potassium, serum glucose, and hepatic enzyme profiles is strongly recommended. Hyperkalemia and hypoglycemia should be promptly detected and aggressively treated in such cases. The cause of this phenomenon is not completely known, although in the latter half of our series this complication has been extremely rare. We believe that maintaining perfusion pressure >40 mmHg on cardiopulmonary bypass has been an important factor in the elimination of this complication.

**FOLLOW-UP MANAGEMENT**

All completely repaired patients are followed clinically, and a cardiac catheterization is performed at about 1 year postoperatively or earlier if necessary. In addition, during the first year the patients are followed every 3 months by echocardiography and nuclear pulmonary flow scan to promptly detect and manage alterations in pulmonary blood flow distribution or pulmonary hypertension. In patients where the VSD is left open after one-stage complete unifocalization, a follow-up cardiac catheterization is performed electively at 3 to 6 months postoperatively and assessed for possible VSD closure. Some patients require one or more balloon angioplasty interventions or surgical pulmonary artery rehabilitation before VSD closure. If the ratio of pulmonary to systemic blood flow \( Q_p/Q_s \) at catheterization is >2:1, the VSD is closed. If the \( Q_p/Q_s \) ratio is <2:1, in all patients with a second-stage closure of the VSD, an intraoperative pulmonary flow study is performed to assess the feasibility of VSD closure.

**FOLLOW-UP RESULTS**

To date approximately 700 operations have been performed in over 500 patients. Early mortality in the last 10 years of our experience is about 2%. However, the late mortality continues to be around 5%. The question always posed is whether the early low RV pressures are maintained during follow-up and whether the collaterals continue to grow. Our experience suggests that the unifocalized collaterals continue to grow and the good early hemodynamics continue to be maintained in the majority of patients. In a recent review of 80 patients who underwent conduit replacement over the last 10-year period, we found that the peak RV-to-peak LV pressure ratio was 0.36 compared with the early postoperative ratio of 0.38. It is true that some of these patients have undergone surgical or catheter intervention to relieve unifocalized pulmonary artery stenosis. But the fact
**Fig. 92.12.** (A) The homograft conduit is anastomosed to the right ventricle with 4-0 or 3-0 nonabsorbable monofilament suture. (B) The ventriculotomy is closed with a hood of homograft or glutaraldehyde-fixed pericardial patch and 4-0 or 3-0 nonabsorbable monofilament suture. (C) The final appearance after complete repair.

**Fig. 92.13.** A variation in the technique of reconstruction. (A) Figure of MAPCAS drawn from an actual angiogram of a patient. (B) Shows the tailored MAPCAS which are to be flayed open along the dashed lines. (C) Completed reconstruction with only native tissue. Here, the central neopulmonary arteries are created using only the collaterals and without any homograft patches. In cases in which there are no true pulmonary arteries and the collaterals are of adequate length and size, we reconstruct the central pulmonary arteries with similar techniques using the collateral tissue only.
that RV pressures remain is an indication that the unifocalized pulmonary arteries continue to grow and the distal pulmonary vasculature is healthy.

**SUGGESTED READINGS**

**EDITOR’S COMMENTS**

Surgical repair of pulmonary atresia with ventricular septal defect and aortopulmonary collateral sources of blood flow is a technical challenge. The aortopulmonary collaterals may supply only a relatively small portion of the total parenchymal volume of the lung or may supply the majority of the pulmonary vascular bed. In addition, some collaterals may be unobstructed, leading to rapid development of pulmonary vascular disease, and others may develop peripheral or proximal stenoses. In the most severe cases, no central pulmonary arteries are present; however, in the majority of cases, there is a very small central pulmonary confluence that may not supply much of the distal parenchyma. Multiple surgical approaches have been applied to this complex congenital heart defect, including staged unifocalizations of the collateral vessels to the lungs by bilateral thoracotomies with pericardial tube reconstruction and unifocalization of the vessels with bilateral shunting and then a repeat operation for central unifocalization and connection to the right ventricular outflow tract, or in cases with diminutive central pulmonary arteries with distal reasonable arborization, connection of the central pulmonary arteries directly to the aorta posteriorly as advocated by Roger Mee.

All of these approaches suffer from the problems of development of distal stenoses and the inability to centrally unifocalize all of the collateral segments at a single setting. In addition, patients who have had bilateral thoracotomies for unifocalization who ultimately fail unifocalization procedures represent a very difficult subset of patients for lung transplantation and cardiac repair at a later time. The severe cyanosis in these patients and the development of significant chest wall collateral vessels have resulted in severe hemorrhage at the time of lung transplant and cardiac repair in our experience and have limited the applicability of lung transplantation in these patients. Therefore, the approach recommended by the authors has appeal because direct intervention to unifocalize all major aortopulmonary collaterals is performed at an early age through a median sternotomy incision, which will, it is hoped, limit the development of aortopulmonary collaterals from the chest wall to the pulmonary parenchyma. Thus, if failure of unifocalization occurs, it may be possible in these patients to undertake lung transplantation with cardiac repair at a later time without the problem of severe hemorrhage from the pleural spaces.

The extensive nature of operations to provide complete unifocalization in infancy is well described in this chapter. The problems with organ system dysfunction from long bypass times for these complex operations and the difficulties in preventing steal from the collateral vessels with initiation of bypass are well described. Nevertheless, in most cases, central unifocalization can be performed with reconstruction to the right ventricular outflow tract or a central aortopulmonary shunt, which has the advantage of providing access to the distal pulmonary vasculature for catheter interventional procedures to deal with distal stenoses.

Despite the outstanding results with surgical treatment of pulmonary atresia, VSD, and MAPCAs presented by Dr. Hanley’s group, these continue to be very difficult for patients. Even when excellent pulmonary flow can be achieved with VSD closure and a relatively low ventricular pressure in the operating room, development of distal stenosis and distortions of the pulmonary vascular bed can result in gradual and progressive elevation of pulmonary resistance with right ventricular failure. The long-term outlook of patients who have VSD closure and unifocalization remains to be completely elucidated.

Nevertheless, the approaches described by Dr. Hanley and associates have resulted in a VSD closure rate that is higher than has been traditionally seen with other staged surgical approaches, suggesting that early intervention with extensive patching of any areas of stenosis may result in better overall long-term outcomes. Nevertheless, these patients require a great deal of attention and observation for the development of distal stenosis that will require catheter or surgical intervention.

The series of one-stage unifocalization and cardiac repair of Drs. Hanley and Reddy has convinced the community of pediatric cardiothoracic surgeons that this approach is favored to staged reconstruction in virtually all cases. The pioneering work by Dr. Hanley and associates has shown that despite the technical complexity of these operations even in very small infants, unifocalization of multiple aortopulmonary collaterals can be performed with technically excellent results and a long-term outlook that is clearly superior to either staged unifocalization techniques or the overall natural history of progressive cyanosis and ventricular failure seen in patients with this condition.

In patients with inadequate collateral vessels to the lungs, severe progressive cyanosis, and a distal pulmonary vascular bed that is not amenable to unifocalization and reconstruction, we use bilateral lung transplantation and cardiac repair. This procedure is best performed in patients who have not had extensive previous pleural surgery because of the severe adhesions and hemorrhage at reoperation. Hemorrhage has been the primary cause of operative mortality with transplantation in this setting. Thus, avoidance of thoracotomy incisions if at all possible at reconstruction in these patients is preferable if later lung transplantation or heart–lung transplantation is contemplated.

TLS
An Overview

The development of effective treatment strategies for variants of tetralogy of Fallot (TOF) is inextricably linked to modern advances in the surgical treatment of congenital heart disease. In many ways, this lesion should be viewed as the benchmark against which other treatment strategies for congenital cardiac defects are compared. In fact, no other condition offers the scope and breadth of treatment history, particularly if one considers those congenital abnormalities involving biventricular circulation and abnormalities of connection of the right ventricle to the pulmonary arteries. In this regard, it is incumbent upon the current era of cardiac surgeons to pay particularly close attention to the evolution of strategies for surgical treatment of TOF and, very specifically, contemporary outcomes as well as long-term follow-up series. Quite clearly, these data should be used to further refine treatment strategies in the present and future eras.

Prior to the advent of surgical therapy, the natural history of untreated TOF offered a dismal prognosis for patients. In the early part of the 20th century, therapeutic options were meager and included avoidance of stressful situations and, in rare circumstances, phlebotomy for those patients with advanced chronic polycythemia.

Without doubt, the field of palliative congenital heart surgery was ushered in with the advent of the successful application of a surgically created systemic to pulmonary artery shunt (Fig. 93.1). The Blalock shunt was enormously successful in augmenting pulmonary blood flow, bringing significant symptomatic, and in some cases durable relief to the chronic sequelae of cyanosis (Fig. 93.2). This was an enormous conceptual advance in surgery and arguably should be heralded as transformative in its impact on surgical thinking about developing other strategies to treat congenital heart disease. The much heralded and lingering debate over credit for the development of this operation probably should be put to rest, in which it appears that the historical record is quite clear. During his tenure on the faculty at Vanderbilt University School of Medicine in Nashville, TN, Dr. Alfred Blalock developed a renowned surgical laboratory, primarily involved in the investigation of shock. In that context, Blalock was introduced to a young man who would become part of one of the most productive surgical investigational relationships of that century when he hired Mr. Vivien Thomas to work in his lab. Much has been written about this storied relationship and the reader is referred to the bibliography for further references of the details of the relationship. However, it is important to emphasize that Mr. Thomas was a disadvantaged African-American man, denied access to formal medical education because of economic hardships during the post-Depression era in the southern United States. Through this providential relationship and the recognition of mutual strengths and aspirations, Blalock and Thomas effectively collaborated on a number of landmark investigations. Of special note is work that was published by Blalock in 1933 on the prospect of the creation of a model of pulmonary arterial hypertension in the canine model. The surgical technique involved the division of the left subclavian artery and a direct end-to-end anastomosis into the divided left pulmonary artery. While unsuccessful in creating hypertension in this animal model because of the extremely low pulmonary vascular resistance in the canine, without doubt the technical nuances of the delicate systemic to pulmonary artery anastomosis were worked out in the research laboratory at Vanderbilt University. After being recruited to become the Chairman of Surgery at the Johns Hopkins Hospital, Dr. Blalock collaborated with Dr. Helen Taussig in applying the previously developed surgical technique to the palliation of children with disorders limiting pulmonary blood flow. The much heralded first clinical application and the series thereafter established the Johns Hopkins Hospital as the early epicenter of surgical treatment of congenital heart disease. The shared credit for this successful series of operations rests with Blalock, Taussig, as well as Thomas and the surgical and medical practitioners of the current era should respectfully acknowledge the contributions of all three of these remarkable individuals and their impact on the treatment of children with heart disease.

Emboldened by the early successes with surgical palliation, Drs. John W. Kirklin at the Mayo clinic and C. Walton Lillehei at the University of Minnesota began to develop successful operations to directly correct the intracardiac pathology in TOF. The first series of surgically corrected patients were reported by these two pioneers in the mid-to-late 1950s. While surgical techniques have been improved and perioperative management has afforded patients a very favorable progress in the current era, it must be emphasized that the cohort of these earliest successful surgeries, now being followed for almost 60 years, represents an unusual, perhaps unique, window of observation into the natural history of surgically repaired congenital heart disease. In the context of TOF, this observation cannot be overemphasized and will be the focus of subsequent commentary in this chapter as it relates to timing and approach for surgery.

Anatomy and Physiology

By way of definition, this chapter will be limited to discussion of classic TOF. This lesion, originally described by Étienne-Louis Arthur Fallot in a postmortem series in late 1888, represents the prototypical cyanotic congenital heart disease. As is well articulated by leading cardiac morphologists, including Drs. Stella and Richard Van Praagh at Boston Children’s Hospital and Dr. Robert H. Anderson at the Royal Brompton Hospital and the
National Heart Trust of the United Kingdom, the central morphologic feature of TOF relates to anterior malalignment of the infundibular septum relative to the conotruncus resulting in a large subaortic ventricular septal defect (“malalignment VSD”) and varying degrees of right ventricular outflow tract obstruction (Fig. 93.3). The additional classic elements of TOF include secondary right ventricular hypertrophy and some degree of aortic override or malalignment relative to the interventricular septum. Again, for the purposes of this chapter, comments will be limited to conditions involving balanced ventricles with atrioventricular concordance, malalignment VSD, typically of perimembranous location and pressure nonrestrictive designation, and the presence of prograde pulmonary blood flow into identifiable native branch pulmonary arteries and the absence of major aortopulmonary collateral arteries and significant arborization abnormalities of the lungs which should be discussed in a separate chapter. Mention will be made, however, of patients with TOF with complete atrioventricular septal defect (AVSD) and double outlet right ventricle with subaortic VSD and RVOT obstruction (tetralogy-type double-outlet right ventricle). It is important to note that the degree of aortic override in this chapter will not be used to distinguish between TOF and double-outlet right ventricle, and all patients with the presence of aortomitral fibrous continuity irrespective of the degree of aortic override are to be considered in the spectrum of TOF (Fig. 93.4A, and 93.4B).

**Associated Conditions**

Conditions frequently found associated with TOF include a persistent left superior vena cava, most commonly to an intact coronary sinus. In some patients, in addition to the outlet VSD there may be additional muscular VSDs. A patent foramen ovale is typically present. The ductal configuration is typically associated with normal ductal insertion, although it is not infrequent to observe ductal entrapment of the proximal left pulmonary artery which may ultimately lead to severe proximal left pulmonary artery stenosis or ductal coarctation.
A significant anomaly that may definitely affect the surgical approach is found in the presence of anomalous origin of the coronary arteries. The most frequent anomaly includes anomalous origin of the anterior descending coronary artery from the right coronary artery coursing across the subpulmonary infundibulum. Less frequently, a dominant left main coronary ostium gives rise to a large right coronary artery that originates from the left main trunk which travels around the pulmonary infundibulum and across the anterior surface of the RVOT. An associated right aortic arch is found in 25% of patients.

**Embryology**

For understanding the embryologic development of TOF, we refer the reader to the normal development of the heart. The truncus arteriosus is divided by the aortopulmonary “spiral” septum that grows down from the midline at 7 to 8 weeks of fetal life to fuse with the ventricular septum. This essentially creates the two great vessels and also isolates the right and left ventricles. In the case of TOF, it is thought that the septum is shifted toward the right leading to three of the four tetralogy defects, that is overriding aorta, pulmonary stenosis, and a malalignment VSD. The fourth defect, that is right ventricular hypertrophy, develops to overcome resistance to blood flow caused by the combination of the earlier mentioned three defects as well as right ventricular pressure load.

TOF is seen in association with a number of chromosomal abnormalities and syndromes. Approximately 15% of patients with TOF have chromosome 22q11.2 deletion syndrome (the presentation of which includes DiGeorge syndrome), whereas 7% of Down’s syndrome (trisomy 21) patients have TOF. Other syndromic presentations include Pentalogy of Cantrell also known as thoraco abdominal syndrome, Alagille syndrome, and CHARGE (Coloboma of the eye/central nervous system anomalies, Heart defects, Atresia of choanae, Retardation of growth/development, Genital/urinary defects, Ear anomalies) syndrome. Certain genetic associations have also been found to exist in tetralogy patients that include mutation in NKK25, JAGGED1, ZFPM2/FOG, VEGF, and CHD7 genes.

**Pathophysiology**

The symptomatology of TOF presents a clinical spectrum related to the severity of RVOT obstruction at the infundibular, valvar, supravalvar, or branch pulmonary artery level. Newborns with severe infundibular and valvar obstruction may present with profound cyanosis and ductal-dependent pulmonary blood flow. However, the majority of patients remain relatively asymptomatic in the early period of life. Progressive hypertrophy of the right ventricle and infundibulum participate in a gradual progression toward a degree of right-to-left shunting at the level of the VSD and propensity for desaturation. Frank “tetralogy spells” representing an elevated catecholamine state and reactive infundibular obstruction may be severe but typically are not present until later in infancy. Nonetheless, the natural history in most patients portends a progressive propensity for cyanosis and ultimately, secondary morbid sequelae from that cause. On the other end of the spectrum, however, are the individuals who have anatomy morphologically consistent with TOF with anterior malalignment VSD, but in whom there is little to no obstruction of the pathway of pulmonary blood flow. These patients may present with normal saturations, and in some cases pulmonary overcirculation. These patients with “pink tetralogy” may actually present with signs and symptoms of congestive heart failure relative to a large left-to-right shunt (Fig. 93.5).

SECTION II

Diagnostic Evaluation

Physical Examination
The level and degree of obstruction in the RVOT governs the symptomatology as well as the findings on physical examination. Those patients presenting with severe obstruction may have evidence of cyanosis, although this may, at times, be very difficult to discern, particularly in dark-skinned individuals. Additionally, many patients with cyanosis present with a dusky or even pale appearance, and the deep plethora of cyanosis is atypical, particularly in the current era with early intervention. Furthermore, the late sequelae of chronic cyanosis, including finger clubbing and profound nailbed cyanosis are also very uncommon in developed countries with the capability of early diagnosis and treatment of the patients. A point of emphasis merits attention here. In our observation, it is often very difficult for parents and even pediatricians to discern cyanosis on physical exam. Thus, in a conservative management strategy, it is unwise to rely too much on parents’ ability to detect desaturation.

Auscultation of patients with severe infundibular obstruction in patients with well-developed branch pulmonary arteries is often consistent with high-velocity flow through these structures, including high-pitched systolic murmur and most often best auscultated at the left sternal border. Paradoxically, patients who present with profound hypercyanosis or frank spells often have diminution or even absence of the murmur as the pulmonary blood flow becomes severely restricted. On the other hand, patients with limited infundibular obstruction will often have very faint murmurs and may, in fact, present with signs of pulmonary overcirculation, including pulmonary crackles and a gallop rhythm.

Chest radiography classically reveals the coeur en sabot or boot-shaped heart configuration consistent with a limited pulmonary trunk shadow and a hypertrophied right ventricle and upturned apex. The arch sidedness may be right or left on chest radiography. In case of decreased pulmonary blood flow, the lung fields will show decreased vascular markings (oligemia).

In the current era, the primary diagnostic modality for patients presenting with TOF is transthoracic echocardiography. Important diagnostic features include the presence of prograde pulmonary artery flow, branch pulmonary artery size and distribution, precise delineation of VSD, and delineation of systemic and pulmonary venous connection. In those centers performing primary neonatal tetralogy repair for all patients, irrespective of symptomatology, the presence of an anomalous anterior descending coronary artery may be of significance and at some centers an extensive effort is made to discern this association, although at our hospital this has not been the standard approach. This issue will be expanded upon further later in this chapter.

The majority of patients with TOF do not require diagnostic cardiac catheterization. At our institution, catheterization now has limited application in TOF except in those cases where delineation of the pulmonary artery architecture has not been achieved through other imaging modalities, and it is perceived that this will have some relevance to the surgical timing and approach (see below). The theoretical application of interventional methods in the palliation of symptomatic TOF will be discussed in subsequent sections.

Computed Tomography Scan/Magnetic Resonance Imaging
These imaging modalities are of limited necessity in the primary diagnosis of TOF, although in some circumstances they may be used to ascertain the pulmonary artery architecture and origins and to screen for the presence of significant aortopulmonary collateral arteries.

Timing and Preoperative Care
The subjects of optimal timing and specific surgical technique remain sources of significant dialog and controversy in patients with symptomatic and asymptomatic TOF. It is this author’s opinion that an individualized strategy designed to optimize both early cardiac and neurodevelopmental function as well as long-term preservation of cardiac function and anatomy should be central features in any center’s perioperative management strategy. It is widely known that the late outcomes of patients with previously repaired TOF are predicated on important factors including tricuspid valve function, rhythm disturbance, right ventricular function, endocardial scarring, pulmonary artery distortion, pulmonary valve insufficiency, and chronic right ventricular pressure-volume overload as well as left ventricular dysfunction. Also of note, there is increasing evidence of late propensity of chronic aortic root dilation, progressive aortic valve insufficiency, and frank aneurysmal degeneration of the ascending aorta. As such, it appears logical that all current treatment strategies should take into account the prospect of affecting these late pathologic sequelae, and every effort should be expended to mitigate these circumstances. This is particularly true of right ventricular function where the timing and mode of therapy as well as the associated surgical “side-effects” must be taken into consideration.

In the current era of pediatric cardiac surgery, the substantial improvements in perioperative mortality rates has allowed for a refined focus on long-term neurodevelopmental outcome, and considerable ongoing effort is being expended in assessing the potential to optimize childhood neurologic potential. In this context, numerous investigators including our own institution have focused efforts on the risk profile for children born with congenital heart disease and whether the timing and mode of cardiac surgery can positively or negatively impact neurodevelopmental potential. Beyond the scope of this chapter, it is important to briefly note that current data would suggest that gestational age, perinatal stress, perinatal cyanosis, and application of cardiopulmonary bypass (including the adjunct of hypothermic circulatory arrest) have potential deleterious consequences on long-term neurodevelopmental outcomes. It is unclear at present whether further strategic refinement of timing and mode of repair can ultimately influence long-term neurodevelopmental potential in these patients, although it is highly intuitive that this is the case. In fact, the early arguments for promoting patients for aggressive primary neonatal repair of TOF were predicated on concerns about early perinatal exposure to cyanosis and the potential deleterious effects of that prospect. In contrast, however, recent evidence has also suggested that prudence is warranted in unnecessarily exposing newborns to the potential negative impact of perinatal stress. This is most markedly evident in the premature brain where numerous studies have demonstrated the vulnerability of the premature oligodendrocytes to stress. While definitive data are lacking and clearly enormous work needs to be done in carefully assessing the variables potentially relevant in brain injury and development, it is reasonable to conclude that surgeons in the current era must carefully consider the risk/benefit ratio of surgical approach, not only in terms of acute mortality but also the effects of neurodevelopmental potential.
Preoperative Preparation

Ductal-dependent newborns with severe RVOT obstruction and near pulmonary atresia being put forward for surgery will be maintained on a prostaglandin (PGE1) infusion until the time of operation. Typically, we favor a small bore percutaneous central catheter to provide durable intravenous access prior to surgery and the PGE, is then discontinued at the initiation of cardiopulmonary bypass.

Infants and older children who have demonstrated a propensity toward cyanotic spells are often started on oral beta blockers by the referring cardiologist. In general, we have believed that patients who have been deemed to require beta-blocker therapy should be put forward for operation as soon as possible as hypercyanotic spells are unpredictable in many patients.

For patients in whom beta-blocker therapy has been initiated, there is a propensity toward periparous sinus tachycardia, and our approach has been to continue the oral beta-blocker therapy up to the morning of surgery. These patients are also typically started on an infusion of short-acting beta blockers (Esmolol) prior to weaning from cardiopulmonary bypass. Frequently, during the preparatory stages there is a tendency for these patients to develop some degree of hyperthermia. This is, in general, not a favorable situation, and a mild degree of ambient hypothermia may be helpful in reducing the propensity for tachycardia and a catecholamine surge. In this setting, the anesthesiologist should work very closely with the surgeon to derive a management plan that is designed to limit the potential for hypercyanosis prior to the surgical correction. This may include oral or intravenous hydration, and as mentioned previously, intravenous beta-blocker therapy. Shunt-dependent newborns or infants referred for surgery should be admitted to hospital the night before operation and intravenous access should provide an opportunity for ongoing hydration as hypovolemia prior to operation may induce a cascade of problems, including acute shunt occlusion or hypercyanosis.

Newborn vs. Non-Neonatal Infant Repair

While several notable investigators and institutions have opined that this approach now represents standard of care, this in fact is a highly debatable conclusion. A recent survey of data from the Society of Thoracic Surgeons confirms that the majority of TOF repairs are not performed in the newborn period. Nonetheless, there is much logic in considering primary repair in a newborn patient. Theoretically, this offers the potential to avoid or mitigate the propensity for cyanosis and the deleterious effects of that issue on organ system function, including neurologic development. As noted previously, this issue is not resolved. A compelling argument for promoting patients to surgery at the time of primary diagnosis rests in the implied follow-up responsibility should one not refer a patient at that time. Quite clearly, patients with ductal-dependent circulation require operation, and in later sections of this chapter, we will discuss that issue specifically. Nonetheless, most patients do not present with ductal dependent circulation and may be managed expectantly from a symptomatology viewpoint. It must be emphasized, however, that the management team, which should include a close interaction between the attending cardiologist and cardiac surgeon, must be highly vigilant for any evidence of progress toward cyanosis or spelling. This should also include careful education of the parents for diligent follow-up and timely intervention. As such, in those settings where these elements cannot be assured, and there is some risk of improper follow-up and timely referral for operation, it is entirely logical to promote these patients for surgery as a newborn. Whether or not this represents the best timing for surgery with regard to the long-term function of the right heart remains an issue of debate and should be the focus of ongoing longitudinal patient follow-up and refinement of surgical practice.

Our institutional policy at Texas Children’s Hospital since 1995 has been to perform non-neonatal infant repair of TOF except in those newborns who have ductal-dependent circulation or have morphology and symptomatology highly indicative of a propensity toward cyanotic spelling. In the current era, there appears to be no justification in delaying complete repair of TOF beyond infancy, and we typically favor performing this somewhere around 6 months of life (Fig. 93.6A–93.6D).

Late Presentation

Successful postoperative management of patients undergoing surgical repair of TOF is predicated on a thorough understanding of the nuances of acute postoperative right heart dysfunction. Successful complete repair of TOF involves elements of manipulation of right heart structures, which will be reflected on in more detail at a later point but that may, to a greater or lesser degree, exacerbate propensity for right heart dysfunction. In this regard, any management strategy that is additive to that in a negative sense will adversely impact patient prognosis through diminution of cardiac output and systemic venous congestion. In this regard, many surgeons, particularly those who strictly perform neonatal repair, will often leave a small patent foramen ovale or atrial septal defect to mitigate the effects of right heart distention and dysfunction. In our experience with selective, individualized management, this is not necessary, and we have not favored leaving an atrial level communication.

The management team in the intensive care unit should be vigilant about issues which affect right heart function and the management approach should be adjusted accordingly. In general, we favor an indwelling left atrial catheter as right and left heart filling pressures are often incongruous in the early perioperative period and accurate and effective fluid resuscitation must be evaluated in terms of right and left heart filling. There is a consistent tendency in practitioners less familiar with TOF to excessively volume resuscitate these patients which will exacerbate the propensity for right heart failure, hepatic congestion, pleural effusions, and prolonged recovery.

Inotropic management should be directed toward limiting tachycardia and systemic vasoconstriction. A vicious cycle that can be initiated by an uninformed or inexperienced management team is highly repeatable in patients with TOF. This, of course, is all the more prevalent in patients who have residual lesions, severe right heart dysfunction, tricuspid regurgitation, and dysrhythmia. Such patients may develop a central hyperthermia with
profound peripheral vasoconstriction. These patients often have a progressive tachycardia and the propensity for junctional ectopic tachycardia (JET) is quite significantly increased (to be discussed further at a later point). In this setting, the tendency is to escalate inotropic support and excessively volume resuscitate the patient. Our view is that every effort should be made to improve peripheral cardiac output and reduce the core hyperthermia. This may be effectively achieved with the addition of intravenous milrinone in addition to other systemic vasodilators. In this setting, we have used low-volume, room temperature peritoneal dialysis as well, usually with a reduction in the heart rate and improved diastolic filling, the cardiac output will improve. The goal is, of course, to avoid this cycle.

Our favored inotropic regimen includes the initiation of intravenous milrinone prior to separation from cardiopulmonary bypass, along with a low-dose esmolol drip (25 to 50 µg/kg/min) to reduce tachycardia. We have tended to avoid intravenous epinephrine as contractility is typically not an issue and we have preferred to avoid the secondary consequences of tachycardia and peripheral vasoconstriction.

Junctional Ectopic Tachycardia

An escalating junctional rhythm (His Bundle tachycardia, JET) can become extremely problematic in children with TOF. This has long been recognized to be the result of mechanical trauma at the time of operation. Quite clearly, the propensity for this rhythm to be induced perioperatively is greatly increased in newborn tetralogy repairs as has been well-documented in
the literature. In our own series of infant tetralogy repair, the incidence of junctional tachycardia is significantly lower and JET, by and large, is an avoidable complication. In those patients in whom the rhythm does become problematic and is not responsive to core cooling, intravenous amiodarone loading has proven quite efficacious.

**Complete Atrioventricular Block**

In the current era with wide recognition of the location of the conduction system, the incidence of surgically induced atrioventricular block should approach zero. In our own series from Texas Children’s Hospital in over 300 patients, no patient has suffered complete heart block and hence, this complication should be avoidable. Right bundle branch block is frequent in TOF patients after surgery and this is typically the result of the location of the suture line for the VSD closure. There are surgeons who favor complete transection of the moderator band; in these instances, there is obligate right bundle branch block, and this has been implied in late functional impairment of the right ventricle. Methods have been described to avoid the right bundle branch at the time of the repair, although this may be quite challenging.

**Intraoperative Transesophageal Echocardiography**

There appears to be wide variability in the application of intraoperative transesophageal echocardiography (TEE) in the management of patients undergoing surgical repair of TOF. In our own institution, the use of TEE has become standard practice, and we have found it useful for assessing the completeness of the repair, including avoidance of residual VSDs, preservation of the tricuspid valve function, and assessment of the RVOT. There are some surgeons who claim that this is not necessary except in selected cases; however, it is not clear that this is the case. In skilled and experienced hands, the risk profile of performing a transesophageal echo study should be extremely low, and in our view there is no strong reason against performing this study in this group of patients.

**SECTION III**

**Surgical Considerations**

The basic surgical elements of complete repair of TOF include correction of the anatomic and functional defects and preservation of overall right ventricular function. Given the wide variety of approaches used by surgeons to accomplish a complete repair, it is quite clear that there is considerable variability in opinion about the optimum surgical approach. Our approach at Texas Children’s Hospital has been to utilize a methodology that minimizes trauma and irreparable damage to the right ventricle. However, the long-term superiority of this approach is, as of yet, unproven.

Patients undergoing TOF repair are typically approached through a standard midline sternotomy incision, although some surgeons have favored an inframammary incision for female patients. We have believed that the inframammary approach is an imprudent approach for these children. To our view, it must be acknowledged to parents in the preoperative consultation that all patients undergoing successful TOF repair face a life-long risk of possible surgical reintervention. As such, we have favored a midline sternal incision. Typically, a partial thymectomy is performed to facilitate exposure for cardiopulmonary bypass. We typically harvest a pericardial patch and have favored glutaraldehyde-prepared autologous pericardium for patch material for the surgical repair, although surgeons have reported successful series using a wide variety of materials including polytetrafluoroethylene (PTFE, Gore-Tex®) patch, polyethylene terephthalate (Dacron®) patch, heterologous pericardium and, more recently, decellularized small intestinal submucosa. It appears that there is, at present, no documented superiority of one material over another, and this choice largely appears to be a matter of surgeon preference. We have favored pericardium because of its availability, theoretical resistance to infection, and lack of porosity which eliminates the potential of early perioperative patch shunting as may be seen in patients having Dacron® patch closure. Patients typically undergo standard cardiopulmonary bypass cannulation. We have favored separate vena caval cannulation with angled cannulas of appropriate size. In those patients with a persistent left superior vena cava, we typically will cannulate this directly, although it is also acceptable to place a vent/drain into the superior vena cava via the coronary sinus. We have completely eliminated the use of hypothermic circulatory arrest in our practice of TOF repair. It is still observed that some surgeons favor using DHCA for facilitation of intraoperative exposure, and in those centers performing exclusive newborn TOF repair, the application of hypothermic circulatory arrest is more widely practiced. Myocardial protection in our unit is achieved through multidose, antegrade, crystalloid cardioplegia with intermittent topical hypothermic normal saline. We have favored moderate hypothermia for our cardiopulmonary bypass strategy, typically cooling patients to a nasopharyngeal temperature of 30°C. We have also favored intraoperative physiologic/neurologic assessment including bicortical near-infrared spectroscopy used as an adjunct to optimized cardiopulmonary bypass strategy.

The basic elements of TOF repair include precise closure of the VSD with preservation of the atrioventricular node and the Bundle of His, relief of RVOT obstruction, preservation of pulmonary valve function if possible, relief of pulmonary artery obstructions and closure of the atrial level communication. For this operation, there have been a significant number of variations of surgical technique that have been adopted and promoted. It must be emphasized that at present no surgical technique has been demonstrated to be clearly superior over another, although there is accruing intermediate term data to support the logical conclusion that operations designed to preserve, as much as possible, native right ventricular contractile function and pulmonary valve competence have a lower incidence of need of intermediate-term reoperation. Thereby, these operations would theoretically confer a life-long outcome benefit. The various techniques will be reviewed in detail. It must be acknowledged that it is the author’s contention that the transatrial/transpulmonary approach offers a superior methodology, although the pros and cons of this versus other surgical methods will be discussed.

**Classic Transventricular Repair**

Historically, the majority of patients undergoing complete repair of TOF have undergone a transventricular approach, which is well described in many outstanding textbooks. This operation is approached through a RVOT infundibulotomy. This gives very good access to the VSD, which can be readily patch-closed with either running or interrupted suture technique. This method is applicable to all ages of patients and appears to be the preferred method for those units committed to all neonatal primary tetralogy repairs. The infundibulotomy also provides access to the obstructing RVOT musculature, and where necessary, a transannular pulmonary valvotomy can be extended up onto the hypoplastic main pulmonary artery. Surgeons then have
the option of either primary closure of the RVOT or a patch augmentation of the infundibulotomy and where necessary, the main and branch pulmonary arteries. This is a very straightforward operation, giving the surgeon excellent view of the critical features of the TOF repair, and is the most widely practiced methodology. There are several important points of concern about this approach. First, it is intuitive that relative to the size of the patient and thereby the size of the heart, the infundibulotomy becomes incrementally longer in smaller children. In the author’s experience, this has translated into patients presenting late in life after transventricular repair with, essentially, the entire anterior wall of the right ventricle being nonfunctional due to extensive right ventricular incision. Second and by necessity, large coronary arteries traversing the anterior wall of the infundibulum including the first conal branch must be transected. In fact, some surgical textbooks note that this is an important component of the technique. This renders a significant portion of the anterior wall of the right ventricle ischemic (see illustration, Fig. 93.7A, and 93.7B). Next, in the setting of a large infundibulotomy which extends across the pulmonary valve annulus, the patient is exposed to an acute compromise of overall right ventricular forces and, as such, it is widely recognized that in those newborns and small infants undergoing transventricular repair, it is often a necessity to leave an atrial level communication to mitigate the effects of acute right ventricular dysfunction.

It is important to re-emphasize that the transventricular operation represents the “gold standard” complete TOF repair technique against which all other methodologies must be compared. Historically, this is the most widely practiced form of TOF repair, and thereby the outcome information which is progressively accruing concerning the long-term outlook for patients after TOF repair, notably progressive right ventricular dilation/dysfunction and pulmonary valve insufficiency are related to this methodology.

Modified Transventricular Repair
To attempt to ameliorate the effects of pulmonary valve insufficiency on both acute and chronic right ventricular performance after TOF repair, a number of investigators have developed techniques to minimize or eliminate the need of a transannular RVOT incision. Mavroudis and Backer have published an interesting series of patients in whom an infundibulotomy was performed for resection of RVOT muscle and VSD closure, but then the pulmonary annulus was spared and an operation involving enlargement of at least two of the pulmonary valve sinuses as per a technique similar to repair of supravalvar aortic stenosis is accomplished. The authors note that in their series, the incidence of pulmonary transannular incision was much lower than previously reported; however, they have accepted in their patients a much higher right ventricular to systemic postoperative pressure ratio of 0.53 ± 0.13.

A more controversial approach has been recently promoted by Bacha and colleagues originally from Boston Children’s Hospital and now more recently from Morgan Stanley Children’s Hospital. This involves a longitudinal right ventriculotomy and transventricular closure of the VSD. The pulmonary valve is left intact and an on-table balloon pulmonary valvotomy is performed, essentially fracturing the pulmonary annulus, but with the theoretical benefit of preserving pulmonary valve competence. The early data for this approach are somewhat encouraging, although by definition it will be many years before follow-up data can be used to compare this against other techniques. To this author’s viewpoint, a concerning feature of this approach is the very extensive right ventriculotomy which is performed to allow access to the VSD and relief of the RVOT obstruction, and to provide access to the pulmonary valve annulus.

Transatrial/Transpulmonary Repair
This is the preferred methodology at the author’s institution over the last 16 years, and as such will be the most detailed technical description (Fig. 93.6A–93.6D and Table 93.1). The transatrial/transpulmonary approach was originally described by Kawashima and later further championed by Pacifico at the University of Alabama, and then broadly applied by Mee and Karl. The later investigators published the first large series of non-neonatal transatrial/transpulmonary repair of TOF. The central feature of this operation is complete avoidance of a transmural RVOT incision. In fact, in our series of operations from Texas Children’s Hospital, a transmural infundibulotomy has been avoided in all but three patients in a series of now approximately 450 cases (Table 93.2).

The transatrial/transpulmonary operation is approached through median sternotomy and full-flow cardiopulmonary

DHCA, deep hypothermic circulatory arrest; NS, nonsustained; PA, pulmonary artery; RV, right ventricle; TA/TP, transatrial/transpulmonary.

musculature becomes less problematic. We have adopted the viewpoint that, “You can’t put back what you have taken out,” and this has been effective in our experience. Typically, in the relaxed heart, the goal of the infundibular resection is to achieve a RVOT dimension of 2-mm larger than the mean expected pulmonary annular size for the patient. After performing the infundibular resection, attention is then turned to the VSD. VSD repair is addressed through the right atrium, and in all patients the VSD is closed, typically with an untreated autologous pericardial patch. In the cases where there is proximal branch pulmonary artery stenosis, we have favored direct autologous pericardial patching during rewarming with the heart beating.

The transatrial/transpulmonary approach is applicable to all anatomic variations, including those patients in whom an anomalous anterior descending coronary artery is present. This technical modification has been well described by us and others and is quite advantageous in comparison to a remote right ventriculotomy which is required for those units in whom a transventricular approach is applied. It must also be noted as an advantage of the transatrial/transpulmonary approach that a right ventricle to pulmonary artery conduit is not necessary in these operations. Furthermore, it is also of theoretic benefit (and this has been opined by several observers) that an additional advantage of this technique is avoidance of injury to any of the major right ventricular coronary arteries. This includes complete avoidance of transecting any of the major conal branches, which is mandatory in the transventricular methodology.

The next significant disadvantage of the transatrial/transpulmonary approach is that it is extremely difficult to teach. The reason for this is quite simple. There is only one person at the operative field who can see the operation, and that is the operating surgeon. The first assistant is severely limited in visualization. In our unit, in teaching the congenital heart surgical fellow, we have typically had that person either scrubbed or unscrubbed, standing immediately behind the operating surgeon, to give the trainee the best view of the specific nuances of the repair, before graduating the trainee on to primary surgeon.

A final observation is that the operative surgeon must be extremely diligent about limiting the potential for traction injury on the heart in achieving adequate exposure. This risk, of course, is exacerbated in the very small patients where visualization may be challenging. The surgeon should be extremely diligent about avoiding excessive operative traction which can cause significant injury to the tricuspid valve, as well as to the conduction system. In our series,
with a very diligent approach to the tenets of the operation, the incidence of complete atrioventricular block has been 0, and the incidence of perioperative JET has been lower than other large reported series (2% vs. 14%).

Finally, there is no question that the transatrial/transpulmonary approach is technically more demanding than the transventricular approach. Operative times tend to be longer as well as myocardial ischemic times. This does not appear to have translated into any demonstrable disadvantage and the published results have been favorable in comparison to other contemporary series. The unanswered question is whether strict adherence to this approach, and thereby the theoretical improvement of acute and intermediate term right ventricular performance, will confer incremental long-term improvement in outcomes in comparison to other methodologies. Due to limited duration of longitudinal follow-up, definitive data are lacking. However, intermediate data from our own and other contemporary series are encouraging. Even if one considers the additional influence of an intervening palliative operation, for patients enrolled in a strict transatrial/transpulmonary methodology, the incidence of intermediate-term reoperation is lower than the incidence of reoperation in patients undergoing a strict neonatal approach. This provides inferential evidence confirming that early right ventricular performance is improved. Indeed, Geva and colleagues, as well as other investigators have confirmed the lack of a functional infundibulum in patients after a TOF repair as an important diagnostic feature portending poor long-term right ventricular performance. It is, therefore, logical that any operation that preserves infundibular contribution to cardiac output would translate into a long-term benefit.

**Intervening Palliations**

Given the current high level of sophistication of perioperative diagnostic imaging, including high-resolution transthoracic echocardiography, an individualized operative strategy can be derived for all patients with TOF. In those limited cases where there is poor delineation of the branch pulmonary architecture, other forms of imaging may be necessary and, depending on the institutional experience and expertise, this may include magnetic resonance imaging, contrast-enhanced computed tomography, or cardiac catheterization.

In patients in whom there is clear ductal dependence of pulmonary blood flow as a newborn, a management algorithm should be derived to optimize long-term right ventricular performance along with acute outcomes. In newborn patients with limited aortic override and limited muscular infundibular obstruction, a transatrial approach can be achieved even in small babies. Typically, those cases are handled as per previous descriptions with either limited or no transannular pulmonary incision depending on morphology. On the other hand, in patients with extreme aortic override and severe infundibular obstruction, the ability to perform a transatrial/transpulmonary approach is compromised in tiny babies. We have, in those patients, continued to advise the use of judicious shunting as an intervening staging palliative operation. In the units that promote patients for an intervening shunt, a strict and careful assessment of outcomes is mandatory. This includes

![Fig. 93.8. (A and B) Illustrations describing the ventricular septal defect closure in a patient with tetralogy of Fallot with sutures avoiding the conduction system. (From Morales DL, Zafar F, Heinle JS, et al. Right ventricular infundibulum sparing (RVIS) tetralogy of Fallot repair: a review of over 300 patients. Ann Surg 2009;4:611-617.)](image)
adherence to diligent follow-up and prompt referral for a complete repair. The palliative operation or intervention is not designed as a durable solution, and as previously mentioned, we typically favor promoting patients for a transatrial/transpulmonary operation somewhere around 6 months. In our unit, we have favored approaching shunt construction through the side of the morphologic right lung. We believe that this is best approached through a right thoracotomy incision, as this offers the operative surgeon the opportunity to place the shunt more peripherally on the subclavian artery, and thereby avoid overshunting and this has worked out quite well for our institution. Of course, other surgeons have recommended sternotomy, and this is certainly acceptable, again with the tenet that this program and strategy is predicated on diligent follow-up and prompt re-referral for definitive repair in infancy.

In some units, including our own, there is growing enthusiasm about the possibility of interventional procedures to stage patients for complete repair. Methods that have been employed include stenting of the ductus arteriosus and stenting of the RVOT. While these are very interesting technical modifications, at present, they cannot be construed as anything other than experimental and these patients should be followed very carefully for deviation from accepted morbidity and mortality data. In the authors’ opinion, there are several concerning features of these methodologies. Stenting the RVOT has the inherent challenge of needing to traverse the tricuspid valve in a very small baby with delicate valvar mechanism. In our experience, there have been patients in whom the tricuspid valve mechanism has been distorted or injured during other interventions as newborns including dilation of the pulmonary valve in patients with critical pulmonary stenosis. It is, therefore, entirely logical that this same approach applied to babies with TOF does place the tricuspid valve mechanism at risk, which of course is one of the features of long-term outcome for TOF patients which has to be considered. Ductal stenting in patients with ductal-dependent pulmonary blood flow requires discontinuation of PGE1, and progressive ductal constriction. This places the child at risk of a hypercyanotic event and can be quite a precarious undertaking. Again, the emphasis in performing such a procedure on a child should be that it is largely experimental and very accurate perioperative and longitudinal follow-up data must be collected if this approach is to be employed.

Finally, any unit that is employing a staged management approach to children with TOF has an obligation follow-up responsibility to ensure that these patients undergo timely reintervention. Interstage attrition is unacceptable in this condition, and if there is an issue in that regard, this management strategy is unjustifiable.

**Tetralogy of Fallot with Anatomic Pulmonary Atresia**

As mentioned in the Introduction, comments concerning this condition will be limited to those patients in whom there are no major arborization defects/major aortopulmonary collateral artery dependent bronchopulmonary segments.

In patients with TOF with pulmonary atresia, our goal has been to accomplish a repair which, as much as possible, achieves the anatomic and functional result that would be aspired to in patients undergoing a transatrial/transpulmonary approach for TOF with pulmonary stenosis. This can be achieved in many cases. We have favored early palliative shunting and infant/non-neonatal referral for an infundibulum sparing operation where the RVOT resection and VSD closure are approached as we would standardly perform for children with TOF with pulmonic stenosis. Typically, a very limited transannular pulmonary infundibular incision can then be augmented with a small pericardial patch avoiding the need of a right ventricle to pulmonary artery conduit. This has allowed many patients to be effectively treated without the obligate need of conduit reoperation in early childhood.

An alternate approach favored in most centers, and in certain settings in our own unit, is a primary newborn repair for this condition. This is quite achievable with good results, but with the premise that any extensive right ventricular incision places the patient at ultimate long-term risk of impaired right ventricular performance as is seen in the longitudinal follow-up of patients after TOF with pulmonary stenosis repair.

**Tetralogy of Fallot with Complete Atrioventricular Septal Defect**

While beyond the scope of this chapter, some discussion of TOF with complete AVSD should be included here. As a general principle, these repairs are more challenging in patients with TOF with pulmonary stenosis repair for several very obvious reasons. As mentioned previously, the elements affecting perioperative morbidity and mortality in TOF repair are related to overall performance of right ventricular forces. As such, patients with TOF with AVSD are, by definition, at increased risk. First, partitioning of the atrioventricular valve tissue with the goal of achieving two ideal atrioventricular valves is always a challenge in these patients and in patients with a very significant malalignment component where there may be severe aortic override, and the surgeon may be in a position of having to compromise in the partitioning of the atrioventricular valve tissue. Of course, in a patient with a large VSD patch and a marginal right atrioventricular valve, there is considerable potential for compromised right heart performance. In general, we have favored, as with other tetralogy patients, a program of non-neonatal repair to optimize the intracardiac repair and thereby, right ventricular performance. This has included a two-patch technique with avoidance of division of the superior bridging component of the common atrioventricular valve. It is beyond the scope of this chapter to focus on the specific elements of AVSD repair, but noteworthy that any element of distortion of the right atrioventricular valve places patients with tetralogy with AVSD at increased risk.

**CONCLUSIONS**

In the modern era, the acute postoperative morbidity and mortality after TOF repair should be minimal with many series reporting operative mortality rates of <1%. This, therefore, is the outcome expectation from which all management strategies should be derived. With the acceptance of the necessity of accomplishing complete repair with very low perioperative morbidity or mortality, the focus should be further refined on optimizing long-term right ventricular performance. As such, the operative surgeon is obliged to take into consideration evolving methodologies and accruing data, which allow us to further improve our operative techniques in optimizing these patients’ long-term prognosis. In counseling parents and ultimately patients with TOF, the operative surgeon is part of an important management team emphasizing our current optimistic prognosis outlook for these patients; but furthermore, the need for diligent long-term follow-up, and where necessary, timely re-referral for intervention as needed including pulmonary valve replacement which is discussed in other chapters in this text.
The optimal approach to tetralogy of Fallot remains somewhat controversial. Although the number of operative deaths has decreased with tetralogy of Fallot repair and approaches zero in many series, the optimal age at repair is unknown. In centers where neonatal repair is commonplace, operative intervention for complete repair of tetralogy of Fallot can be undertaken at any age. We have elected to perform tetralogy repair at the age of presentation when patients have significant cyanosis. If this approach is used, there is a small subset of patients who present early in neonatal life with significant cyanosis and ductal dependence of pulmonary blood flow. These patients often have the most severe forms of tetralogy of Fallot with significant outflow tract obstruction, small pulmonary arteries, and significant risk for left branch pulmonary artery stenosis after repair. Nevertheless, direct primary repair in these patients may have better results than staged reconstruction with palliative shunting because involution of ductal tissue in these patients often results in pulmonary artery discontinuity when a shunt is placed, and then the advantages of forward flow in the pulmonary arteries may be lost.

Anomalous origin of the left coronary artery has not generally been a contraindication to complete repair in our experience. Short transannular incisions are now the rule and often are able to avoid anomalous coronary arteries in the right ventricular outflow tract (RVOT). Sometimes a flap of left atrial appendage can be used to cover the coronary artery on the RVOT to maintain an autologous tissue connection to the pulmonary arteries, or in unusual cases the pulmonary artery can be divided and brought down to the ventriculotomy incision directly, bridging the anomalous coronary vessel. It, therefore, is not generally necessary to use a valved conduit in reconstruction in these patients. When neonatal repair is undertaken, we have generally left the foramen ovale open or partially closed the secundum atrial septal defect to allow a pop-off of pressure in the right atrium, which may result from elevation of pulmonary resistance and decreased RV compliance in the newborn. In older patients, we agree with Dr. Fraser that closure of the atrial septal defect should be performed to prevent right-to-left shunting and cyanosis in the early postoperative period due to right ventricular compliance decrease.

The primary controversy in repair of tetralogy of Fallot is the age of the patient at primary repair and the use of transatrial/transpulmonary approaches to complete reconstruction with avoidance of transannular patching. Patients with extensive transannular patches may develop progressive late right ventricular dilation because of progressive pulmonary insufficiency, and these patients have a significant late morbidity and mortality from ventricular arrhythmias and right and ultimately left ventricular dysfunction. Pulmonary valve replacement may be necessary. It is unclear, however, whether pulmonary regurgitation is a result of extensive right ventricular muscle resection or extensive patching as a result of tubular hypoplasia of the RVOT. The exact cause of right ventricular dysfunction and pulmonary insufficiency is not clear. It seems logical, however, to limit the extent of right ventriculotomy and transannular patching to the minimal amount possible to prevent late right ventricular dysfunction. In many cases, even with transannular patching, pulmonary regurgitation is only modest, and right ventricular dilation does not occur. Although it is important to relieve RVOT obstruction if at all possible even at the cost of more extensive transannular patching, the extensive studies of late ventricular function performed by Dr Andrew Reddington and his associates suggest that the characteristics of the right ventricle are more important than the pulmonary insufficiency alone in late function of the right ventricle. These studies suggest that residual stenosis is well tolerated and can limit the magnitude of pulmonary insufficiency with resultant ventricular dilation and late RV failure. Thus, the trend is to leave more residual RV outflow tract obstruction than has typically been the case in the past with the anticipation that there will be a gradual decrease in the ventricular systolic pressure over time and that mild degrees of obstruction (20 to 30 mm) are well tolerated over a lifetime. Thus, minimal transannular patches are becoming more standard and attempts to preserve pulmonary valve function are becoming increasingly desirable.

Nevertheless, the relative advantages of leaving residual obstruction that may in fact progress over time and require reoperation and the problems of placing monocusps or other valve-bearing or valve-creating procedures in the RV outflow tract with the potential need for reoperation make continued follow-up of these patients mandatory. If postoperative residual pulmonary hypertension is anticipated, we have also used monocusp valves in the RVOT to aid in the postoperative hemodynamic stability of these patients. Primary repair in the neonatal or infant period without previous palliative procedures such as systemic-to-pulmonary shunts has been possible in the majority of cases.

Transatrial and transventricular approaches to the ventricular septal defect are both suitable; however, transatrial repair allows the greatest exposure to avoid the conduction tissue. Closure of the ventricular septal defect before muscle resection allows adequate endocardium for anchoring the patch and avoids having to sew the patch for the ventricular septal defect to raw divided muscle, which may not hold sutures well. We have elected to use pulmonary homograft material or PTFE for RVOT reconstruction when necessary. Although nonfixed homologus pericardium can be used. If a small residual ventricular septal defect is present, a jet directed toward the outflow patch can result in aneurysmal dilation and require reoperation. Therefore, if outflow tract reconstruction is necessary, we have generally preferred to use either glutaraldehyde-fixed autologous pericardium or homograft or Gore-Tex material, which has less tendency to stretch.

Patients with particularly difficult situations are those with tetralogy of Fallot and absent pulmonary valve. In these patients, the ductus arteriosus is typically absent and the to-and-fro blood flow in the main pulmonary arteries causes severe central pulmonary artery dilation and bronchial compression. Ventricular septal defect closure and extensive posterior and anterior internal plication of the pulmonary arteries to a normal
EDITOR’S COMMENTS

(continued)

...diameter with the placement of a valved homograft from the right ventricle to the pulmonary arteries may result in the most optimal repair of this defect. The use of a valved conduit decreases the pulsatility in the central pulmonary arteries and therefore decreases the tendency for bronchial compression. Extensive posterior internal plication of the pulmonary arteries results in a more normal anatomic diameter of the pulmonary arteries and adds substance to the pulmonary artery, which can support the underlying bronchial wall. In spite of these technical modifications, some patients will require long-term ventilatory support because of distal arborization abnormalities and distal tracheomalacia with significant developmental abnormalities of the lung. Nevertheless, we believe that obtaining the most normal hemodynamic and physiologic conditions of the RVOT at the initial operation will maximize early recovery and the ability to wean the patient from ventilatory support. It is not uncommon in these patients to require reoperation for additional pulmonary artery plication in the first 2 to 3 months after initial repair because pulmonary artery size can continue to enlarge even with adequate initial plication and can compromise lung function late after the procedure. There has been increasing interest in the use of a Lecompte maneuver to bring the dilated central pulmonary arteries anterior to the aorta in tetralogy of Fallot with absent pulmonary valve syndrome to avoid bronchial compression. It is not clear how this technique affects the malacia that has been assumed to be present in the bronchi because this would not be addressed by this technique. Nevertheless, the results with this approach seem to be good and can avoid the need for placing a competent valve in the right ventricular outflow tract in patients with respiratory compromise. Presumably also progressive dilation of the pulmonary arteries will not result in increased airway symptoms as has been seen in the more traditional plication approaches. The exact physiology of tetralogy of Fallot with absent pulmonary valve syndrome and dilated pulmonary arteries and the effect of the pulmonary pulsatility on the airways have not been extensively studied. Prone positioning in these patients seems to result in some improvement, even when the VSD is open, suggesting that rather than specific airway compression by the dilated pulmonary arteries, distribution of blood flow in the lungs may be a more important factor.

Repair of tetralogy of Fallot now is associated with mortality approaching zero in many large series from several pediatric cardiovascular surgical centers. The optimal age at repair is unknown; however, we have generally elected to repair these patients early in infancy in the majority of cases. Because symptoms generally occur early in neonates with the most complex forms of tetralogy of Fallot, operative intervention, therefore, must be initiated early in these patients. Asymptomatic neonates with tetralogy of Fallot in our center generally are followed until they are 2 to 4 months of age, at which time elective complete repair can be undertaken with very low morbidity and mortality.

As noted by the authors of a chapter, tetralogy of Fallot has become benchmark against which other treatment strategies for congenital heart disease must be compared. It was one of the first conditions successfully treated by open intracardiac repair and as such one of the defects for which we have the longest follow up. As these patients have aged, the issues related to preservation of ventricular performance and the need for reoperation have become evident. Perhaps, there is no area in congenital heart surgery currently where there is a greater amount of debate and surgical modification. Because of the well-recognized issue of late development of right ventricular dilatation and its affect on exercise performance and late left ventricular function, there has been an increasing interest in trying to preserve the pulmonary valve as much as possible at the initial operation. In spite of the logic that would suggest that preservation of valve function will improve overall right heart function with time, this hypothesis has not been completely studied. It is unclear whether extensive infundibular resection with a transatrial and transpulmonary approach has similar effects on infundibular function as limited infundibular incision and patch augmentation or primary closure. Preservation of epicardial conal branches when intramural coronaries are disrupted by extensive infundibular resection may not in fact preserve overall ventricular performance in the long term. Newer approaches to try to balloon dilate the pulmonary valve through a ventriculotomy or to augment the pulmonary valve to maintain valve function are creative, but there are no data currently that these approaches can result in any better long-term outcome and in the majority of valve-preserving operations, valve function is preserved over a relatively short-term period. Patients who have extensive malalignment of the ventricular septum with tubular hypoplasia of the right ventricular outflow tract and main pulmonary artery will still require more extensive patching to relieve obstruction, and the incidence of reoperation for recurrent right ventricular outflow tract obstruction appears to be greater in series of patients who have had more valve-preserving operations. Thus, tetralogy of Fallot is probably the condition in congenital heart surgery now where there is the greatest amount of controversy and opinion but there is relatively little good data comparing one technique versus another.

Most centers have largely avoided aortopulmonary shunting in patients with tetralogy of Fallot. The indications for aortopulmonary shunts appear to be quite limited. Despite the excellent results with the series from the authors with the use of shunts in newborns, similar long-term outcomes have been reported in centers who have not performed primary shunting. In the majority of centers now the mortality rate for tetralogy of Fallot repair even in infancy approaches 0% to 1%.

There is increasing interest as was described in this chapter, in the use of interventional techniques for palliation in tetralogy of Fallot patients. Stenting of the right ventricular outflow tract and the ductus arteriosus has been recommended by some centers and has been increasing utilized in a few. There are...
concerns, however, with the use of these techniques. Stenting of the right ventricu­lar outflow tract in tetralogy of Fallot may allow for improved oxygen saturation and to allow a patient to escape the neonatal period to undergo a repair at a later time in infancy but has the disadvantage of creating a rigidity of the RV outflow tract that may make intraoperative repair quite difficult. I have experienced situations where the stent in the outflow tract has become incorporated enough into the myocardium that it is not been able to be completely removed without significant disruption of underlying structures including portions of the tricuspid valve. If the stent extends down into the ventricle across the infundibulum, then the ability to manipulate the cardiac structures to gain exposure of the VSD through the right atrium can be extremely limited due to the rigidity of the stent fixing the infundibular septum superiorly. With the outstanding results of even neonatal repair of tetralogy of Fallot in the current era, it would seem that the use of these techniques should be limited to patients who have significant contraindications to the primary surgical repair.

TLS
Cavopulmonary Shunts and the Hemi-Fontan Operation

Marshall L. Jacobs and Robert D. Stewart

HISTORY AND RATIONALE

The earliest palliative operations that were developed to treat various forms of congenital heart disease include the systemic-to-pulmonary artery shunt, first described by Blalock and Taussig in 1944, and the pulmonary artery band, first described in 1952 by Muller and Damman. In the earliest cases, these palliative procedures were not performed as elements of a planned approach that anticipated eventual definitive reconstruction, but rather in an attempt to prolong survival and improve the functional status of markedly compromised patients with either severe cyanosis or profound congestive heart failure. During the same era of innovation by pioneer cardiovascular surgeons, a third approach to palliation was explored by a number of investigators and surgical teams. This approach involved diverting some or all of the systemic venous return directly to the pulmonary arteries, bypassing the heart. The concept of cavopulmonary anastomosis may have had its origin in early studies of the concept of the “dispensable right ventricle.” Rodbard and Wagner in Chicago in 1949 had experimentally anastomosed the right atrial appendage to the pulmonary artery and ligated the main pulmonary artery in dogs, demonstrating the feasibility of excluding the right ventricle from the circulation. The first report of experimental cavopulmonary connection was published in 1950 in Italy by Carlo Carlon and associates, who hypothesized that an “advantage would be received if the blood of the superior vena cava (SVC) should reach the capillary region of the right lung by way of a convenient anastomosis between the great venous trunk and the arterial system of the right lung.” Carlon’s canine preparation was an end-to-end anastomosis between the proximal end of the divided azygous vein and the right pulmonary artery with pre-atrial ligation of the superior vena cava. In 1951, in the first English language report of these experiments, Carlon and associates wrote, “We are not aware that anyone else has foreseen and studied the problem of oxygenation of the pulmonary blood under venous pressure and without cardiac output.” Carlon’s first clinical experience was not reported until 1964. In the meantime, Glenn and Patino at Yale published their first report of experimental cavopulmonary shunts in 1954, and in 1955 reported a large study of 59 operated dogs, with six long-term survivors. Glenn’s experimental preparations explored the feasibility and physiology of both superior cavopulmonary connections and inferior cavopulmonary connections, noting the occurrence of chylothorax in some instances of the former strategy and ascites in the latter. The first clinical report by Glenn was published in 1958. It is following that report, and a subsequent series of publications by the same authors, that the superior cavopulmonary anastomosis has become widely known as the “Glenn shunt.” Interestingly, however, a fundamentally similar operation was at the same time being developed and evaluated in Budapest by Frances Robiskeck and associates, in Russia by Galankin and Darbiniand and by Meshalkin, in the United States by Shumacher, and in Italy by Carlon and others, as stated above. In retrospect, it appears likely that the first attempts at clinical cavopulmonary shunts were by Harris B. Shumacher in 1954. His two young patients, one with truncus arteriosus and one with transposition, both had markedly elevated pulmonary vascular resistance and both died within hours of operation.

The “Glenn shunt” (unidirectional superior cavopulmonary anastomosis) found a unique and important place in the management of cyanotic heart disease in general, and functionally univentricular hearts in particular. The resulting physiology was fundamentally different from that achieved by creation of systemic-to-pulmonary artery shunts. The cavopulmonary anastomosis was capable of increasing pulmonary blood flow and thus systemic arterial oxygen saturation without increasing the volume load on the systemic ventricle. It also proved the feasibility of transpulmonary flow without complete dependence on a subpulmonary ventricle. During the 1960s and early 1970s, the classic “Glenn shunt” was used extensively, with good results, to palliate patients with tricuspid atresia, and to a lesser extent other forms of functionally single ventricle. Unfortunately, it became apparent after a number of years that cyanosis would eventually recur in a high proportion of patients. This was in part attributable to maldistribution of blood flow in the involved lung (favoring flow to the lower lobe), and in part to the development of arteriovenous shunting within the lung that was perfused exclusively with superior vena caval blood. The “unidirectional” Glenn shunt was eventually modified in a variety of ways by Dogliotti, Haller, and Azzolina to allow the flow of superior vena caval blood into both pulmonary arteries. They utilized either an end-to-side or side-to-side anastomosis of the superior vena cava to the right pulmonary artery with maintenance of continuity between right and left pulmonary artery branches. This technique, which preserves the confluence and the integrity of the central pulmonary arteries, eventually supplanted the classic Glenn anastomosis as preferred palliation for functional single ventricles. Currently, without particularly good reason, the bidirectional superior cavopulmonary anastomosis is generally and widely referred to as the “bidirectional Glenn shunt.” It is most widely used as a preliminary or interim procedure (following neonatal palliation) in patients with functionally univentricular hearts for whom a staged approach to reconstruction culminating in completion of the Fontan circulation is anticipated. Occasionally, construction of a superior cavopulmonary...
connection, together with maintenance of a physiologically restrictive source of antegrade pulmonary blood flow from the functionally univentricular heart or from a small patent arterial duct or shunt, is considered as a final or definitive palliative arrangement, as an alternative to the Fontan procedure. Other applications of the bidirectional superior cavopulmonary connection are less common. They include those circumstances where mild-to-moderate degrees of hypoplasia of the right ventricle and its associated valves permit the use of the right ventricle as a subpulmonary ventricle that handles venous return from the inferior vena cava, while superior caval return is diverted directly to the lungs. This arrangement has come to be known colloquially as “one-and-a-half ventricle repair.” Occasionally, in the setting of complex malformations with atrioventricular discordance, the superior cavopulmonary connection has been used in conjunction with a simplified atrial baffle procedure that deals only with inferior caval return. Finally, superior cavopulmonary connection has, in rare instances, been used to achieve right ventricular volume unloading in the setting of ischemic right ventricular failure. It has been suggested that it may have an analogous role in patients with reduced right ventricular function who are candidates for left ventricular mechanical support.

**ROLE OF THE SUPERIOR CAVOPULMONARY CONNECTION IN THE MANAGEMENT OF FUNCTIONALLY UNIVENTRICULAR HEARTS**

By the 1980s, refinement of the technical aspects of modified Fontan operations and development of guidelines for patient selection led to a decrement in the overall mortality associated with these procedures. Nonetheless, a troublesome degree of morbidity and early mortality occurred following modified Fontan operations, even among those who met all criteria for “favorable candidate” status. Too often, even among carefully selected patients with adequate preoperative ventricular function and pulmonary vascular anatomy and resistance, the postoperative course was characterized by elevation of central venous pressure, tachycardia, with sequestration of fluid in the pleural and peritoneal spaces, and hypotension which was only transiently responsive to volume administration at the expense of further increases in venous pressure. Little improvement was seen with administration of inotropic agents and vasodilators, or with external compressive devices to promote venous return while minimizing volume administration. Echocardiography frequently showed a striking degree of ventricular wall thickness relative to cavity volume, vastly out of proportion to the preoperative degree of myocardial hypertrophy. This appearance of a thickened ventricle with relatively small cavity volume was associated with tachycardia and poor perfusion, regardless of the contractile state of the myocardium. It became evident that the conversion from the unoperated or palliated state to the post-Fontan circulation was associated with rapid removal of a chronic volume load on the ventricle. The change in loading conditions took place abruptly, while regression of myocardial mass proceeds slowly. As a consequence, a maladaptive response to removal of the ventricular volume load occurs, characterized by markedly increased ventricular myocardial mass-to-volume ratio. The persistence of increased muscle mass in the setting of acutely diminished ventricular volume results in increased ventricular wall thickness and decreased cavity dimensions. This change in the geometry of the ventricle can result in significant alterations in both systolic and diastolic functions. Perhaps most importantly, the diminished compliance of the acutely thickened ventricle results in poor filling, at the expense of elevated pressure in the cavopulmonary pathway and diminished cardiac output. This realization shed light on earlier observations that older age (longer duration of volume loading) and increased ventricular hypertrophy (increased muscle mass) were risk factors for mortality in association with the Fontan operation. More importantly, it leads to the hypothesis that dividing Fontan’s operation into two procedures could accomplish early reduction of the volume work of the single ventricle, at the same time minimizing the impact of changes in ventricular geometry on outcome and survival. Following construction of a superior cavopulmonary connection and elimination of all other sources of pulmonary blood flow (the first stage), a gradual adaptive process characterized by normalization of the mass-to-volume relationship of the functionally single ventricle would make it possible to perform the completion Fontan procedure (the second stage) with the expectation of minimal change in ventricular geometry and favorable conditions with regard to the ventricle’s diastolic properties (compliance).

At the end of the decade of the 1980s, and in the early 1990s, several groups explored the potential benefits of a two-staged approach to Fontan operation. For some, the protocol of performance of an early bidirectional superior caval pulmonary Anastomosis followed later by a completion Fontan procedure was a pathway selected specifically for high-risk Fontan candidates. Others, notably Norwood and Jacobs in Philadelphia, pursued a two-staged approach to Fontan operation for virtually all patients. They postulated that some of the morbidity and mortality associated with Fontan operation would be eliminated by staging. Performance of a superior cavopulmonary connection in the first year of life achieved construction of part of the Fontan pathway. More importantly, the duration of the palliated state was minimized, and the volume load on the single ventricle was reduced as early in life as is practical. Thus in 1989, Norwood introduced the hemi-Fontan procedure, as the first step in a two-stage process of achieving total cavopulmonary connection. Obligating superior vena caval return to pass through the lungs before returning to the functional single ventricle, the hemi-Fontan operation is the physiologic equivalent of the bidirectional Glenn anastomosis. Because it is planned as an intermediate step before an anticipated completion Fontan procedure, it differs technically from a bidirectional Glenn anastomosis in ways that simplify the eventual completion Fontan.

**INDICATIONS AND PREOPERATIVE ASSESSMENT**

The most common indication for a cavopulmonary shunt is anatomy that is not amenable to eventual biventricular repair as a means of achieving systemic and pulmonary circulations in series. Superior cavopulmonary connections are generally considered as a preparatory stage for any unoperated or palliated patient older than about 3 months of age in which a univentricular repair is anticipated, particularly for those patients with risk factors for a Fontan-type procedure. In these situations, a cavopulmonary connection may be combined with a procedure to address factors that may increase the risk of Fontan operation, such as systemic ventricular outflow tract obstruction, atrioventricular valve (AV) insufficiency, excessive ventricular volume load associated with systemic-to-pulmonary artery shunts, impediments to pulmonary venous return, or pulmonary artery distortion. It may also be a rational
staging procedure for selected patients for whom the ultimate choice between univentricular and biventricular repair is not clear. Finally, some patients with functionally univentricular hearts may be destined for heart transplantation because of either poor myocardial function or severe organic systemic AV valve abnormalities. In these rare instances, reduction of the volume burden on the ventricle by means of superior cavopulmonary connection may stabilize the physiology while awaiting transplantation and may even result in improved ventricular function and/or lessened AV valve regurgitation.

The cavopulmonary connection has several advantages as an interim procedure in preparation for an eventual completion Fontan procedure. First, it can be performed with a lower mortality and morbidity than a Fontan procedure or a total cavopulmonary connection, particularly in infants from 3 to 12 months of age. Second, in contrast to a systemic-to-pulmonary artery shunt, a cavopulmonary shunt increases effective pulmonary blood flow by directing fully desaturated blood into the pulmonary circulation. Third, the risk of developing pulmonary vascular disease is reduced by lowering pulmonary arteriolar pressure. Fourth, the risk of pulmonary artery distortion is less than with a systemic-to-pulmonary artery shunt. Finally, and perhaps most important, the cavopulmonary shunt, when combined with removing systemic-to-pulmonary artery shunts or antegrade pulmonary blood flow, reduces ventricular work by reducing the volume load on the single ventricle. As noted above, this often improves ventricular function and reduces systemic AV valve regurgitation, which would compromise candidacy for a Fontan procedure.

Careful assessment by echocardiography is undertaken as part of the preoperative planning prior to surgery to create cavopulmonary connections. Comprehensive evaluation of the anatomy includes assessment of the segmental relations and connections, the morphology and function of the ventricle(s), presence and degree of AV regurgitation, presence and degree of systemic ventricular outflow tract obstruction (including aortic arch obstruction), and the nature of systemic and pulmonary venous connections. In particular, the existence of bilateral superior caval veins and/or the possibility of interrupted inferior vena cava with aygos continuation must be considered. All potential sources of pulmonary blood flow (antegrade from the heart, patent ductus, surgically created shunt(s), aortopulmonary collaterals) should be evaluated and the architecture of the intrapericardial pulmonary arteries must be assessed. Cardiac catheterization is indicated when these details cannot be reliably assessed by means of echocardiography or cardiac magnetic resonance imaging, or when a physiologic assessment is critical to surgical decision making or risk stratification. Determination of pulmonary vascular resistance may be important in the uncommon circumstance presented by an operated or palliated older patient. Measurement of pulmonary venous wedge pressure is generally informative if direct measurement of pulmonary artery pressure and pulmonary blood flow is not easily accomplished. Occasionally, imaging studies will suggest the presence of abnormalities of venous anatomy that may best be managed by catheter-directed intervention prior to surgery. An example would be venovenous collateral connections from systemic veins to pulmonary veins, or the presence of a small secondary (usually left-sided) superior vena cava or cardinal vein, which is considered too small to be effectively incorporated into bilateral superior cavopulmonary connections.

Significant pulmonary artery distortion or stenosis should be identified during preoperative evaluation so that it can be addressed as part of the cavopulmonary shunt operation. Some centers rely on determination of pulmonary artery size prior to performance of cavopulmonary connection. We do not generally exclude patients from superior cavopulmonary connection on the basis of hypoplasia of the intrapericardial pulmonary artery branches. Superior cavopulmonary anastomosis has been accomplished successfully in patients with Nakata indices as low as 70 mm²/m².

**OPERATIVE TECHNIQUE**

**The Unidirectional Superior Cavopulmonary Anastomosis (“Classic Glenn Shunt”)**

The “unidirectional” or “classic Glenn” cavopulmonary shunt is largely of historical interest and is rarely performed in the current era. Typically, the procedure was undertaken without cardiopulmonary bypass support. The surgical approach was most often a posterolateral thoracotomy incision through the fourth intercostal space. Once this exposure has been accomplished, the pleura and pericardium are incised posterior to the phrenic nerve, which is left attached to the widely mobilized anterior pleuroperticardium to avoid excessive traction directly on the nerve (Fig. 94.1). The superior vena cava is dissected free from the level of the

---

**Fig. 94.1.** Exposure for a unidirectional or “classic Glenn” cavopulmonary shunt. RA, right atrium; RPA, right pulmonary artery; SVC, superior vena cava.
innominate vein to the right atrium. The azygos vein is ligated and divided to provide better mobility of the superior vena cava and to prevent collateral venous connection with the inferior vena cava. The right pulmonary artery is dissected from its central origin to beyond the first hilar branches. After intravenous administration of heparin, the proximal right pulmonary artery is occluded with a vascular clamp. Oxygen saturation at this time is dependent entirely on flow to the contralateral lung. If oxygenation and hemodynamics are acceptable in the face of this test occlusion of the right pulmonary artery, the distal branches of the right pulmonary artery are occluded with silastic vessel loops or small atraumatic clamps. The right pulmonary artery is then divided at a point medial to the superior vena cava, the proximal end is oversewn, and the clamp is removed. The orifice of the right pulmonary artery may be enlarged slightly by extending the opening inferiorly. A partially occluding (side-biting) vascular clamp is placed on the superior vena cava from above the divided azygos vein to just above the right atrium, isolating a long segment of vena cava (Fig. 94.2). Careful placement of the clamp avoids complete obstruction of superior vena caval drainage to the right atrium. An incision is made in the lateral aspect of the superior vena cava, beginning where the inferior margin of the right pulmonary artery crosses the vena cava and extending superiorly through the orifice of the divided azygos vein. End-to-side anastomosis of the right pulmonary artery to the superior vena cava is then accomplished using fine monofilament suture. Care is taken to avoid “purse stringing,” including the placement of a few interrupted sutures. Distal vessel loops are released, followed by removal of the side-biting clamp from the superior vena cava (Fig. 94.3). Following a period of manual ventilation to fully inflate the right lung, the superior vena cava is temporarily occluded above its junction with the right atrium. It is customary to make a direct measurement of pressure in the superior vena cava at this point, before proceeding with definitive ligation of the superior vena cava above its junction with the right atrium. An alternative surgical method of creating a unidirectional superior cavopulmonary anastomosis involves transection of the superior vena cava above its junction with the right atrium and direct end-to-end anastomosis of the cava to the divided right pulmonary artery. This approach may be facilitated either by the use of a decompressing shunt from the innominate vein to the right atrium or by a brief period of cardiopulmonary bypass support.

The unidirectional Glenn anastomosis involves iatrogenic disruption of continuity between the right and left pulmonary arteries, which is viewed as disadvantageous in patients for whom eventual Fontan circulation is anticipated. A rare circumstance where the unidirectional cavopulmonary anastomosis might be performed today would be in a patient with an isolated or very hypoplastic left pulmonary artery that is being “resuscitated” with a systemic-to-pulmonary artery shunt. Superior vena caval flow may be entirely diverted to the right pulmonary artery in order to achieve reduction of the volume load on the functionally single ventricle. In general, awareness of technical issues related to the unidirectional Glenn shunt is primarily of importance today because of the likelihood of encountering older patients who underwent such palliative procedures in the past and the need to reestablish pulmonary artery continuity in the context of a Fontan procedure, a Fontan conversion, or even heart transplantation.
The Bidirectional Superior Cavopulmonary Anastomosis ("Bidirectional Glenn")

The bidirectional cavopulmonary anastomosis is most frequently constructed as part of the staged palliation of functionally univentricular heart disease in a patient for whom eventual completion of the Fontan circulation by means of an extracardiac conduit type of completion Fontan procedure is anticipated. Median sternotomy is by far the most common surgical approach. Cardiopulmonary bypass support is used in the majority of instances. Cardiopulmonary bypass can be avoided selectively, in cases where no intracardiac procedures are required, as long as blood flow to the contralateral lung is sufficient to maintain adequate systemic arterial saturation during clamping of the ipsilateral branch pulmonary artery, and adequate cerebral blood flow is maintained with the avoidance of severe cerebral venous hypertension. In general, this involves the use of a temporary shunt that diverts blood from the superior vena cava to the right atrium. This is accomplished under conditions of systemic heparinization, by the placement of a cannula in the innominate vein and another in the right atrium, and connecting them. The use of cardiopulmonary bypass support is required if total occlusion of the ipsilateral proximal pulmonary artery results in an unacceptable degree of systemic arterial desaturation, if an ipsilateral aortopulmonary shunt is present and is the principle source of pulmonary blood flow, if superior vena cava pressure is too high following caval occlusion despite the presence of the cava to right atrium shunt, or if cerebral oxygen saturation falls to an unsafe level. Cardiopulmonary bypass is required, of course, if concomitant intracardiac procedures are anticipated. Many, but not all surgeons, prefer to routinely use cardiopulmonary bypass support for cavopulmonary shunt operations.

Cardiopulmonary bypass support for the construction of a superior cavopulmonary anastomosis generally involves placement of one cannula in the superior vena cava near its junction with the innominate vein or in the innominate vein directly. A second drainage cannula is positioned in the right atrium, or in the inferior vena cava, if intracardiac procedures are anticipated (Fig. 94.4). Once satisfactory parameters are present with either a caval-to-right atrium shunt or a conventional cardiopulmonary bypass, it is customary to ligate and divide the azygos vein. If an ipsilateral aortopulmonary shunt is present, it is occluded and divided. The superior vena cava is occluded with a tourniquet or clamp at or just below the site of cannula placement. A vascular clamp is placed just above the junction of the superior vena cava with the right atrial junction, avoiding injury to the sinoatrial node and its blood supply. The superior vena cava is transected at the level of the inferior border of the right pulmonary artery and the cardiac end of the vena cava is oversewn. The upper end of the divided superior vena cava is prepared for anastomosis to the pulmonary artery. The orifice of the vena cava may be enlarged slightly by cutting back on either the lateral or the medial side. A vascular clamp is placed across the origin of the right pulmonary artery for proximal control. The distal branches may be controlled with silastic vessel loops oratraumatic vascular clamps. A longitudinal pulmonary arteriotomy is created along the superior aspect of the right pulmonary artery. If a previously placed systemic-to-pulmonary artery shunt has been occluded and divided, the location of the shunt determines whether it is preferable for the arteriotomy to extend through the shunt site or be separate from it. The placement of traction sutures in the pulmonary arteriotomy and in the divided superior vena cava may be helpful in orienting the anastomosis. Many surgeons use a combination of running and interrupted monofilament sutures to accomplish the cava to pulmonary artery anastomosis (Fig. 94.5). What is most important is avoidance of purse stringing and avoidance of torsion or twisting of the vessels. If for any reason it appears that the anastomosis may be narrowed, incorporation of a small patch of pericardium may be advisable. When performed under cardiopulmonary bypass, the bidirectional cavopulmonary anastomosis can generally be accomplished with a beating heart under conditions of normothermia or mild hypothermia. Moderate or greater degrees of hypothermia and cardioplegic arrest are generally utilized when concomitant intracardiac procedures are performed. The decision regarding elimination or maintenance of additional sources of pulmonary blood flow is a matter or surgeon’s preference and

---

**Fig. 94.4.** Exposure and cannulation for a bidirectional cavopulmonary anastomosis. In this instance, the orifice of the vena cava is enlarged slightly by cutting back on the lateral side (inset).
may be determined by specific patient-related issues. As a general policy, we eliminate all other sources of pulmonary blood flow when performing superior cavopulmonary anastomoses in patients who will eventually go on to completion of the Fontan circulation. Elimination of antegrade pulmonary blood flow from the heart via the pulmonary valve should be accomplished not by simple ligation but by means of division of the pulmonary trunk and oversewing the cardiac end at the level of the valve leaflets, in order to avoid leaving a blind-ending pouch of proximal pulmonary artery, which is known to be a risk factor for thrombus formation secondary to stasis. At the completion of any superior cavopulmonary anastomosis procedure, ventilation should be sufficient to eliminate atelectasis. Hyperventilation and hypocarbia should be avoided, however. Optimal systemic oxygenation is often accomplished with a mild degree of hypercarbia, as the slight elevation of PaCO₂ maximizes cerebral blood flow. Maximizing the fraction of total cardiac output that perfuses the upper body and returns via the superior vena cava (thus passing through the lungs before returning to the heart) seems, in most cases, to be of greater importance than the mild degree of pulmonary vasodilation that may be achieved as a result of hyperventilation.

The Hemi-Fontan Procedure

As previously noted, Norwood introduced the hemi-Fontan procedure in 1989 as the first step in a two-stage process of achieving total cavopulmonary connection. Though the hemi-Fontan operation is the physiologic equivalent of the bidirectional Glenn anastomosis, it differs technically from a bidirectional Glenn anastomosis in ways that simplify the eventual completion Fontan. While any type of completion Fontan procedure can be accomplished in a patient who has undergone a hemi-Fontan operation, it is optimal preparation for a Fontan connection of the lateral atrial tunnel type. In the hemi-Fontan operation, the natural connection of the right atrium with the superior vena cava is maintained, but the caval orifice is first enlarged (to be as large as the inferior vena caval right atrial connection), and then closed with a patch that is easily removed at the final stage. Other sources of pulmonary blood flow including systemic-to-pulmonary shunts and antegrade flow to the pulmonary arteries are eliminated. Architecture of the central pulmonary arteries is optimized by augmentation of the central confluence with homograft vascular patch material. Other potential hemodynamic burdens such as systemic ventricular outflow tract obstruction or AV valve regurgitation are addressed as part of the hemi-Fontan procedure. Proponents of the bidirectional Glenn anastomosis argue that the hemi-Fontan is a technically more complex procedure, which always requires cardiopulmonary bypass and is sometimes performed using hypothermic circulatory arrest. They also argue that the hemi-Fontan procedure involves potential injury to the sinus node or its blood supply, Bove and associates later modified Norwood's original operative technique, using an incision that does not cross the cavoatrial junction, with the theoretical goal of preserving the integrity of the sinoatrial node and its blood supply, with the hope that this would enhance the likelihood of preserving sinus rhythm.

The operative technique described here is essentially the methodology introduced by Norwood. After the placement of monitoring devices, the infant is positioned supine and prepped for median sternotomy. Surface cooling is begun, including the use of a cooling blanket beneath the patient, the application of ice bags to the head, and cooling of the operating room. After sternotomy, the surgical dissection prior to heparinization is limited to what is needed to achieve access to the aorta and the right atrium for cannula placement. After heparinization, bypass is established with ascending aortic perfusion and drainage via a single cannula in the systemic venous atrium. All systemic-to-pulmonary artery shunts are occluded upon initiation of bypass and flow is adjusted to 150 ml/kg/min. The perfusate is gradually cooled to approximately 16°C. During the cooling phase of cardiopulmonary bypass, the remainder of the dissection is accomplished, with particular attention to freeing the pulmonary artery confluence behind the ascending aorta. When cooling has been completed (generally to nasopharyngeal and esophageal temperatures below 20°C), the aortic cross-clamp is applied and circulation is temporarily discontinued. Blood is drained via the venous cannula into the cardiotomy reservoir, and the cannula is then removed. Cold crystalloid cardioplegic solution (30 ml/kg) is infused into the aortic root. An incision is made in the most superior portion of the right atrium and carried superiorly onto the medial aspect of the right superior vena cava (Fig. 94.6A). Through this incision, the atrial septal defect is inspected and is enlarged if necessary. The confluence of the right and left branch pulmonary arteries is opened anteriorly to a point just medial to the upper lobe branch on each side. If patent, the main pulmonary artery is transected and oversewn proximally at the level of the pulmonary valve. The posterior
Fig. 94.6. The hemi-Fontan procedure. (A) The systemic-to-pulmonary artery shunt is occluded and may be excised. The confluence of the pulmonary arteries is opened anteriorly. (B) The right superior vena cava and right pulmonary artery are anastomosed to one another in a side-to-side manner. (C, D, E, F, G) A gusset of cryopreserved pulmonary artery homograft tissue is used to augment the confluence of the pulmonary arteries, to create a roof over the large anastomosis of the superior vena cava to the pulmonary arteries, and as a dam to close the surgically enlarged junction of the right atrium with the right superior vena cava. Flow from the superior vena cava is into the right and left branch pulmonary arteries.
lip of the opened right superior vena cava is anastomosed in a side-to-side manner to the right pulmonary artery (Fig. 94.6B). If a left superior vena cava is present, it too is opened along its medial aspect, occluded at its cardiac end, and anastomosed in a side-to-side manner to the ipsilateral branch pulmonary artery. A single patch of cryopreserved pulmonary artery homograft tissue is used to augment the confluence of the pulmonary arteries, and to occlude the inflow of the right superior vena cava into the right atrium (Fig. 94.6C,D). The technique of enlarging and then patching the junction of the right superior vena cava with the right atrium effectively enlarges this connection to a caliber equivalent to that of the junction of the inferior vena cava with the right atrium, but temporarily occludes this connection that will eventually be reopened at the time of the completion Fontan procedure. While some surgeons have stressed the importance of ligation and division of the azygos vein (which may enhance mobilization of the superior vena cava for simple bidirectional Glenn anastomosis), we have not appreciated any important disadvantage in those instances where we have performed hemi-Fontan procedures and left the azygos vein intact. When the cavopulmonary amalgamation and any concomitant procedures have been completed, bypass is resumed and the cross-clamp is removed. In general, the hemi-Fontan procedure itself can be accomplished during a period of about 30 minutes, either
under conditions of hypothermic circu-
lar-ory arrest or on continuous cardiopulmo-
nary bypass support. During rewarming, the
lungs are ventilated to eliminate atelecasis
and to minimize impedance to transpulmo-
nary flow. Conventional ultrafiltration may
be accomplished while rewarming. After
rewarming, separation from bypass is gen-
erally accomplished with minimal inotropic
support. Modified ultrafiltration may then
be accomplished. Following decannulation,
catheters inserted through the cannulation
puncture string in the right atrium are used
for infusions and to monitor cardiac filling
pressure (percutaneous central venous lines
are not used). Sternal closure is accom-
plished routinely.

Postoperative management is the same
for the hemi-Fontan procedure as for the
bidirectional Glenn anastomosis. This
includes judicious administration of fluids
guided by cardiac filling pressures and early
extubation that can usually be accomplished
a few hours after completion of surgery.
Diuretics are generally administered begin-
ing on the first postoperative day. Hospi-
talization usually lasts a week or less. Facial
swelling and irritability (which we suspect is
attributable to "headache" from transiently
elevated venous pressure) often persist for a
days and are more common in younger
infants. Pleural effusion and chylothorax are
extremely rare. Oxygen saturation in room
air at discharge from the hospital is generally
in the range of 80% to 84%.

While the construction of a large side-
to-side amalgamation of the superior vena
cava and the confluence of the pulmonary
arteries are facilitated by the absence of a
drainage cannula from the superior vena cava,
the same surgical result can be achieved using continuous cardiopulmo-
nary bypass with venous drainage accom-
plished by placing one cannula in the
inferior vena cava and one cannula high
in the superior vena cava near its junction
with the innominate vein if the surgeon
wishes to use continuous bypass rather
than hypothermic circulatory arrest.

Technical modifications introduced by
Bove and others include the use of an
incision that does not cross the cavaoatrial
junction and the use of a separate pros-
thetic patch (rather than a portion of the
homograft as a dam) to occlude the junc-
tion of the superior vena cava with the
right atrium. It remains to be determined
whether these maneuvers actually result in
the intended consequence of lowering the
incidence of sinus node dysfunction and
subsequent arrhythmias.

Other surgeons prefer a modification of
the simple superior cavopulmonary anas-
tomosis in which both ends of the divided
superior vena cava are anastomosed to
the right pulmonary artery (superiorly
and inferiorly), and the cavoatrial junction
is occluded with a prosthetic patch. Such
modifications of the "bidirectional Glenn"
operation are often erroneously referred to
as hemi-Fontan procedures.

### SPECIAL SITUATIONS

#### Bilateral Superior Caval Veins

Bilateral superior caval veins are present
in many patients with functionally univen-
tricular hearts. In most instances of situs
solitus (normal arrangement of the atria),
the left-sided superior vena cava drains to
the coronary sinus. In cases of viscerocava-
heterotaxy with atrial isomerism, it is com-
mon for the left-sided superior caval vein
to drain directly to the left-sided atrium or
left side of the common atrium. In the
vast majority of cases with bilateral supe-
rior caval veins, it is advisable to include
both veins in the cavopulmonary amal-
gamation, either as described above for the
hemi-Fontan operation or as simple bilat-
eral end-to-side cavaoatrial anastomoses, if
the so-called "bidirectional Glenn proce-
dure is preferred. Alternatively, if the less
dominant of the two superior caval veins is
tiny, it may simply be ligated, particularly if
there is a crossing vein (innominate vein)
that allows it to drain into the dominant
caval vein. Some studies have suggested
that bilateral superior caval veins are a
risk factor for adverse outcomes following
superior cavopulmonary anastomosis, with
one report from Toronto suggesting that
bilateral superior vena cava-to-pulmonary
artery anastomosis is associated with an
increased risk of thrombus formation and
unfavorable growth in the central pulmo-
nary arteries. Van Arsdell and associates
suggested the construction of a centrally
located "V-shaped" amalgamation of the
right and left caval veins and the pulmo-
nary arteries. A recent risk factor analysis
of mortality and morbidity associated with
the bidirectional Glenn operation by Kogon
and associates in Atlanta did not reveal any
association between bilateral bidirectional
cavopulmonary anastomoses and adverse
outcomes.

### Interrupted Inferior Vena Cava
and Azygos Continuation

Approximately 80% of patients with het-
erotyax syndrome of the left isomerism
variety (polysplenia syndrome) have supra-
renal interruption of the inferior vena cava.
In most such cases, the infrarenal
vena cava drains via the azygos vein (or a
hemi-azygos vein) to a superior caval vein
(most often left-sided). The hepatic veins
enter the atria directly, either though a sin-
gle confluence or in two or more groups.
This systemic venous arrangement often
occurs in the setting of functionally univ-
entrical heart—frequently with com-
mon AV valve and with double-outlet right
ventricle (DORV). In 1984, Kawashima and
associates described a new type of total
cavopulmonary shunt operation, which
consisted of end-to-side anastomosis
between the superior vena cava with azy-
gos or hemiazygos continuation and the
confluence of the pulmonary arteries. The
operation was initially proposed as a defini-
tive form of palliation. Experience at sev-
eral centers, however, soon revealed that
these patients appeared to be at risk for
recurrent cyanosis due to the development
of significant and progressive right-to-left
shunting via pulmonary arteriovenous
malformations. In many cases, the prob-
lem was ameliorated by subsequent direc-
tion of the hepatic vein effluent to the
pulmonary circulation, with the observa-
tion of gradual improvement in arterio-
venous saturation and evidence of regression
of the pulmonary arteriovenous malforma-
tions. Consequently, patients who undergo
Kawashima’s total cavopulmonary shunt
operation should have planned comple-
tion of the Fontan circulation. This can be
accomplished by diverting the hepatic vein
flow to the pulmonary arteries using either
lateral atrial tunnel or extra-cardiac con-
duit technique, or by creating a connection
between the hepatic veins and the azygos
vein. In most instances, these procedures
should be completed not more than a
year after the Kawashima operation, and
sometimes within a few months.

### One and a Half Ventricle Repair

For patients with a marginal subpulmonary
ventricle, conventional therapeutic path-
ways include the establishment of function-
ally univentricular circulation or pursuit
of a high-risk biventricular repair. Another
alternative is the establishment of biven-
tricular physiology with partial bypass of
the subpulmonary ventricle by means of a
superior cavopulmonary connection. This
“one and a half ventricle repair” reduces
the volume work of the subpulmonary
ventricle, which then must handle only the
inferior caval return. Theoretical advantages
include avoidance of the degree of pressure
elevation in the sub-diaphragmatic venous
circulation that would accompany com-
plete Fontan circulation, together with the
preservation of pulsatile pulmonary blood
flow and some contribution to total cardiac
output by the marginal subpulmonary right ventricle. A theoretical disadvantage is the possibility of transmission of elevated pressure to the superior vena cava, sometimes with systolic flow reversal. That complication can sometimes be addressed by gentle banding of the proximal right pulmonary artery. The one and a half ventricle repair was originally proposed for cases of mild- to-moderate right ventricular hypoplasia in the setting of pulmonary atresia with intact ventricular septum. It has subsequently been extended to other anomalies including unbalanced atrioventricular canal defect, straddling AV valves, and as an adjunct to repair of Ebstein's anomaly. Another unique circumstance where concomitant superior cavopulmonary connection has proved useful in the setting of biventricular physiology is in association with the double switch operation for congenitally corrected transposition of the great arteries. The use of the cavopulmonary anastomosis allows for a simplified approach to the atrial baffle repair portion of the double switch operation. Hanley and associates refer to the modified atrial procedure that baffles inferior vena cava return to the tricuspid valve in conjunction with a bidirectional Glenn operation as "a hemi-Mustard procedure." Theoretical advantages include potential reduction of baffle- and sinus node-related complications. It also makes the atrial baffle repair much less challenging in cases with atrial situs solitus and dextrocardia.

RESULTS AND COMPLICATIONS

The physiology that results from superior cavopulmonary connection should be the same regardless of whether one chooses the technique of bidirectional Glenn anastomosis or hemi-Fontan operation, as long as the cavopulmonary connection is non-restrictive and all areas of pulmonary artery distortion or obstruction are addressed. Computational fluid dynamic studies have failed to show a significant or consistent advantage of one type of connection over the other, with respect to energy conservation and distribution of flow. The difference between the two procedures probably becomes most important once the Fontan circulation has been completed. In studies by Migliavacca and associates, the hemi-Fontan and bidirectional Glenn procedures performed equally well, but important differences in energy losses and flow distribution were found after the completion Fontan procedures. They observed superior hydraulic performance of the lateral tunnel Fontan operation after the hemi-Fontan procedure relative to any other type of Fontan connection, including all of those with simple bidirectional cavopulmonary anastomosis. They suggested that this observation may be explained by more optimal caval offset achieved in the surgical reconstruction that includes the hemi-Fontan connection. It is important to emphasize that these inferences are derived using three-dimensional models of typical hemi-Fontan and bidirectional Glenn operations based on anatomic data derived from magnetic resonance scans, angiograms, and echocardiograms. Other investigators have used a variety of other strategies to model the cavopulmonary shunt and Fontan circulation and have drawn different conclusions.

When originally proposed as a strategy for high-risk Fontan patients or as part of a plan to accomplish the Fontan circulation in two stages, the superior cavopulmonary connection was typically created in the second half of the first year of life. In 1996, Jacobs and Norwood reported on 400 hemi-Fontan procedures with mean age at operation of 8.5 months (range: 2 to 24 months). Operative mortality was 8% for the entire cohort. For the last 200 patients, operative mortality was 4.0%. Younger age at operation was not an independent risk factor for operative mortality. Urgent operation in the presence of a hemodynamic burden requiring concomitant procedures was associated with increased mortality. Numerous studies since that time have demonstrated the safety and efficacy of early superior cavopulmonary connection.

The age at which elective bidirectional Glenn shunt or hemi-Fontan procedures are undertaken has declined at many centers from 6 to 8 months down to 3 to 4 months, particularly for patients with hypoplastic left heart syndrome and related anomalies. For these patients, the period between initial palliation and second stage surgery is perceived as being a time of significant risk. At any rate, in patients with appropriately low pulmonary vascular resistance, it has been possible to accomplish superior cavopulmonary connections as early as 8 to 10 weeks. Recent series have reported operative mortality rates for hemi-Fontan and bidirectional Glenn operations in the range of 1% to 4%. While younger age has not generally been identified as a risk factor for mortality, younger patients do appear to be at greater risk for perioperative morbidity, including transient periods of lower systemic oxygen saturation.

Most patients undergoing superior cavopulmonary connections can be liberated from ventilatory support and have tracheal extubation within several hours after surgery. While it is not our specific goal, management at some centers includes extubation within the operating room. Arterial oxygen saturation may be as low as the 70% range early after surgery, but generally stabilizes in the low-to-mid 80% range within the first few days. This is consistent with the fact that superior cavopulmonary connection in infants generally results in a pulmonary-to-systemic blood flow ratio (Qp:Qs) of approximately 0.6:1. In older patients, a smaller fraction of total cardiac output goes to the upper body, and Qp:Qs after superior cavopulmonary connection is proportionately lower. Profound or persistent hypoxia following surgery should be investigated to rule out the presence of an undiagnosed left superior vena cava, other venous anomalies including connections resulting in diversion of superior vena cava blood away from the lungs, or a baffle leak between the superior vena cava and the right atrium following a hemi-Fontan procedure.

Early postoperative complications are rare. A mild-to-moderate degree of systemic hypertension is common early after surgery. While this may be treated pharmacologically, it is generally self-limited. Transient sinus node dysfunction is observed commonly following both the bidirectional Glenn anastomosis and the hemi-Fontan procedure. Nearly all patients recover sinus rhythm or a normally conducted atrial rhythm prior to hospital discharge. A mild degree of facial swelling and upper body plethora are not uncommon, and generally resolve spontaneously. Superior vena cava syndrome with significant upper body edema suggests the possibility of high superior vena cava pressure that may be the result of a restrictive anastomosis, high transpulmonary gradient, poor ventricular function, or AV valve regurgitation. Pleural effusions are uncommon after superior cavopulmonary anastomosis. Pleural fluid collections that cannot be accounted for by postoperative bleeding, that are large, and that persist in the face of diuretic administration should be aspirated to determine whether they are chylous in nature. The potential for phrenic nerve injury should always be kept in mind during the course of surgical dissection. While phrenic paresis is a rare complication of superior cavopulmonary connection operations, it can have a dramatic effect on overall physiology and contribute importantly to morbidity following the eventual completion Fontan procedure.
The time interval between superior cavopulmonary connection and completion of the Fontan circulation is important. While the degree of arterial desaturation associated with superior cavopulmonary connection is generally well tolerated, it appears that longer intervals between this procedure and the completion of the Fontan circulation are associated with the development of systemic-to-pulmonary arterial collaterals, in particular from vessels such as the internal thoracic arteries and other branches of the brachiocephalic vessels. In addition, the complete absence of hepatic vein effluent from the pulmonary circulation appears to be associated with time-related risk of development of pulmonary arteriovenous malformations, which eventually account for clinically important hypoxemia. While this process may be accelerated in the setting of heterotaxy, it nonetheless appears to be a general phenomenon and has been observed in patients with a variety of underlying cardiac diagnoses, including hypoplastic left heart syndrome and others where atriovisceral arrangements are entirely normal. The phenomenon is undoubtedly related at least in part to the role of an as-yet-identified hepatic factor but is likely to be multifactorial.

**ADDITIONAL SOURCES OF PULMONARY BLOOD FLOW**

The issue of whether or not all additional sources of pulmonary blood flow should be eliminated at the time of creation of superi­or cavopulmonary connection(s) remains unresolved. With respect to the strategy of creating the Fontan circulation in two stages, the idea of early reduction of the volume load of the functionally single ventricle, followed by a period of adaptation with normalization of mass-to-volume ratio and thus ventricular compliance, is consistent with a strategy of elimination of other sources of pulmonary blood flow when the superi­or cavopulmonary connection is created. The improved results of Fontan procedures achieved using a staged approach have been attributed, at least in part, to this concept. On the other hand, proponents of preserving additional sources of pulmonary blood flow (patent ductus, restrictive right ventricular outflow tract, or tight pulmonary artery band) argue that the additional flow can promote pulmonary artery growth and that comparisons of patients with and without additional sources of pulmonary blood flow after a bidirectional cavopulmonary anastomosis have shown no negative effect on the outcome of the eventual Fontan procedure. Importantly, these comparisons are based on populations of patients who have tolerated the additional pulmonary blood flow and been considered acceptable for completion of the Fontan connection. Some patients do not tolerate additional sources of pulmonary blood flow in the setting of superior cavopulmonary connection and show signs of superior vena cava syndrome (occasionally with chylothorax) or ventricular dysfunction. In such instances, the superi­or cavopulmonary connection must be investigated to rule out anatomic problems. Then, the additional source(s) of pulmonary blood flow should be eliminated by either catheter intervention or surgical means. Finally, some believe that superior cavopulmonary connection together with accessory source(s) of pulmonary blood flow should be considered definitive palliation and an alternative to completion of the Fontan circulation.

**SUGGESTED READINGS**

Macdver RH, Stewart RD, Backer CL, Mavroudis C. Results with continuous cardiopulmonary bypass for the bidirectional cavopulmonary anastomosis. Cardiol Young 2008;18(2):147-152.

The use of early cavopulmonary shunts and the hemi-Fontan operation in staged reconstruction for single-ventricle physiology has resulted in marked improvement in late outcomes after the Fontan procedure. The primary reason for this salient benefit is the ability to address pulmonary artery distortions and minimize excessive pulmonary blood flow early to prevent problems with pulmonary vascular resistance. Thus, in many cases, staged reconstruction with an initial cavopulmonary shunt is the preferable approach to a one-stage complete Fontan procedure. In very favorable patients with optimal ventricular anatomy and protected pulmonary vascular beds, a one-stage Fontan procedure can be contemplated; however, the staged reconstruction has particular benefit in patients with hypoplastic left heart syndrome in whom a high incidence of left pulmonary artery hypoplasia is noted. In addition, decreasing volume loading of the functional right single ventricle early may improve late ventricular function and minimize the significance of tricuspid valve regurgitation in these patients. While Dr. Jacobs has clearly described the use of the hemi-Fontan operation and interim cavopulmonary shunts as a way to decrease the late morbidity of the Fontan operation, the strategy he has described is based on the concept of the earliest completion of the Fontan circulation that is possible. The primary need to complete the Fontan operation is the consideration that creating a normal systemic oxygen saturation will decrease the development of aortopulmonary collateral arteries, which increase the volume load on the single ventricle. For many years, it was assumed that the creation of a cavopulmonary shunt early in life with elimination of systemic-to-pulmonary shunts would decrease the volume load on the single ventricle and improve ventricular performance at the Fontan operation. It is now known that most of these patients, even after creation of cavopulmonary connections, will develop significant aortopulmonary collateral flow due to continued cyanosis. Thus, it is not completely true that the volume load on the single ventricle is eliminated by the creation of cavopulmonary shunts. Early completion of the Fontan may mitigate the development of more aortopulmonary collateral flow; however, this has not been directly examined. It is now becoming common in our center for patients to undergo MRI calculation of aortopulmonary collateral flow with elimination of additional sources of pulmonary blood flow aggressively in the catheterization laboratory prior to the completion Fontan operation at 1/2 to 2 years of age. This approach seems to decrease the development of pleural effusions early postoperatively; however, the effect on long-term function of the Fontan circulation and the redevelopment of additional sources of pulmonary blood flow have not yet been completely determined.

Although the unilateral cavopulmonary anastomosis as advocated by Glenn can be accomplished technically without the use of cardiopulmonary bypass, there is little use for this technique at present. The bilateral cavopulmonary connection has supplanted the standard Glenn anastomosis in virtually all circumstances. The use of a unilateral cavopulmonary connection has been associated with significant development of late arteriovenous malformations of the lung. An additional disadvantage of unilateral cavopulmonary connections is the fact that the connection of the superior vena cava to the right pulmonary artery directly generally supplies the larger right pulmonary vascular bed with a smaller amount of blood flow from the upper body, leaving the smaller left pulmonary vascular bed supplied by the larger flow from the inferior vena cava or right ventricle. Thus, there is a relative flow distribution abnormality with the use of these unidirectional Glenn shunts. Even with bilateral cavopulmonary connections and certainly with the Kawashima operation (in which the majority of inferior vena caval flow is directed to the lungs without contributions from hepatic venous return), development of arteriovenous malformations of the lung is commonplace and results in progressive cyanosis. Early conversion of these patients to the completed Fontan procedure with fenestration is advocated to maintain some hepatic flow to the lung to diminish or resolve the development of arteriovenous malformations.

Although the bidirectional cavopulmonary anastomosis can be accomplished simply with the use of either decompressing shunts from the superior vena cava to the right atrium or with the use of cardiopulmonary bypass (as is preferred in our institution), we continue to use the hemi-Fontan procedure for some patients with single-ventricle physiology. This operation uses a homograft patch to widely enlarge the pulmonary bifurcation and create a dam between the superior vena cava and the right atrium without actual disconnection of the superior vena cava from the atrium at operation. Although this operation is extensive and is often done under a brief period of circulatory arrest, the reconstruction of the pulmonary bifurcation eliminates causes of maldistribution of pulmonary blood flow and permits a very simple completion Fontan procedure, which is generally done when the patient is 1/2 to 2 years of age. More complex types of hemi-Fontan reconstruction with a Gore-Tex dam in the superior vena caval orifice in the right atrium followed by division of the superior vena cava with anastomosis to the right pulmonary artery superiorly and inferiorly result in additional multiple suture lines and a longer operative procedure. In addition, the superior vena cava at the right atrial junction is often augmented with additional pericardium to create a larger opening into the pulmonary artery. It is unclear whether this technique offers any distinct advantage over the hemi-Fontan procedure. The only relative advantage is the lack of an incision crossing the superior vena cava-to-right atrial junction, which can interfere with the blood supply to the sinus node and potentially increase the risk of late development of atrial arrhythmias. While the hemi-Fontan operation often will divide the sinus node artery, it is not clear that the late incidence of atrial arrhythmias is higher with the use of this technique and, in fact, the bidirectional Glenn shunt has also been associated with junctional rhythm early postoperatively, possibly due to disruption of nerve pathways along the superior vena cava and right atrium. The contribution of sinus node injury to late development of atrial arrhythmias has not been clearly determined.

Whereas the azygos vein is usually ligated or divided with creation of bidirectional Glenn shunts or the hemi-Fontan operation, it has been left open in many patients in our center and has not resulted in significant decompression of the superior vena cava in most cases. It is not clear that decompression through the azygos vein will occur in the majority of cases after the cavopulmonary anastomosis if
left open. It appears that if the pulmonary vascular resistance remains low, leaving the azygous vein open is not a disadvantage and does not decompress the superior venous system. The azygous vein, however, can become an important steal of blood from the upper body and away from the pulmonary vascular bed if patients have elevated pulmonary vascular resistance or AV valve regurgitation and, therefore, in the majority of cases disruption of the azygous vein is performed at the time of cavopulmonary anastomosis to eliminate a potential source of decompression and potential desaturation. Most decompression of superior vena cava-to-pulmonary anastomoses occurs when there is a left-sided vein of Marshall, which can decompress to a low-pressure chamber such as the right atrium through the coronary sinus.

Although the Nakata index has been useful for defining the extent of the pulmonary vascular bed for completion Fontan operation, we have not used this index in our center. In most cases, patients with an adequate oxygen saturation with an aortopulmonary shunt and a pulmonary venous wedge pressure that is low can undergo a cavopulmonary anastomosis with satisfactory results, even with a low Nakata index number. It is not uncommon for patients with even a single pulmonary arterial supply to have satisfactory results with a cavopulmonary anastomosis in the presence of discontinuous pulmonary arteries if pulmonary vascular resistance is low in the remaining vascular bed.

In our operative techniques, no monitoring lines are placed in the superior vena cava or jugular veins. Such monitoring lines can result in thrombosis and have catastrophic consequences if pulmonary embolization occurs after a cavopulmonary anastomosis. We have used transthoracic lines positioned through the hemi-Fontan reconstruction into the pulmonary artery directly or into the pulmonary venous atrium by placing these catheters on either side of the homograft baffle at the superior vena cava-to-right atrium anastomosis. These lines are generally left in place for <24 hours. In all cases, operations are performed through a median sternotomy incision because there is little benefit to the thoracotomy incision for the construction of the cavopulmonary anastomosis. The majority of these patients require a later completion Fontan procedure and, therefore, the ease of creation of the anastomosis by sternotomy is not a disadvantage. In addition, we use right-sided systemic-to-pulmonary artery shunts at initial palliation and take down the shunt and place the cavopulmonary anastomosis at the shunt insertion site at reoperation through the same sternotomy incision. This eliminates the need for left-sided aortopulmonary shunts and the difficulty in takedown of these shunts with its potential risk to the left phrenic nerve.

A significant addition to the creation of cavopulmonary shunts or hemi-Fontan procedures is the use of modified ultrafiltration postoperatively. In our experience, the use of modified ultrafiltration markedly decreases the risk of pleural effusions after these operations and is associated with a mortality rate that approaches zero.

Currently, almost all patients undergoing the Fontan procedure have had intermediate staging with a cavopulmonary shunt. As the results with surgery for hypoplastic left heart syndrome have improved, the cavopulmonary shunts have been done at a younger age to decrease the risk of interstage mortality between the first-stage reconstruction and the second stage. It is unclear which age is the minimum at which one can complete a cavopulmonary shunt with low morbidity. Many centers routinely perform the cavopulmonary shunt at 3 to 4 months of age rather than 6 months of age, which was our practice in the past. In rare cases and with documented low pulmonary resistance, even earlier cavopulmonary shunt can be contemplated in some cases. Although the mortality does not appear to be higher with early cavopulmonary shunt, the morbidity does appear to be slightly greater, with a longer hospital stay and possibly more venous congestion early after the procedure. Nevertheless, early conversion to a cavopulmonary connection may decrease the morbidity of shunt thrombosis from aortopulmonary shunts and improve oxygen saturations in patients who have shunt stenosis and limited pulmonary blood flow.

At the Children's Hospital of Philadelphia, we continue to use the hemi-Fontan procedure in patients in which extensive pulmonary arterial reconstruction is necessary at the time of the second-stage reconstruction for hypoplastic left heart syndrome or other single ventricle abnormalities. With the increased use of the right ventricular to pulmonary artery shunt in the first-stage reconstruction for hypoplastic left heart syndrome, we have seen distortion at the pulmonary bifurcation to the left of the neoaorta in many patients. This can be very readily addressed with the hemi-Fontan operation where patch augmentation of the pulmonary bifurcation is a routine part of the operative procedure. The hemi-Fontan operation is designed to make the completion Fontan with a lateral tunnel procedure extremely straightforward. Thus, the use of a hemi-Fontan operation at second-stage reconstruction generally predisposes the patient to a lateral tunnel completion Fontan operation. If a bidirectional Glenn shunt is used as a second-stage reconstruction, then extra-cardiac Fontan completion operation is generally preferred. Some centers have divided the superior vena cava and anastomosed both ends to the right pulmonary artery with a dam in the atrial portion of the connection. This seems to be a suboptimal approach in our opinion since the superior vena cava orifice is not adequately sized to carry the entire vena caval flow with the use of a lateral tunnel connection. In some centers at the completion Fontan operation, the cavoatrial junction is enlarged. This seems to be an unnecessary step to us if the hemi-Fontan is used as a second-stage reconstruction. In addition, the enlargement of the cavoatrial junction has the same disadvantage of disruption of sinoatrial node blood supply, which can increase the risk of junctional rhythm early after the Fontan completion procedure.

An area of continued controversy regarding cavoatrial shunts is the potential decrease of right-sided AV valve regurgitation with the elimination of
volume load on the single ventricle. There are conflicting reports in the literature regarding the effect of a bidirectional Glenn shunt on tricuspid regurgitation in patients with single ventricle physiology. In most cases, it does not appear that volume unloading of the ventricle actually significantly changes the amount of AV valve regurgitation. In only a small percentage of patients can significant reduction of AV valve regurgitation be documented.

The increasing use of the extracardiac conduit Fontan procedure has limited the use of hemi-Fontan operations in most centers. The long-term comparison of lateral tunnel Fontan operations done with a previous hemi-Fontan operation and extracardiac Fontan operations has not been performed. It appears that in both cases, the incidence of arrhythmias is now relatively lower postoperatively at long-term follow-up than in previous reports, and the use of extra cardiac Fontan connections has not completely eliminated the incidence of late arrhythmias.
Tricuspid Atresia/Single Ventricle and the Fontan Operation

Stephanie Fuller and Pradeep Kaushik

INTRODUCTION

Atresia of any heart valve, atrioventricular (AV) or semilunar, results in single-ventricle physiology. A variety of anatomic defects should be considered as a single ventricle from the standpoint of surgical interventions (Table 95.1). Patients born with a single functional ventricle have a dismal long-term prognosis without eventual surgical intervention. But the results of staged surgical palliation, culminating in the Fontan procedure as the final palliative surgical procedure for these patients, are generally quite good.

CLASSIFICATION OF SINGLE-VENTRICLE ANATOMY

The classic defect for which the Fontan operation was first performed is tricuspid atresia. In this defect, there is no identifiable tricuspid valve tissue or valve remnant. Instead, the floor of the right atrium is completely muscular, and the floor is separated from the ventricular mass by the fibrofatty tissue of the AV sulcus. Generally, in association with the atretic right AV valve, there is a total absence of the inlet and varying portions of the trabecular portion of the right ventricle.

There is almost always an associated ventricular septal defect (VSD), which is frequently restrictive. The great vessels may be transposed with the aorta arising from the infundibular chamber or normally related with the aorta arising from left ventricle (LV). The VSD is frequently restrictive, which results in restriction of pulmonary blood flow when the great vessels are normally related but results in subaortic stenosis when there is transposition of the great arteries (TGA). When transposition is present, even if the bulboventricular foramen (BVF) is initially large and unrestricted, with time it can be expected to become smaller, resulting in subaortic stenosis later in life. If there is a coarctation present, then it is very likely that the BVF will be restrictive in the newborn period.

The natural history in tricuspid atresia is quite variable, but it is predicted by the underlying pathophysiology as in all single-ventricle hearts. Most patients with tricuspid atresia and normally related great arteries have some degree of obstruction to pulmonary blood flow. This generally progresses as the VSD becomes more obstructive or infundibular obstruction increases. As a result, there is increasing cyanosis. Without surgical intervention, over 90% of patients will die by 1 year of age from complications of hypoxia. Early palliation is, therefore, advocated for every neonate with tricuspid atresia. In the neonatal and early infantile period, when pulmonary vascular resistance (PVR) is high and pulmonary blood flow is inadequate, a systemic-to-pulmonary artery (PA, modified Blalock-Taussig) shunt is performed.

In contrast, those patients with tricuspid atresia and ventriculoarterial discordance (associated TGA) generally have a worse prognosis. Unobstructed pulmonary blood flow results in congestive heart failure and death within the first year of life. Subaortic obstruction complicates the scenario, further shortening the survival time. In the extreme case, there is ducal dependency of the systemic circulation in the newborn. In the case of exessive pulmonary blood flow, it is imperative to limit the pulmonary blood flow, usually with a PA, to protect the patient from developing pulmonary vascular disease and ventricular dysfunction caused by chronic volume overload.

Some children with single ventricles who present in infancy or later develop systemic ventricular outflow tract obstruction (subaortic stenosis). The resultant myocardial hypertrophy can adversely affect the suitability for a Fontan procedure. Patients at risk are those in whom the aorta arises above a small outlet chamber, such as in tricuspid atresia with double-inlet LV, rudimentary right ventricle, and TGA, particularly if the VSD is small or if there is coexisting aortic arch obstruction. A modified Damus-Stansel-Kaye procedure should be performed to establish unobstructed systemic arterial outflow.

PLANNING FOR SINGLE-VENTRICLE PALLIATION

Because the ultimate success of the Fontan operation depends on a suitably low PVR and adequate PA architecture, it is critical to commence the preparation for a Fontan procedure in the newborn period by appropriately regulating pulmonary blood flow and allowing for adequate growth of the PAs. The ultimate goal of palliative interventions leading up to Fontan operation are to improve clinical symptoms with simultaneously providing optimal PA architecture with low PVR, preserve systolic and diastolic ventricular function, avoid AV valvar regurgitation, and relieve systemic ventricular outflow obstruction. Thus, surgical management of patient with tricuspid atresia is based on the concept that systemic venous blood can be made to pass through healthy mature lungs without the assistance of a ventricular pump.

Physiologically, after the first few months of life, PVR generally falls, and then the goals of subsequent surgical interventions should be to reduce the volume load on the single ventricle. Once systemic arterial-to-PA shunts are eliminated, pulmonary blood flow reestablished by creating direct connections between the venous system and the PAs (by means of a bidirectional cavopulmonary artery shunt or hemi-Fontan). Any residual anatomic problems such as PA distortion, obstruction to systemic blood flow, AV valvar regurgitation, or a restrictive atrial septal defect should be dealt with at the same procedure to simplify the “definitive” management (Fontan operation). Staging of the Fontan procedure is performed because of the high incidence of pleural effusions and ventricular failure that occurred when patients were taken.

If the Glenn is performed on normothermic cardiopulmonary bypass, typically with a beating heart. Bicaval cannulation is performed and, once on cardiopulmonary bypass, the shunt is ligated. The aygos vein is ligated and divided. It is important to maintain proper orientation of the superior vena cava (SVC) to avoid twisting and obstruction of the vessel. The SVC is divided from the right atrium and the cardiac end is oversewn. The distal end of the SVC is anastomosed to the ipsilateral PA in an end-to-side manner (Fig. 95.1). Typically, no prosthetic material is used when performing a Glenn. In cases of pulmonary distortion or narrowing, however, a separate patch of homograft may be necessary to augment the PA. However, if augmentation is necessary, we typically prefer to perform a hemi-Fontan in the cases of PA narrowing.

STAGE II OPERATION

Indications for Stage II Palliation

Infants who have had neonatal palliation become candidates for a second-stage operation by 3 to 6 months of age. Younger age at the time of second-stage surgery is associated with better exercise performance than when surgery is delayed until a later age. Adequate ventricular function remains a prime determinant for a successful Fontan circulation. Indications for second stage include cyanosis secondary to inadequate pulmonary blood flow after initial palliation, congestive heart failure from ventricular volume overload caused by either severe AV valve regurgitation or an elevated Qp:Qs. Prior to cavopulmonary anastomosis, an echocardiogram should be performed. If there is concern regarding the anatomy, patency, or tortuosity of the PAs, then cardiac catheterization is an indication. Cardiac catheterization is also recommended if there is a clinical concern that can be treated interventionally after initial palliation such as aortic arch obstruction, or cyanosis resulting from either decompressing veins or stent stenosis.

The two options for a stage II palliation are the bidirectional Glenn (BDG) and the hemi-Fontan. While they are similar physiologically, each procedure has some unique advantages and different surgical techniques. Typically, our choice at Children’s Hospital of Philadelphia is to perform a BDG on most patients unless a pulmonary arterioplasty is required in which case a hemi-Fontan is the natural choice. Ultimately, the choice of stage II operation will dictate the type of Fontan performed. The BDG is converted to an extracardiac fenestrated Fontan, whereas the hemi-Fontan is easily converted to a lateral tunnel fenestrated Fontan.

Bidirectional Glenn

Glenn performed the first cavopulmonary connection. He used a unidirectional (classic) superior cavopulmonary anastomosis to the right PA. Eventually, this operation was modified to allow continuation of flow to both PAs. This has now become the standard of care for infants with single-ventricle physiology and route to end-stage completion.

The Glenn is performed on normothermic cardiopulmonary bypass, typically with a beating heart. Bicaval cannulation is performed and, once on cardiopulmonary bypass, the shunt is ligated. The aygos vein is ligated and divided. It is important to maintain proper orientation of the superior vena cava (SVC) to avoid twisting and obstruction of the vessel. The SVC is divided from the right atrium and the cardiac end is oversewn. The distal end of the SVC is anastomosed to the ipsilateral PA in an end-to-side manner (Fig. 95.1). Typically, no prosthetic material is used when performing a Glenn. In cases of pulmonary distortion or narrowing, however, a separate patch of homograft may be necessary to augment the PA. However, if augmentation is necessary, we typically prefer to perform a hemi-Fontan in the cases of PA narrowing.
between the hemi-Fontan and the Glenn are
(1) mandatory use of homograft material for
PA augmentation, (2) use of deep hypother­
ic circulatory arrest, and (3) no division
of the SVC to right atrial junction. Alterna­
tively, a “dam” is created using a homograft
patch in the orifice of the SVC to obstruct
draining directly into the atrium and force
blood into the PAs.

The hemi-Fontan procedure is accom­
plished using hypothermic cardiopulmo­
nary bypass combined with surface cooling
before use of deep hypothermic circulatory
arrest allowing for adequate visualization of
the complex baffle. The PAs are freed from
behind the aorta, and a longitudinal inci­
sion is made in the anterior aspect of the
PAs extending from the level of the origin
of the right upper lobe branch to the level
of the origin of the left upper-lobe branch
(Fig. 95.2A). An incision is made in the most
superior portion of the right atrium and is
extended onto the medial aspect of the SVC.

Fig. 95.2. Steps of hemi-Fontan procedure. (A) An incision is made in the pulmonary artery (a.) from hilum to hilum to allow the widest
possible opening of the pulmonary bifurcation. An incision is also made in the medial aspect of the superior vena cava (SVC) across the
cavoatrial junction onto the right atrial appendage, as delineated in this figure. The azygos vein (v.) is ligated and divided. (B) With the
pulmonary artery widely opened and the incision in the SVC—right atrial junction, suturing is initiated connecting the posterior aspect
of the SVC and right (R.) atrium to the right pulmonary artery by using a running 6-0 polypropylene suture. In this manner, a wide con­
nection between the SVC and pulmonary artery can be ensured. (C) After the posterior suture line is created, a large triangular patch of
pulmonary homograft is used to augment the pulmonary artery bifurcation. As the suture line along the inferior aspect of the pulmonary
bifurcation is created, the suture line is carried into the cavoatrial junction, using the pulmonary homograft to create a dam between the
SVC and right atrium. The suture line is brought completely across the cavoatrial junction to the anterior incision across the cavoatrial
junction. Next, the homograft is folded down to create the dam at the level of the atrium and secured with a 5-0 polypropylene suture.
Care must be taken with this suture line to incorporate the doubled flap of pulmonary homograft completely along the right lateral
aspect of the suture line to prevent any baffle leaks entering the right atrium after the repair.
At the most rightward extent of the pulmonary arteriotomy, the right PA is anastomosed to the posterior lip of the opened SVC (Fig. 95.2B). A gusset of cryopreserved PA homograft is used to augment the confluence of the PAs and to create a roof over the patulous anastomosis of the PAs to the SVC. A portion of the same homograft gusset is rotated posteriorly and used as a dam to close the junction of the right atrium with the SVC, obligating superior vena caval return to flow exclusively through the branch PAs (Fig. 95.2C). When bilateral superior vena cavae are present, each is anastomosed to the ipsilateral branch PA using cryopreserved homograft to augment the anastomosis in a manner similar to that described above.

**Concurrent Procedures**

In some cases, additional surgical revision is required at the time of the second-stage operation. One of the most common lesions requiring revision is recoarctation of the aorta. In many centers, this is diagnosed by echocardiography and the diagnosis is confirmed by cardiac catheterization. We favor balloon dilation of the coarctation once detected as long as the patient is approximately 8 weeks from surgical reconstruction. If distal aortic arch recoarctation is neither suitable nor responsive to balloon dilation, patch augmentation at the time of the cavopulmonary anastomosis may be required.

Another indication for more extensive operation at the second stage is AV regurgitation. Often, unloading the volume stressed ventricle and performing the cavopulmonary anastomosis ameliorates the severity of regurgitation. However, in cases of severe regurgitation, inspection and possible intervention upon the AV valve is recommended. Commissuroplasty, annuloplasty, choral shortening, and leaflet extension are common valvuloplasty techniques to minimize regurgitation.

**Postoperative Management**

Conversion from an aortopulmonary shunt to a stage II operation decreases the work of the single ventricle by decreasing the volume load on the ventricle. Postoperative management includes judicious administration of fluids guided by cardiac filling pressures and early extubation, which usually can be accomplished in the operating room or within 3 to 5 hours after completion of surgery. Positive pressure ventilations can cause increased airway pressures and adversely affect both PVR and ventricular filling. Spontaneous breathing likely leads to an increase in PCO₂ that promotes cerebral blood flow therefore increasing SVC return to the lungs or pulmonary blood flow.

Typically, hemodynamics are robust. In fact, transient hypertension has been observed after the cavopulmonary shunt. One of the goals of postoperative management is to minimize the transpulmonary gradient to allow passive blood flow through the lungs guaranteeing return of oxygenated blood to the common atrium. An elevated transpulmonary gradient may cause cyanosis and could result from elevated PVR, downstream pulmonary venous obstruction, or from impaired lung expansion due to hemo- or pneumothorax. Elevation of PVR due to cardiopulmonary bypass may be decreased by the administration of nitric oxide as a pulmonary vasodilator.

Facial swelling and irritability (which is attributable to “headache” or “hangover” from transiently elevated venous pressure) often persist for a few days and are more common in younger infants. Also common, patients may develop dermarchation of the upper body secondary to venous congestion in the upper chest, bilateral arms, and head. Persistent facial swelling, particularly of the fontanelle and eyelids, or the development of a chylothorax should prompt investigation for SVC narrowing. The gradient can usually be estimated by echo and cardiac catheterization pursued if necessary.

Diuretics are generally administered beginning on the first postoperative day. Hospitalization usually lasts a week or less. The late development of cyanosis can be the result of the development of atriovenous malformations or collateral venous drainage. Both may be treated by transcatheter coil embolization. Although it is a more extensive operation, the hemi-Fontan allows for the technically simpler lateral tunnel Fontan procedure. It also has the potential advantage of allowing nonsurgical completion of the Fontan circulation in the cardiac catheterization laboratory.

**FONTAN OPERATION**

The last stage of reconstructive surgery for children with single-ventricle physiology is the Fontan completion. The modified Fontan circuit allows systemic return from both the upper and lower extremities to return to the PAs passively and directly by bypassing the heart. Therefore, there is complete separation of the systemic and pulmonary circulations. Improved patient selection, multiple technical modifications, and better postoperative management have reduced the mortality of the operation to <2% in many centers with acceptable postoperative morbidity and decreased length of stay.

**History of the Fontan**

Fontan and Baudet reported the first “physiologic” correction of tricuspid atresia in 1971. Shortly thereafter, in 1973, Kreutzer and colleagues reported the first Fontan procedure with a direct connection of the right atrium to the PA. In 1983, Norwood and colleagues reported the first successful Fontan in an HLHS patient.

The early Fontan operation, a direct atrio-pulmonary anastomosis was modified to an intra-atrial lateral tunnel because of the high incidence of tachyarrhythmia in the atrio-pulmonary circuits. The most recent modification is the addition of an extracardiac conduit from the IVC to the PA. This technique eliminated the need for suture lines in the right atrium, thereby minimizing the incidence of sinus node dysfunction and both atrial flutter and fibrillation after the Fontan.

In those patients who went directly to a Fontan without the intermediate superior cavopulmonary anastomosis, outcomes were not as good. The acute decrease in single-ventricle end-systolic and end-diastolic volume without a change in ventricular mass or wall thickness results in impaired diastolic function and low cardiac output. Many of these patients suffered from prolonged pleural effusions ultimately resulting in hypoalbuminemia, volume overload due to replacement, and Fontan failure. Over the last two decades, the most significant modification was the formation of a fenestration in either pathway. The fenestration allows for a communication between the systemic venous and pulmonary venous pathways, creating a right-to-left shunt. At the cost of desaturation, approximately the same as that with a cavopulmonary anastomosis pre-Fontan, the fenestration reduces mortality and morbidity by decreasing the incidence of pleural effusion and increasing the ventricular preload by shunting.

**Indications for Surgery**

Traditionally, candidates for the Fontan completion include those with normal ventricular function, minimal AV valve...
regurgitation, normal PAs, and low PVR. Yet many less than “ideal” candidates are rendered suitable for the Fontan operation given proper perioperative management. Risk factors for poor outcome after the modified Fontan operation include ventricular hypertrophy, elevated PVR or PA pressure, PA distortion, AV valve regurgitation, and ventricular dysfunction. Severe ventricular dysfunction and fixed elevated PVR (>4 Wood Units) remain the most significant contraindications to surgery. Historically, patients underwent preoperative echocardiogram and cardiac catheterization to assess anatomic and hemodynamic suitability. Any lesions that can be intervened upon by catheterization such as recoarctation of the aorta, PA coarctation opposite the Fontan site or cavopulmonary narrowing is addressed at the time of catheterization.

**Lateral Tunnel Fontan**

For the lateral tunnel Fontan completion, which patients undergo approximately 18 to 24 months after the hemi-Fontan, minimal dissection is needed because of the preparative nature of the hemi-Fontan stage (Fig. 95.3A). We choose to perform this operation under a brief period of deep hypothermic circulatory arrest with cannulation of the aorta and the common atrium. An incision is made in the lateral wall of the right atrium, anterior and parallel to the sulcus terminalis, extending inferiorly to the level of the Eustachian valve of the IVC and superiorly to within a few millimeters of the junction of the right atrium and the SVC, thus exposing the homograft dam that divides the right atrium and SVC. The portion of the PA homograft that was used as a dam is excised to expose internally the SVC and the branch PAs (Fig. 95.3B). An appropriate length segment is then cut from a portion of a 10-mm polytetrafluoroethylene (PTFE) tube graft that has been opened longitudinally (Fig. 95.4). This is used to create a lateral atrial tunnel or intra-atrial baffle by which inferior caval flow is directed to the reopened atrial inlet of the SVC and thus to the PAs (Fig. 95.5). This suture line is then completed by incorporating the walls of the right atrium into the superior edge of the lateral tunnel to close the atriotomy (Fig. 95.6).

Two important features of this type of lateral atrial tunnel Fontan are (1) ensuring that the opening of the right atrium into the SVC and PAs is as large as the inferior vena caval opening and (2) avoiding direct suturing to the sulcus terminalis, which has been implicated in the development of postoperative tachyarrhythmia’s. In most

---

**Fig. 95.3.** Lateral tunnel completion Fontan. (A) Working through the right atrial incision, the homograft dam between the superior vena cava and right atrium is readily identified. (B) This dam of tissue is excised under direct vision, creating an opening that is adequate in size for baffling of the inferior vena cava flow into the pulmonary arteries. This opening is created in such a way that a rim of tissue can be used for the suture line of the intracardiac lateral tunnel (inset).
instances, we choose to fenestrate the lateral tunnel prior to insertion and usually accomplish this by creating one hole in the gusset using a 4-mm punch device (Fig. 95.4). Fenestrations of this size promote decompression of the venous pathway and enhance ventricular filling postoperatively. They usually close spontaneously, avoiding the need for device placement in the venous pathway. As previously mentioned, several studies have shown a significant decrease in pleural effusions and hospital stay compared with nonfenestrated patients.

The completion of Fontan procedure as described here can generally be done with a period of hypothermic circulatory arrest of about 20 minutes duration. Total cavopulmonary connection had mainly laminar flow patterns. In this design, the superior vena caval blood drains directly into the PA, and inferior vena caval blood is baffled through a straight intra-atrial conduit into the PA. Additional theoretical advantages are a reduced risk of thrombosis because of less blood stasis, and exposure of only a limited portion of the right atrium to high
Section III: Congenital Cardiac Surgery

the last centimeter of atrium. An end-to-end anastomosis is completed between the transected IVC and the distal conduit (Fig. 95.7). A side-to-side anastomosis is performed between the fenestration in the conduit and the atrium. The underside of the right PA directly across from the Glenn anastomosis is incised and the proximal graft sutured to the inferior aspect of the PA. Typically, the graft is beveled toward the main PA segment. In addition, the underside of the graft is cut with a concave curvature to allow more natural filling of the PAs and slight elevation of the graft over the right pulmonary veins. The completed extracardiac Fontan is shown in Figure 95.8.

Associated Lesions

Patients undergoing a third stage are at risk of the same associated lesions as at the time of the second stage. With an older and larger patient, however, many of these can be managed interventionally during cardiac catheterization. The most common associated lesions are left PA stenosis either from compression by the neo aorta or constriction of the ductus arteriosus, AV valve regurgitation, and neoaortic arch obstruction. Therefore, if necessary, patients should undergo left pulmonary venous pressures, thus reducing the risk of arrhythmias. Also, because the coronary sinus remains in the lower pressure pulmonary venous atrium, there is unobstructed myocardial venous drainage.

Extracardiac Fontan

For those children who have undergone a BDG as their second-stage operation, we favor an extracardiac Fontan completion. Similar to the lateral tunnel Fontan completion, this is performed at approximately 2 years of age. Although performed using bicaval cannulation at some institutions, we prefer to perform the extracardiac Fontan under deep hypothermic circulatory arrest as well. An 18- or 20-mm PTFE conduit is used and a 4-mm punch for fenestration on the medial aspect of the conduit at approximately the lower half of the conduit. In preparing the conduit, the outer layer of PTFE is stripped from around the hole to avoid thrombogenicity at the anastomosis of the fenestration. The IVC must be extensively mobilized at the level of the hepatic veins and divided at its entrance into the right atrium. The atrium is closed using a running suture to approximately

\[
\text{rvc}
\]

the last centimeter of atrium. And end-to-end anastomosis is completed between the transected IVC and the distal conduit (Fig. 95.7). A side-to-side anastomosis is performed between the fenestration in the conduit and the atrium. The underside of the right PA directly across from the Glenn anastomosis is incised and the proximal graft sutured to the inferior aspect of the PA. Typically, the graft is beveled toward the main PA segment. In addition, the underside of the graft is cut with a concave curvature to allow more natural filling of the PAs and slight elevation of the graft over the right pulmonary veins. The completed extracardiac Fontan is shown in Figure 95.8.

Associated Lesions

Patients undergoing a third stage are at risk of the same associated lesions as at the time of the second stage. With an older and larger patient, however, many of these can be managed interventionally during cardiac catheterization. The most common associated lesions are left PA stenosis either from compression by the neo aorta or constriction of the ductus arteriosus, AV valve regurgitation, and neoaortic arch obstruction. Therefore, if necessary, patients should undergo left pulmonary venous pressures, thus reducing the risk of arrhythmias. Also, because the coronary sinus remains in the lower pressure pulmonary venous atrium, there is unobstructed myocardial venous drainage.

Extracardiac Fontan

For those children who have undergone a BDG as their second-stage operation, we favor an extracardiac Fontan completion. Similar to the lateral tunnel Fontan completion, this is performed at approximately 2 years of age. Although performed using bicaval cannulation at some institutions, we prefer to perform the extracardiac Fontan under deep hypothermic circulatory arrest as well. An 18- or 20-mm PTFE conduit is used and a 4-mm punch for fenestration on the medial aspect of the conduit at approximately the lower half of the conduit. In preparing the conduit, the outer layer of PTFE is stripped from around the hole to avoid thrombogenicity at the anastomosis of the fenestration. The IVC must be extensively mobilized at the level of the hepatic veins and divided at its entrance into the right atrium. The atrium is closed using a running suture to approximately

\[
\text{rvc}
\]
arterioplasty, valve repair, or arch augmentation at the time of the Fontan.

**Postoperative Management**

Postoperative care for the Fontan is not so different from that for a stage II operation. Ideally, patients should maintain high cardiac output with low atrial filling pressures. However, the same ventricular changes occur when offloading the ventricle at the Fontan as do at the BDG or hemi-Fontan. Immediate issues are maintaining hemodynamic stability with minimal inotropic support, hemostasis, and early extubation. Low cardiac output may be attributable to hypovolemia or inadequate preload, elevated PVR, anatomic obstruction of the systemic venous pathway, or ventricular failure. Atrial catheters in the systemic atrium and the Fontan pathway help to delineate the etiology.

**RESULTS**

Early mortality after the Fontan procedure has steadily come down to 0% to 5.5%. This is in spite of liberalizing patient selection criteria and extending the procedure to many forms of complex single ventricle. Multiple factors contributed to this improved early outcome. Certainly, volume unloading of the single ventricle by an early BDG or hemi-Fontan procedure has markedly improved the suitability for a subsequent Fontan operation. The introduction of total cavopulmonary connection with its energy efficient circulation, with the use of lateral tunnel or extracardiac conduit, has clearly been a huge advance in the improved outcome of the Fontan operation.

Plural effusions constitute the most common early morbidity after the Fontan operation and often dictate the length of stay. The use of a baffle fenestration has been reported to reduce the duration of postoperative chest tube drainage. Replacement of the fluid with intravascular saline, albumin, clotting factors, and immunoglobulins may all be necessary in cases of prolonged drainage. Correctable causes such as baffle obstruction, innominate or SVC vein thrombosis, fenestration occlusion, and PA distortion should all be ruled out. Thoracic duct ligation or coil embolization with lymphangiogram is rarely needed.

After the Fontan operation, patients are at risk for venous thrombosis secondary to transient liver dysfunction and coagulation abnormalities due to the low flow state through the cavopulmonary circulation, presence of atrial arrhythmias and fresh suture lines. This can lead to increased incidence of perioperative stroke. It is important to avoid dehydration and maintain adequate preload. Anticoagulation is, therefore, usually advocated after the immediate postoperative period with aspirin and in some cases warfarin.

Sinus node dysfunction and atrial arrhythmias occur frequently after the Fontan procedure, particularly in patients with heterotaxy syndrome. Atrial pacing may be required in the perioperative period. Many studies support, based upon both univariate and multivariate analysis, that patients undergoing extracardiac Fontan are more likely to maintain sinus rhythm compared with those undergoing lateral tunnel Fontan.

Rogers et al. looked at our single institution experience with the Fontan in 771 consecutive patients. Despite increasing patient complexity, mortality was low at 3.5% throughout the series but only 1% since 1996, the current era. The likelihood of morbidity, mainly persistently draining plural effusions, was similar to that experienced in other contemporary series. Many other institutions have published their contemporary results, as depicted in Table 95.2, and there clearly appears to be an era effect.

The incidence of late sequelae and complications related to the Fontan procedure and single-ventricle physiology are not yet completely known nor the mechanisms thereof understood. Patients are at risk for the development of protein-losing enteropathy and plastic bronchitis. Despite normal systolic function and even in cases of preserved cardiac output, Fontan patients will have failing physiology as a result of diastolic dysfunction and noncompliance of the single ventricle.

**CONCLUSION**

The mortality rate of the Fontan operation for tricuspid atresia and other complex forms of single-ventricle physiology has been drastically reduced by advances both technical and perioperative. The second-stage procedure allows early reduction of the volume work of the single ventricle and remodeling of ventricular geometry before completion of Fontan operation. The introduction of the fenestration to maintain ventricular preload has led to a marked decline in postoperative complications, namely, the development and duration of prolonged plural effusions.
The long-term results of the Fontan procedure are not yet known. While early failure of the Fontan requiring takedown is now rare, late morbidities are pervasive. Additional palliative strategies have been developed. For example, the development of late arrhythmias in lateral tunnel patients can be treated by Fontan conversion to an extracardiac tunnel. And late development of either semilunar or AV valve regurgitation may be treated with replacement. However, for those patients who have no further palliative options, cardiac transplant is recommended. It is important to note that all those patients must undergo thorough evaluation of hepatic function and fibrosis to rule out the need for dual organ transplant secondary to chronic hepatic changes as a result of the Fontan circulation.

**EDITOR’S COMMENTS**

The Fontan operation has been a major advance in the treatment of complex congenital heart disease. It is applicable to multiple forms of complex defects, including all forms of single ventricle and situations in which biventricular repair is either not feasible or is associated with long-term complications and late reoperation. Multiple modifications of the Fontan procedure have permitted a marked improvement in late morbidity and mortality, such that the Fontan operation is associated with a mortality of <5% in most centers and long-term results remain quite good despite the lack of a ventricle pumping blood through the pulmonary circulation.

In spite of these very salient features of the Fontan operation, multiple modifications have been recommended to decrease late morbidity. Perhaps, the most significant advance in the Fontan operation has been the advent of a fenestration in the intra-atrial baffle, which has been shown to maintain ventricular preload in situations of elevated pulmonary vascular resistance and improve cardiac output. Initial use of the fenestration in high-risk Fontan procedures at Children’s Hospital Boston was associated with a marked improvement in the incidence of pleural effusions and a decreased incidence of takedown of the Fontan operation even in “high-risk” Fontan candidates. Although initial approaches were directed at closure of the fenestration at a later catheterization procedure, it is interesting that in all patients with temporary occlusion of the fenestration, cardiac output dropped, suggesting that there is a potential benefit of maintaining ventricular preload with a fenestration. For these reasons, we use fenestrations in all Fontan operations, and although spontaneous closure occurs in at least 60% of patients with a 4.0-mm fenestration of an intra-atrial baffle, it is unclear whether closure of the fenestration is necessarily beneficial in all patients. This controversy is heightened by the fact that patients who have developed protein-losing enteropathy after the Fontan operation or who have persistent effusions that are not resolving with medical management may have complete resolution of the problems by creation of a fenestration in a previously nonfenestrated atripulmonary connection. This fact would suggest that the optimal hemodynamics with fenestration of the atrial baffle may be very beneficial in the long term for Fontan patients. Arterial desaturation may be an acceptable price to pay for adequate oxygen delivery with improvement in cardiac output in these patients if late morbidity is in fact improved.

A major issue for long-term function after the Fontan operation is the incidence of atrial flutter and fibrillation, which can compromise ventricular function and cardiac output. Much attention has been directed to the contribution of atrial
suture lines to the development of atrial arrhythmias. The creation of extensive atrial suture lines has resulted in areas of conduction block that may contribute to atrial flutter. For this reason, some centers have advocated the use of extracardiac connections from the IVC to the pulmonary artery to completely eliminate pressure loading of the right atrium and to eliminate suture lines in the right atrium. Long-term follow-up of these extracardiac connections is not available, however, and longitudinal growth may result in constriction of the conduits and require late conduit replacement in some cases. In addition, it is difficult to fenestrate extracardiac Fontan connections with a satisfactory degree of long-term patency. Direct anastomosis to the right atrial wall results in rapid spontaneous closure, and a graft from the extracardiac conduit to the right atrium may also thrombose rapidly. We have modified our technique for creation of a fenestration with an extracardiac conduit by creating a medial fenestration in the extracardiac graft and then suturing the residual opening from the IVC entrance into the right atrium around the graft, approximately 4 to 5 mm from the edges of the fenestration. In this manner, the fenestration is exposed directly to the interior of the right atrium with a small rim of graft material separating it from the suture line. This appears to decrease the risk of stenosis and thrombosis of the fenestration. Nevertheless, in our own experience of over 770 Fontan operations, the use of an extracardiac conduit with fenestration results in a less consistent fenestration and a slight increase in the duration of postoperative pleural effusions. The use of a lateral tunnel with a fixed fenestration of 4 mm has been associated with the lowest incidence of prolonged pleural effusions and the shortest hospital stay in our experience. If a hemifontan procedure done with a homograft baffle from the SVC to the right atrium is used as an initial-stage procedure, extracardiac Fontan connection can be performed with the creation of a fenestration through the “dam” between the SVC and right atrium at the hemi-Fontan connection and results in adequate fenestration patency over the intermediate term in most cases, although a lateral tunnel Fontan approach is certainly preferable.

The long-term benefits from Fontan reconstruction remain to be determined; however, it is apparent that the late results with single-ventricle repairs have been markedly better than most surgeons would have anticipated. Although a certain population of patients will develop protein-losing enteropathy late after the operative procedure, the incidence of this condition at intermediate follow-up is relatively low. Thus, the Fontan operation has become a mainstay of repair for complex congenital heart disease, and continued refinement is being undertaken to optimize late hemodynamic results. Modification of atrial suture lines and division of potential conduction zones for atrial flutter may be added to the Fontan operation in the future to prevent late arrhythmias. In addition, diversion of inferior vena caval flow preferentially to the right lung with superior vena caval flow directed to the left lung may optimize flow distribution in the pulmonary arteries after the operation. The use of lateral tunnel techniques has decreased the incidence of significant stasis in the right atrium, and giant right atrium after the operation, although rare, must be taken down to create the lateral baffle superior to the right pulmonary vein entrances to prevent compression of the pulmonary veins and late stenosis. Failure of Fontan operations requiring takedown is now extremely unusual with attention to staging of the operations and addressing of significant sources of pulmonary artery distortion before a complete Fontan procedure.

There has been great interest in modifying the Fontan operation to provide the most optimal hemodynamic efficiency of flow into the pulmonary vascular bed. Many studies using MRI flow calculations and distributions have suggested that various Fontan modifications can be adapted to individual patients to improve postoperative hemodynamics. In some cases, the use of the Y-shaped graft can optimize flow into each pulmonary artery from the inferior vena cava and in situations of heterotaxy syndrome with interrupted inferior vena cava and azygous continuation, direct connection of the hepatic veins to the azygos vein to ensure distribution of hepatic flow to both lungs has been suggested. It is now possible to model the cardiac anatomy in patients prior to the completion Fontan operation in order to define the best individual anatomy for the patient. In most cases, an extracardiac conduit is the simplest way of reconstructing the Fontan circulation since it allows for any pulmonary venous anatomy and can be directed to either pulmonary artery if necessary. While there has been a great deal of interest in the extracardiac conduit as an improvement over lateral tunnel operations in terms of late development of atrial arrhythmias, long-term follow-up studies with contemporary patients using both surgical techniques have not been reported. Most series that have compared the lateral tunnel with the extracardiac conduit Fontans have a significantly longer follow-up in the lateral tunnel group. It is known that atrial arrhythmias are more frequently followed by the longer patients after the Fontan operation and therefore this may be a confounding factor. Nevertheless, fewer atrial suture lines and the lack of exposure of the atrium to high pressure are likely to improve the incidence of late arrhythmias. It should, however, be noted that even in the extra cardiac Fontan patients, previous atriotomy and atrial septal resections have been performed in most cases and these are highly arrhythmogenic incisions. The late follow-up of the extra cardiac Fontan has continued to show arrhythmias in a significant proportion of patients.

The late complications of the Fontan operation including protein-losing enteropathy and AV valve regurgitation are concerning. Patients who develop protein-losing enteropathy may often have a progressive course to die within 3 to 5 years of diagnosis. Many attempts have been made to improve the hemodynamics in these patients including creation of a fenestration (which is poorly tolerated in a patient who has not been previously cyanotic), infusions of anticoagulants, pacing to improve cardiac output, and recently the use of enteric steroid therapy, which may improve the enteral protein loss. Most of these therapies have been largely palliative but can in some cases significantly improve the patient’s quality of life.

TLS
Hypoplastic Left Heart Syndrome
Peter J. Gruber and Thomas L. Spray

INTRODUCTION

Hypoplastic left heart syndrome (HLHS) comprises a wide spectrum of anatomic abnormalities with the common features of left ventricular hypoplasia and hypoplasia of the ascending aorta. At one end of the spectrum, there may be some mild left ventricle hypoplasia, mild aortic stenosis, and aortic coarctation. At the other end of the spectrum, however, there is complete absence of the left ventricle, aortic atresia, and aortic arch hypoplasia or even interrupted aortic arch.

HLHS is a uniformly fatal disease if untreated. It represents 5% of all congenital heart disease and is responsible for nearly 25% of cardiac deaths in the first week of life. Of 10,000 live births, approximately 1.8 will be born with HLHS, with a slight male predominance. Of these, 25% will also have a noncardiac anomaly and 5% a chromosomal abnormality (trisomies 13, 18, and 21). Syndromic lesions are rare, with Turner syndrome (monosomy X) the most common. The recurrence risk is 2.2% for one affected sibling and 6% for two affected siblings, suggesting some genetic predisposition but arguing against a simple effect.

Surgery for HLHS is one of the great successes in the management of congenital heart disease. Before the 1980s, HLHS was a uniformly lethal condition. However, over the last 25 years the repair of HLHS has become a standard operation in nearly all institutions. In 1952, Lev first described maldevelopment of the left-sided cardiac structures in combination with a small ascending aorta and transverse arch. By 1958, Noonan and Nadas had further defined the syndrome to describe a variety of cardiac malformations of left heart structures. The first report of any attempt to palliate a patient with mitral atresia was by Redo in 1961, who performed an atrial septectomy using inflow occlusion through a right thoracotomy; the patient died soon after the operation. In 1968, Sinha outlined the management principles still in use today that include creation of an unobstructed atrial communication, unrestricted ductal flow, and control of pulmonary blood flow. Cayler described an anastomosis between the right pulmonary artery (RPA) and ascending aorta with banding of both right and left pulmonary arteries (LPAs).

It is of interest that 35 years later, pulmonary artery (PA) banding is being used in certain centers for selected children who present with a medical or anatomic situation unsuitable for stage 1 Norwood reconstruction; this first-stage hybrid procedure involves stenting the ductus arteriosus and atrial septal defect and using bilateral PA bands. Litwin, Mohri, and others performed operations that were variations of the principles of palliation that were unsuccessful but contributed to the development of the knowledge of the disease and its repair. In 1977, Doty described primary reconstruction that included atrial septation and a right atrium (RA)-to-PA Fontan circuit. Again, although no patients survived, this experience established the principle that one-stage reconstruction with a Fontan repair would not be successful due to high neonatal pulmonary vascular resistance. Levitsky, Behrendt, and others described multiple variations of surgical procedures that, although they demonstrated no long-term success, established the principle of staged reconstruction with initial palliation followed by later separation of the systemic and pulmonary circulations. However, it was Norwood who in 1980 first achieved successful palliation in infants. In 1983, he described the first successful staged approach culminating in a Fontan repair. Today, the Norwood procedure remains the primary reconstructive approach.

ANATOMY

Patients with HLHS are currently categorized on the basis of atrioventricular (AV) and semilunar valvular morphology into three primary subsets: (1) aortic atresia with mitral atresia (40%), (2) aortic stenosis with mitral stenosis (30%), and (3) aortic atresia with mitral stenosis (30%) (Fig. 96.1). Aortic stenosis with mitral atresia is rare. HLHS variants include malaligned AV canal, double-outlet right ventricle with mitral atresia, tricuspid atresia with transposed great arteries, and univentricular heart with aortic stenosis. There is frequent leftward and posterior deviation of the septal attachment of the septum primum, but this feature is unlikely to be a causal developmental mechanism because it is commonly seen in other congenital heart disease phenotypes. Usually, the superior vena cava (SVC) and inferior vena cava (IVC) are normally connected to the RA, although in about 15% of patients a left SVC-to-coronary sinus is present. Other structural abnormalities of the heart are rare, with <5% of patients demonstrating AV valvaral dysplasia. Also, rare in nonsyndromic forms (<5%) are abnormalities of pulmonary venous return or an interrupted aortic arch. Abnormalities in brain development are increasingly associated with children with severe congenital heart disease, and these may be a high-risk group for operative repair. The pulmonary vascular tree is also abnormal, with an increase in number of vessels as well as muscularity.

The developmental mechanisms that underlie HLHS are obscure from a molecular standpoint because there are no mutations that have been robustly associated with this condition. Despite the existence of rare family clustering of HLHS, linkage analysis has been largely unproductive. Indeed, it is likely that there exists considerable genetic heterogeneity in this as well as other CHD phenotypes. However, embryologically, there are clues. The severe hypoplasia of left heart structures may be a consequence of limited flow during development secondary to a primary abnormality of either left ventricular inflow or left ventricular outflow. Primary defects of myocardial growth are unlikely to be a mechanism for this disease because the myocardium appears normal. In addition, approximately 5% of patients with aortic atresia demonstrate an unrestrictive ventricular...
ventricular hypoplasia. However, the primary cause of the obstructive flow lesion leading secondarily to HLHS is unknown. There are no known genetic animal models that fully recapitulate HLHS despite the existence of a large number of mutations that affect valvular development. This argues either for a complex early event that is the result of multiple factors or an early insult influence by subsequent modifiers.

The presentation of infants with congenital heart disease has changed dramatically over the last 15 years. In most large centers, the majority of patients are identified through prenatal echocardiography, although this early identification has not consistently correlated with better outcome. Although some tachypnea and mild cyanosis may be present, it is not until the ductus arteriosus begins to close that the children exhibit impaired systemic perfusion with pallor, lethargy, and diminished femoral pulses. Cardiac examination reveals a dominant right ventricular impulse, a single-second heart sound, and often a nonspecific soft systolic murmur. Electrocardiogram examination reveals right atrial enlargement and right ventricular hypertrophy. Chest X-ray occasionally shows mild cardiomegaly and increased pulmonary vascular markings.

Physical examination of children with HLHS usually appears normal. The examination is determined by the underlying anatomy as well as the duration of the disease. Poor perfusion, weak distal pulses (that may or may not be present, depending on the size of the ductus), acidosis, and a sepsis-like picture may all confound the diagnosis. In the absence of risk factors or laboratory findings consistent with sepsis, one should search for left-sided obstructive lesions. There are no specific laboratory indicators of HLHS, and most patients usually exhibit normal values. With ductal closure and malperfusion, end-organ compromise may be reflected by altered hepatic and renal function tests.

Many mothers of fetuses with HLHS will have had a fetal echocardiogram at 20 weeks with reasonable visualization of cardiac structures. It is neither feasible nor cost effective to screen all pregnancies; therefore a selective approach is taken in which only those mothers at high risk are screened. Frequently, a ventricular size discrepancy is the first hint of impending problems. Certainly, the presence of an intact or restrictive atrial septum with HLHS should prompt term high-risk delivery in an institution in which an urgent postdelivery palliation can be performed safely and rapidly. Emergent operative atrial septicotomy is poorly tolerated. The use of prenatal screening improves the prenatal condition of the child but may not improve outcome (at least in cases of transposition of the great arteries or HLHS). After delivery, the infant should undergo two-dimensional and Doppler echocardiography, which defines the anatomy sufficiently for medical and surgical decision-making. It is important to distinguish HLHS from other diseases that may mimic certain features. Chest radiography often demonstrates mild cardiomegaly and excessive pulmonary blood flow. Head ultrasound should be obtained in all patients to rule out intracranial hemorrhage and minimize the risks of hepaterization and potential circulatory arrest. Patients with medical necrotizing enterocolitis should ideally have a 7-day course of intravenous antibiotics before repair if they are hemodynamically stable. Preoperative stabilization is critical to the ultimate outcome of patients with HLHS regardless of anatomic subtype, though operation should not be substantially delayed. Nearly all patients with suspected HLHS are transported on prostaglandin E1, at a dose of 0.01 to 0.025 μg/kg/minute. Two clinically important dose-dependent side effects of prostaglandin E1 infusion are hypotension and apnea, although these are infrequent. Umbilical arterial and umbilical venous lines are used for central access in most patients. Most patients can ventilate with a natural airway and demonstrate more favorable hemodynamics while extubated. Supplemental oxygen should generally be avoided as it acts as a pulmonary vasodilator, decreasing pulmonary vascular...
resistance, increasing the ratio of pulmonary-to-systemic blood flow, and thus decreasing systemic perfusion. Inotropic support is rarely necessary, although it may be required for support in patients who have suffered a perinatal insult. The goal of these maneuvers is to get the patient to the operating room in as stable condition as is possible.

**SURGICAL THERAPY**

The primary therapy for HLHS is staged reconstructive surgery leading to a modified Fontan–Kreutzer procedure. Over the last 25 years, the Norwood procedure has evolved and is now a standard operation in nearly all institutions for HLHS. There are three primary goals of stage I palliation: (1) establishment of unrestricted interatrial communication to provide complete mixing and avoid pulmonary venous hypertension, (2) establishment of a reliable source of pulmonary blood flow, allowing pulmonary vasculature development and minimizing the volume load on the single ventricle, and (3) providing unobstructed outflow from the ventricle to the systemic circulation.

We offer surgical palliation to nearly all patients with HLHS, including very low birth weight infants and those with nonlethal genetic syndromes. In certain complicating situations, primary transplantation (or other forms of palliation described below) may be considered, such as in severe aortic or AV regurgitation, or dilated cardiomyopathy.

**Stage I Reconstructive Surgery**

The child is brought to the operating room and ventilated on room air, with care taken to avoid hyperventilation. A full midline sternotomy is performed and a sternal retractor placed. The thymus is removed in its entirety, with care being taken to avoid the phrenic nerves. The pericardium is opened, and an obligatory mediastinal inspection is performed to confirm the echocardiography, especially to identify the abnormalities of the aortic arch and coronary arteries as coronary orientation may alter the surgical approach. The ascending and descending aorta, brachiocephalic vessels, ductus arteriosus, and PAs are extensively mobilized, with care taken to avoid damage to the recurrent laryngeal nerve. No attempt is made to dissect the systemic veins. Purse-string sutures are placed in the proximal main pulmonary artery (MPA) and generously around the right atrial appendage, through which heparin is administered. A previously thawed homograft pulmonary hemipatch is then trimmed in an extended arrowhead shape and set aside (Fig. 96.2A). Two perfusion techniques are commonly used for operative repair: deep hypothermic circulatory arrest (DHCA) and selective antegrade continuous cerebral perfusion. Despite intensive investigation, there is no consensus regarding the superior approach. After the activated clotting time reaches 300 seconds, the patient is cannulated with the arterial cannula at the base of the MPA and a single venous cannula in the RA. Cardiopulmonary bypass is initiated and tapes brought down around the branch PAs. The patient is cooled to 18°C over 15 minutes, during which time any remaining dissection is performed. During this period of cooling, a side-biting clamp is placed on the innominate artery, and a polytetrafluoroethylene (PTFE) graft (usually 4.0 mm for patients > 3.2 kg and 3.5 mm in smaller infants) is anastomosed in an end-to-side manner. The clamp is removed and flow assessed. If blood does not briskly flow from the open shunt, the anastomosis should be revised. A large hemoclamp is placed to temporarily occlude the shunt. On initiation of circulatory arrest, tapes are brought down around the brachiocephalic vessels and a vascular clamp is placed on the descending aorta distal to the ducal insertion site. Cardioplegia is administered antegrade through a side port on the arterial cannula. After draining the patient of blood, all cannulas and PA tapes are removed. The ductus arteriosus is ligated on the PA side and divided on the aortic side. The atrial septum is completely excised working through the atrial purse string (Fig. 96.2B). Visualization can be improved through a right atriotomy, although this is seldom necessary. Next, the MPA is divided close to the branch PAs, and the defect in the distal MPA segment is closed either with an oval homograft patch or primarily in a vertical manner.

At a point beginning immediately adjacent to the divided MPA, the diminutive aorta is incised medially and the incision carried superiorly along the underside of the transverse arch through the ducal insertion site to a point approximately 1-cm distant. It is important that all redundant ducal tissues be excised from the previous insertion site and the coarctation shelf be debrided (or the segment excised and the remaining vessel reanastomosed). The proximal aortic-to-proximal PA connection is now performed using interrupted, fine polypropylene sutures (Fig. 96.2C). Next, the arch is reconstructed using the homograft patch, carrying this suture line down to complete the Damus–Kaye–Stansel proximally (Fig. 96.2D). The distal Blalock–Taussig shunt–PA anastomosis is now performed to the origin of the RPA, although some surgeons prefer to do this with the cross-clamp off during warming (Fig. 96.2E). The arch is infused with cold saline to assess the geometry or residual obstruction, the atrium is infused with cold saline to deair, and the cannulas are replaced. Cardiopulmonary bypass is begun and the patient warmed to 37°C over 22 minutes. It is important at this point to assess prompt and equivalent filling of coronary distributions. Any perfusion defect should be addressed immediately with revision of the aortic-to-PA anastomosis. During warming, obvious bleeding should be controlled. After the patient has been warmed to 37°C, the clip is removed from the shunt and atrial lines are brought through the chest wall and positioned in the RA. The patient is begun on low-dose dopamine and milrinone support and weaned off cardiopulmonary bypass-modified ultrafiltration is routinely performed. Oxygen saturations should be in the mid-80% range, indicative of adequate pulmonary blood flow. Any base deficit is corrected completely with sodium bicarbonate, and continued persistent acidosis is a relative indication of poor cardiac function requiring examination of the repair. After protamine is administered to reverse the heparin, hemostasis is meticulously obtained. If there are no issues with bleeding, the chest is routinely closed. In approximately 20% of cases, either hemodynamic or respiratory instability or continued potential bleeding results in the potential for cardiac compromise with chest closure. In these cases, a PTFE patch is cut to an appropriate size and approximated to the skin edges, leaving the sternum open for 12 to 24 hours. Postoperative management of these patients includes low-dose dopamine and milrinone, although some centers use phenylephrine as an afterload-reducing agent. The use of afterload reduction results in vasodilation with right ventricular support and generally removes the need for any greater inotropic therapy. In some cases, low-dose epinephrine is used if there is significant hypotension. Patients are lightly sedated and administered either low-dose fentanyl as a continuous drip or intermittent morphine. Patients are not routinely paralyzed with pancuronium unless the sternum is left open. An attempt is made to allow the patient to awaken and to wean the ventilator support such that extubation can be performed on the first or second postoperative day. If the chest is
left open, the chest is generally closed the day after surgery and the patient allowed to waken, weaning from the ventilator over the next 24 to 48 hours. Rapid deintensification with the removal of nasogastric feedings and removal central lines is preferred. Aspirin is usually administered after the first night when heparin is used at a low dose to decrease the risk of shunt thrombosis. When oral intake is established, low-dose aspirin is administered entirely. Patients are usually extubated between postoperative days 1 and 3. Average duration of hospitalization is between 7 and 21 days, the limiting factor often being establishment of adequate oral caloric intake. In all cases, the principle is continued clinical progress, and any migration from that pathway should prompt investigation into the cause of deviation.

A number of reports including a multi-institutional collaborative effort organized

---

**Fig. 96.2**. Standard repair of hypoplastic left heart syndrome by the Norwood procedure. (A) Incision sites are shown for the main pulmonary artery, which is transected just proximal to the origins of the branch pulmonary arteries, and the diminutive aorta, which is incised along the inferior aspect past the insertion of the ductus arteriosus. (B) The proximal portion of the right modified Blalock-Taussig shunt (RMBTS), usually 3.5 to 4.0 mm, is completed during cooling. After deep hypothermic circulatory arrest is initiated, the main pulmonary artery segment is closed, and the atrial septum is excised through the atrial purse string. (C) The posterior aspect of the Damus-Kaye-Stansel (DKS) anastomosis is completed with interrupted sutures, and the aortic arch is augmented with a homograft patch. (D) The remainder of the DKS is completed with the homograft patch. (E) The distal end of the RMBTS is completed to the right pulmonary artery.
through the Pediatric Heart Network suggest that a right ventricular-to-PA (RV-PA) shunt as popularized by Sano may improve outcome after stage I reconstruction (Fig. 96.3). However, a number of contradictory studies further comment that before broad adaptation of the RV-PA conduit, other considerations apply. For example, there may be anatomic substrates better suited to one shunt type compared with another. With respect to the RV-PA conduit, there is an increased incidence of shunt reintervention, an earlier return for stage II reconstruction, and no difference in overall mortality. Certainly, consensus exists that staged palliation consists of multiple surgeries that result in the Fontan circulation. Increasingly, an understanding that uniform adaptation of any approach prior to stage III data may be premature.

For high-risk infants, some have advocated a catheter-based hybrid approach: stage I: palliation includes ductal stenting and PA banding; stage II: septectomy, arch augmentation, and cavopulmonary anastomosis; and stage III: catheter-based Fontan completion. Although there have been promising results, these techniques may be limited in certain anatomic subsets such as aortic atresia in which preductal, retrograde coarctation is a significant problem (Fig. 96.4). Palliative catheter-based hybrid approaches may be the most useful in identifiable subsets of patients with HLHS who have very low birth weight or associated cardiac anomalies. These patients are still a high-risk group for stage I reconstruction in most series. Otherwise, catheter-based approaches have no demonstrable advantage over surgical staged palliation.

### Stage II Reconstructive Surgery

Two important observations by Norwood and colleagues early in the reconstructive experience prompted the institution of an intermediate stage. The first was that there

![Fig. 96.3](image1.png)

**Fig. 96.3.** Alternative approach to stage I palliation using the Sano modification. Instead of a right modified Blalock-Taussig shunt, pulmonary blood flow is supplied by a 5.0-mm polytetrafluoroethylene (Gore-Tex) shunt from a right ventriculotomy to the main pulmonary artery.

![Fig. 96.4](image2.png)

**Fig. 96.4.** Alternative approach to stage I palliation using ductal stenting and pulmonary artery bands. (A) Unrestricted, stable systemic and pulmonary blood flow is created by insertion of an expandable stent in the ductus arteriosus. (B) Next, pulmonary blood flow is restricted by placement of bilateral pulmonary artery 3.0-mm bands.
was a time-related interstage mortality. The second was that the chronic volume load of a systemic-to-pulmonary shunt could create diastolic ventricular dysfunction. Thus, an intermediate stage was initiated as either a bidirectional cavopulmonary (Glenn) shunt or a hemi-Fontan procedure. A bidirectional cavopulmonary anastomosis sets the stage for an extracardiac conduit, whereas a hemi-Fontan sets the stage for a lateral tunnel completion Fontan. There is no long-term data that prove the efficacy of one approach over another. In general, at approximately 4 to 6 months of age, stage 1 survivors are catheterized to evaluate both pressures throughout the heart and the anatomy of PAs. The use of a cavopulmonary anastomosis before approximately 3 months of age is sometimes associated with increased hypoxia and upper-body venous congestion, although bidirectional Glenn shunts have been done in children at even 6 weeks to 2 months of age with good results when there is clearly demonstrable low pulmonary vascular resistance. The technique for a bidirectional cavopulmonary anastomosis is standard (Fig. 96.5).

An alternative operative approach is the hemi-Fontan procedure, which we perform under DHCA. The approach is through a reoperative median sternotomy, during which time care is taken around the dissection of the neoaorta. The patient is cannulated in a standard manner with an arterial cannula in the neoaorta and a single straight venous cannula in the body of the RA. Cardiopulmonary bypass is begun, and the patient is cooled to 18°C. The previous shunt is divided and ligated and the azygos vein ligated. After cardioplegic arrest, the PAs are opened on the anterior aspect and the pulmonary insertion of the shunt excised. If preoperative catheterization revealed PA stenosis, the incisions are carried beyond this point well onto the left PA and onto the right lower lobar branch. Next, the RA is incised superiorly and medially from 12 to 6 o’clock beginning just superior to the cannulation site and ending at the level of the right upper PA (Fig. 96.6). The SVC and the right aspect of the pulmonary arteriotomy are anastomosed with fine monofilament suture. Next, an extended triangular pulmonary homograft patch is used to augment the PAs and create a roof over the anastomosis of the SVC to the RPA, as well as simultaneously create a dam to prevent blood flow between the SVC and RA. The patch-augmented PAs are infused with saline to examine anatomy and deair. The venous cannula is replaced, cardiopulmonary bypass is reinitiated, aortic cross-clamp removed, and warming to 37°C is completed over 22 minutes. Occasionally, additional procedures such as atrial septectomy or arch augmentation may need to be completed in the same setting. One or two right atrial lines are inserted into the body of the RA or into the PA through the suture line. The patient is weaned from cardiopulmonary bypass, and modified ultrafiltration is performed, during which time all suture lines are checked for hemostasis. All cannulas are removed, and protamine is administered. The chest is then closed in a standard manner and the patient returned to the intensive care unit (ICU). In general, these patients can be extubated either in the operating room or soon after returning to the ICU. With reduction in the volume load provided by this procedure, inotropic support is usually brief. Blood–oxygen saturations are generally 80% to 90%, and patients are generally discharged within 5 to 7 days after surgery.

Stage III Reconstructive Surgery

Between ages 1.5 and 5 years (usually determined by a combination of the patient’s weight, growth characteristics, and arterial saturations) the patient is reimaged by either echocardiography or magnetic resonance imaging and, if necessary catheterization. If there are no anatomic issues to be addressed via catheterization (e.g., distal arch coarctation), the patient is referred for Fontan reconstruction via either an extracardiac conduit or lateral tunnel completion Fontan. For the extracardiac conduit, DHCA or continuous bypass with or without aortic cross-clamp is employed, while we use DHCA for the lateral tunnel. The approach is again through a reoperative median sternotomy.

For the extracardiac Fontan procedure, the patient is bicavally cannulated in a standard manner and an arterial cannula placed high in the aortic reconstruction. Cardiopulmonary bypass is begun and tourniquets are applied around the caval cannulas. A vascular clamp is placed at the IVC–RA junction and the IVC divided (Fig. 96.7). The atrial portion is partially closed in two layers with fine monofilament suture. The conduit (18 to 22-mm PTFE) is trimmed to the appropriate length to avoid compression of the right pulmonary vein (shorter than one might expect), and a 4-mm fenestration is punched in the medial aspect near the IVC portion. The IVC-conduit anastomosis is completed with monofilament suture followed by a side-to-side anastomosis of the remaining cardiac portion of the IVC opening with the exterior conduit, leaving a rim of conduit around the fenestration.
Fig. 96.6. The hemi-Fontan procedure. (A) The pulmonary artery is incised widely from the left lower pulmonary artery to the left pulmonary artery. The right atrium is incised vertically in a spinal clockwise manner from the superior portion of the right atrial (RA) appendage into the superior vena cava (SVC) to the superior aspect of the right pulmonary artery. The azygos vein is ligated. (B) The posterior aspect of the incision in the SVC is anastomosed to the rightward aspect of the pulmonary arteriotomy. (C) An extended triangular homograft patch is trimmed and sewn to augment the pulmonary arteries. (D) The homograft patch suture line continues along the SVC-RA junction to create the bottom of the dam. (E) The patch is folded on itself to create a triangular-shaped dam. (F) The suture line is continued to complete the dam. (G) The same homograft patch is used to simultaneously complete the pulmonary artery augmentation and SVC-PA anastomosis.
Next, the PAs are opened along the inferior margin and inspected directly. If preoperative studies revealed any PA stenosis, and the beveled end of the PTFE conduit will not span the area of stenosis, this is addressed with pulmonary homograft patch augmentation. The conduit is then anastomosed to the inferior aspect of the PAs angled slightly medial to the SVC. Practically, the angled nature of the superior portion of the conduit augments the PAs from LPA to the RPA. The conduit is infused with saline to deair, and the patient is weaned from cardiopulmonary bypass. The SVC cannula is removed, and a period of modified ultrafiltration is begun. All suture lines are checked for hemostasis. At the completion of modified ultrafiltration, the SVC pressure is measured directly with a transthoracic line and subsequently removed. An additional monitoring line is placed in the RA. All cannulas are removed, and protamine is administered. The chest is then closed in a standard fashion and the patient returned to the ICU. In general, these patients are extubated soon after return to the ICU.

An alternative operative approach is the lateral-tunnel Fontan procedure, which we perform under DHCA using a piece of fenestrated PTFE patch to baffle blood from the IVC to the PAs (Fig. 96.8). The patient is cannulated in a standard manner with an arterial cannula in the neoaorta and a single straight cannula in the body of the RA. Cardiopulmonary bypass is begun, and the patient is cooled to 18°C. An aortic cross-clamp is applied and cardioplegic arrest achieved. The patient is drained of blood and the venous cannula removed. A vertically based incision is made in the body of the RA parallel to Waterson groove. The previously constructed PA-RA homograft dam is excised and the Eustachian valve is removed. A 10-mm PTFE tube graft is split longitudinally and trimmed to length, and a 4-mm fenestration is created. Inferiorly, the graft is sewn around the IVC orifice.
and the suture line carried superiorly along the line of the interatrial communication. Superiorly, the baffle is sewn around the edge of the newly created opening between the atrium and PAs. Care must be exercised here to assure that the trabecular portion of the atrium contains no leaks. The free, superior edge of the PTFE baffle is then closed in a single sandwich between the two free edges of the RA. Thus, the medial aspect of the lateral tunnel is PTFE, whereas the lateral aspect is native right atrial tissue. The heart is infused with saline to deair and the venous cannula replaced. Cardiopulmonary bypass is reinitiated, and the patient is warmed to 37°C over 22 minutes. Atrial lines are brought into the atrium on either side of the baffle through the suture line. The patient is weaned from bypass and undergoes modified ultrafiltration. Inotropic support is rarely necessary.

RESULTS

Despite continued developments, patients with HLHS continue to present formidable challenges. Since its institution in 1984, results from staged reconstruction have improved significantly. This has been the case across multiple institutions, and many centers report excellent outcomes, often exceeding 90% hospital survival. There is conflicting opinion that variability in outcome may be influenced by anatomy. However, it appears that the HLHS is not a predictor of mortality compared with stage I palliation for other HLHS variants. It is clear that risk factors such as low birth weight, associated cardiac anomalies, longer total support time, and extracorporeal membrane oxygenation (ECMO) or ventricular assist device (VAD) support are predictors of operative mortality. Additional perioperative or operative treatment strategies may improve morbidity and mortality based upon either anatomic or genetic stratification. Home surveillance programs for interstage infants are now common practice in multiple institutions and suggest significant benefits toward the reduction of interstage mortality.

Our group compared the outcomes of all neonates who underwent a stage I reconstruction between 2002 and 2004 with use of the RV-PA conduit and modified Blalock-Taussig shunt. In all, 149 infants underwent a stage I reconstruction for HLHS or variants. There was no difference in surgical mortality, time to extubation, or length of hospital stay. However, there was an increased incidence of shunt reinterventions in the patients with the RV-PA conduit. Patients with RV-PA conduit returned earlier for stage II reconstruction but there was no difference in overall mortality. These data have been confirmed in some centers and refuted in others. However, the PHN-based multi-institutional study of single-ventricle reconstruction support the notion that local, team-based factors may outweigh shunt type.

Although promising for certain high-risk populations, catheter-based hybrid approaches are still in an experimental phase. These techniques may be inadvisable in certain anatomic subsets such as aortic atresia in which preductal retrograde coarctation is a significant problem. However, in some groups there is increasing interest in studying this approach compared with Norwood reconstruction.

Results for the final palliation to the Fontan circulation and for the second- and third-stage reconstruction for HLHS continue to improve. Survival rates for the bidirectional Glenn or hemi-Fontan are well above 95% in most centers, and similarly the survival rates for Fontan completion are >95% to 98% in most recent reports. These excellent results confirm the utility of staged reconstructive surgery to the Fontan circulation as the preferred strategy for patients with HLHS, saving transplantation for patients who fail at any stage of the reconstruction sequence. Our experience with the Fontan procedure for HLHS shows a >95% survival with a median hospital stay of 5 to 6 days. Effusions are common though rarely last more than a few days. Prolonged effusions of more than 2 weeks occur in <15% of patients with current strategies.

**Fig. 96.7.** The extracardiac Fontan procedure. **(A)** The inferior vena cava is detached from the right atrium, and the right atrial portion is partially closed. An 18- to 22-mm polytetrafluoroethylene (PTFE; Gore-Tex) conduit is anastomosed to the inferior vena cava (IVC), and a 4.0-mm fenestration is created next to the partially closed IVC. **(B)** A side-to-side anastomosis is fashioned between the fenestration and IVC opening in the right atrium. The distal end of the PTFE conduit is beveled to create a large opening that augments the pulmonary arteries, and the conduit-PA anastomosis is completed.
This improvement in overall Fontan survival has been reflected in reports from many institutions, suggesting that there has been a marked improvement in cardiac function in survivors of single-ventricle staged reconstruction over the last 15 years. Hospital survival of >90% is common, with guardians reporting their child’s overall health as excellent or good. Physical activity is normal in one-third of patients, with one-half reporting only slight physical limitations. School performance varies widely, with about one-third of patients above average, one-third average, and one-third below average.

When comparing outcomes of extracardiac conduit and lateral tunnel Fontan connections, results are conflicting. Some have reported that the lateral tunnel Fontan procedure has a significantly higher incidence of postoperative sinoatrial node dysfunction, supraventricular tachycardia, duration of ICU stay, and ventilator support. However, others have found contrasting data with a lower incidence of sinus node dysfunction in the lateral tunnel versus extracardiac Fontan reconstruction. The potential advantages of extracardiac Fontan reconstruction include the lack of complicated atrial suture lines, although most patients with HLHS will have atrial septectomy as part of their initial procedure. The incidence of late atrial arrhythmias is unknown in this population of patients, and it is not clear whether the extracardiac conduit Fontan will have
significant advantages over the lateral tunnel operation. There have been studies suggesting that the hemodynamic flow characteristics of the extracardiac Fontan may be superior to a lateral tunnel connection. However, the offset created by a hemi-Fontan procedure may be beneficial. These conflicting results have not been correlated with clinical findings and late outcomes.

With the progression of improvement in surgical techniques and perioperative management, current survival to the Fontan procedure for all patients with HLHS as a group is approximately 75% in centers with the greatest experience. Survival rates of >90% are common in low-risk patients who have normal birth weight and no associated cardiac or noncardiac anomalies. However, the frequent coexistence of low birth weight or tricuspid regurgitation or other noncardiac anomalies continues to create a high-risk group that lowers overall survival in centers who see a large proportion of patients with these comorbidities. Selective application of the variations in the Norwood procedure and hybrid strategies for these subsets of high-risk patients may improve overall survival with greater experience. Developments in preoperative evaluation, operative techniques, and postoperative management based on rigorous controlled trials and rational application or these results will provide continued progress with this challenging disease.

**SUGGESTED READINGS**

**EDITOR’S COMMENTS**

The group at CHOP has really developed most of the changes in technique in hypoplastic heart syndrome. Dr. Norwood initially and now Dr. Spray and Gruber and their colleagues have made this a highly successful operation. The major issue is the delicate of the balance of circulation. There are multiple controversies that have been dealt with well by this chapter. Probably, the most important relates to the standard shunt versus a right ventricular to pulmonary artery conduit as popularized by Sano. The Sano procedure seems to result in a much more stable initial postoperative course. However, as the authors have stated there is usually earlier reintervention and more complications in the mid-term as compared with the standard shunt. Having said that I think in those groups were the volume of these patients is relatively small, the Sano probably allows for easier initial postoperative care.

The second question is the proper kind of Fontan procedure. The authors have preferred the hemi-Fontan followed by a lateral tunnel. The other techniques now available include the extracardiac Fontan and in some cases catheter-based Fontan procedures. The authors make a very good case for the hemi-Fontan followed by the lateral tunnel but certainly they have clearly included all the other possibilities.

The procedure keeps changing and continues to evolve and I think the results will continue to improve.

TLS
Anomalies of pulmonary venous return form a spectrum of embryologically related congenital heart defects that have in common the failure of the pulmonary veins to unite normally with the left atrium. The lesion may involve anomalous connection of all four pulmonary veins with the systemic venous circulation (total anomalous pulmonary venous return, TAPVR) or abnormal drainage of at least one but not all pulmonary veins into the systemic venous circulation (partial anomalous pulmonary venous return, PAPVR).

**TOTAL ANOMALOUS PULMONARY VENOUS RETURN**

**Historical Aspects**

The earliest description of TAPVR was given by Wilson in 1798. In 1942, Brody presented an autopsy series of patients with this anomaly. Muller at UCLA is credited with the initial attempt of surgical treatment of TAPVR in 1951. He described a closed operation consisting of a side-to-side anastomosis between the common pulmonary vein trunk and the left atrial appendage. In 1956, Lewis, Varco, and associates at the University of Minnesota Minneapolis, MN, reported the first successful total correction of TAPVR using hypothermia and inflow occlusion. The same year, Burroughs and Kirklin described their experiences with surgical correction using cardiopulmonary bypass (CPB). The introduction of deep hypothermic circulatory arrest by Barratt-Boyes and colleagues in the early 1970s was a major advance toward accomplishing surgical repair because this technique provides a bloodless operative field. Further advances in early diagnostic modalities, neonatal intensive care, including the availability of extracorporeal membrane oxygenation (ECMO), and pediatric cardiac surgical anesthesia, as well as an awareness of the merits of early surgical intervention, have contributed to the excellent results with TAPVR repair reported recently by many centers.

**Embyrology**

The respiratory system develops as an evagination from the foregut at 26 days. The venous plexus from the early lung buds drains into the anterior cardinal and umbilico vitelline veins, both of which are part of the splanchnic (systemic) venous system. The anterior cardinal veins give rise to the right and left superior vena cavae (SVC), the coronary sinus, and theazygos vein. The umbilico vitelline veins form the inferior vena cava (IVC) and the portal vein. In normal circumstances, the common pulmonary vein to unite with the pulmonary venous plexus leads to persistence of these embryonic pulmonary venous-to-systemic venous anastomoses, yielding total anomalous pulmonary venous drainage into right atrial tributaries. In some instances, abnormal leftward displacement of the developing atrial septum results in anomalous connection of all four pulmonary venous ostia directly to the right atrium.

**Anatomic Defects and Classification**

The common underlying anatomic defect in all cases of TAPVR involves anomalous drainage of the entire pulmonary venous circulation into the right atrium, either directly, or via the SVC, IVC, or coronary sinus. The pulmonary venous blood may drain into the systemic venous circulation through a single common channel or by multiple portals of entry. An intratral communication, usually manifested as a patent foramen ovale (PFO) or secundum atrial septal defect (ASD), is mandatory for shunting of partially oxygenated blood to the left heart.

There are several classification schemes for TAPVR. The most commonly used system is the one described in 1957 by Darling and associates. This four-tier system is based on the site of pulmonary venous drainage into the systemic circulation. In type I, or supracardiac TAPVR, all four pulmonary veins form a horizontal common pulmonary venous confluence behind the left atrium that gives rise to a vertical vein that drains into a supracardiac systemic vein (innominate vein, SVC, or azygos vein) (Fig. 97.2). The most common configuration involves an ascending left vertical vein or persistent left SVC that drains into the innominate vein. Type II, or cardiac TAPVR, is characterized by total pulmonary venous drainage into a markedly dilated coronary sinus (Fig. 97.3) or, less commonly, directly into the right atrium. Type III, or infracardiac TAPVR, involves a more vertical pulmonary venous confluence giving rise to a descending vertical vein that travels through the esophageal hiatus to below the diaphragm, where it most often makes an anomalous connection with the portal vein, one of its branches (Fig. 97.4), or the ductus venosus. In such cases, pulmonary venous blood returns to the right atrium by way of the IVC. Type IV, or mixed TAPVR, comprises all mixed defects with connections at different levels.

According to most series, a supracardiac connection is the most common TAPVR variant (45% to 60%), whereas the cardiac and infracardiac types are encountered somewhat less frequently (15% to 30% each) and the mixed type is the rarest (5% to 10%). In general, the infracardiac variants of TAPVR are usually associated with significant obstruction of the anomalous draining vein due to the length of the venous channel and the resistance created in the hepatic portal system. Supracardiac variants are significantly obstructed approximately half of the time while cardiac variants rarely present with significant obstruction. Alternate classification systems have used the embryologic origin of the anomalous connection, the length

of the draining veins, and the degree of obstruction between the pulmonary venous and systemic venous pathways. The most complete system, proposed by Herlong and associates as part of the Congenital Heart Surgery Nomenclature and Database Project, describes the anatomic variant, the presence or absence of obstruction, and the type of obstruction (extrinsic or intrinsic compression). Whereas the majority of TAPVR cases are isolated anomalies, the lesion occasionally coexists with other cardiac and extracardiac congenital malformations. TAPVR, especially in autopsy series, has been diagnosed concomitantly with a variety of other acyanotic and cyanotic heart defects, including patent ductus arteriosus, valvular atresia and stenosis, ventricular septal defect, transposition of the great arteries, tetralogy of Fallot, double-outlet right ventricle, and common atrioventricular canal. In addition, there is a well-known association between TAPVR and the heterotaxy syndrome, which includes visceral heterotaxy, isomerism, dextrocardia, and splenic abnormalities (asplenia, polysplenia, hyposplenia). In some series, up to 30% of patients with TAPVR have heterotaxy syndrome.

Pathophysiology

The physiologic consequences of TAPVR depend largely on the presence and magnitude of pulmonary venous obstruction. In those cases with no significant obstruction, TAPVR functions as a large left-to-right shunt. Pulmonary blood flow is greatly increased, and right ventricular overload occurs as a result of both the pulmonary venous and systemic circulations returning to the right atrium. Consequently, pulmonary hypertension, pulmonary edema, right ventricular enlargement, and congestive heart failure supervene. Cyanosis results from the mixing of fully oxygenated pulmonary venous blood with desaturated systemic venous blood. A compensatory right-to-left shunt through a PFO or an ASD is mandatory for survival because this allows shunting of partially oxygenated blood to the left atrium for systemic distribution. Although left atrial and left ventricular volumes are generally small due to shunting, these chambers are rarely hypoplastic.

Obstruction to pulmonary venous blood flow in TAPVR may occur as a result of extrinsic compression, intrinsic luminal narrowing of the vein, a restrictive communication at the atrial level (e.g., a small PFO or ASD), or a combination of

Fig. 97.4. Pathologic anatomy of infracardiac-type total anomalous pulmonary venous return via the descending vertical vein to the portal vein. IVC, inferior vena cava; LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle; SVC, superior vena cava.

these. The infracardiac TAPVR is associated with significant obstruction in 80% to 100% of patients. Usually, the descending vertical vein is obstructed at its junction with the portal vein or ductus venosus. In addition, resistance to blood flow through the hepatic sinusoids in the setting of a closed ductus venosus produces a functional obstruction. Supracardiac TAPVR variants may be obstructed due to a “vise-like” compression of the vertical vein between the left pulmonary artery anteriorly and the left mainstem bronchus posteriorly.

In patients with pulmonary venous obstruction, significant pulmonary edema results from the increased hydrostatic pressure in the pulmonary capillary bed proximal to the obstruction. The degree of cyanosis will depend on the balance between systemic and pulmonary blood flow. Patients with significant obstruction will have profound cyanosis due to a significantly decreased amount of oxygenated blood returning to the heart and mixing with the much larger volume of systemic deoxygenated blood. Pulmonary hypertension is usually present and most severe in patients with significant obstruction. In those patients, pulmonary artery pressures approach or exceed systemic pressures.

Diagnosis

Signs and Symptoms
The condition of infants with TAPVR is determined largely by the presence and degree of obstruction to pulmonary venous return. Nonobstructed TAPVR often eludes diagnosis at birth and in the early neonatal period. Months later, patients may present with the gradual onset of tachypnea, dyspnea, congestive heart failure, and mild cyanosis. Often, subtle complaints of feeding difficulties and failure to thrive may be the only clues of congenital heart disease in these children. Liver congestion with hepatomegaly and cardiomegaly along with a prominent right ventricular impulse are consistent features.

Cardiac examination may be unimpressive. There may exist either a gallop or a faint diastolic murmur, most often a result of increased flow across the tricuspid valve. Other findings are the hallmarks of increased pulmonary blood flow, such as a systolic ejection murmur over the left second interspace and a prominent fixed S2 component.

In contrast, infants with obstructed TAPVR may present in extremis within hours to days after birth. These infants are profoundly cyanotic and show severe congestive heart failure. Hypotension and metabolic acidosis are frequently present. Findings on cardiac examination are inconsistent, but the right-sided cardiac chambers may be of normal size. The liver may also be of normal span and free of congestion if the ductus venosus remains patent and thus is able to divert pulmonary venous blood directly into the inferior vena cava.

Chest X-Ray
Chest X-ray features of TAPVR are again dependent on the presence or absence of significant pulmonary venous obstruction. Nonobstructed TAPVR is characterized by a normal-sized heart with increased pulmonary vascularity, possibly a distinct pulmonary artery silhouette, and occasional enlargement of the right cardiac silhouette. The classic X-ray images of a “snowman” or “figure-of-eight” in supracardiac connection are rarely appreciated before 6 months of life. In cases of obstructed TAPVR, the cardiac silhouette is usually of normal size but there is marked engorgement of the pulmonary vasculature and diffuse interstitial infiltrates in a reticular pattern indicative of severe pulmonary edema due to venous obstruction (Fig. 97.5).

Echocardiography
Modern two-dimensional echocardiographic technology and techniques have revolutionized the noninvasive diagnosis of TAPVR. In unstable, critically ill neonates, echocardiography prevents any undue delay in diagnosis and surgical therapy. Since the 1980s, echocardiography has become the mainstay for preoperative diagnosis and classification of TAPVR. Two-dimensional echocardiography with Doppler color-flow
mapping is extremely accurate and reliable in diagnosing TAPVR, delineating the exact drainage pattern of each individual pulmonary vein, detecting the presence and degree of obstruction, and identifying any concomitant cardiac malformations. The absence of pulsatile pulmonary venous blood flow and dilatation of the venous confluence or the vertical vein indicate obstruction. The vertical vein is usually well visualized and can be followed to its site of drainage in the systemic circulation.

**Computerized Tomography and Magnetic Resonance Imaging**

Contrast computerized tomography (CT) and magnetic resonance imaging (MRI) may be useful in patients in which echocardiography fails to delineate the exact anatomy. These modalities can provide important information, particularly in cases of mixed TAPVR or complex anatomy (Figs. 97.6 and 97.7). The downsides of these diagnostic studies (the time needed to obtain them and the administration of contrast) must be weighed against the information to be obtained, especially in patients with obstructed TAPVR that need urgent surgical intervention.

**Cardiac Catheterization and Angiocardioangiography**

In the current era, cardiac catheterization is rarely required and is mainly of historical interest. It should be reserved only for cases in which echocardiographic, CT, and MRI findings are inconsistent with the clinical course. The precise site of anomalous pulmonary venous connection is identified by a “step-up” in oxygen saturation in a systemic vein, whereas the exact course of pulmonary venous drainage is delineated during the levophase of selective pulmonary arteriography.

It is common for the blood in all four cardiac chambers to have equal or similar oxygen saturations, which reflects the mixing of pulmonary and systemic venous circulations. TAPVR and transposition of the great arteries are the only two conditions in which the oxygen saturation of blood in the main pulmonary artery is equal to or greater than that in the aorta. Right ventricular and pulmonary artery pressures are frequently elevated in TAPVR but are virtually always so in the presence of obstruction. The adequacy of the PFO in terms of its ability to shunt partially oxygenated blood to the left side of the heart may be estimated by the difference between right atrial pressure and pulmonary capillary wedge or left atrial pressure. The detection of a transatrial pressure gradient suggests a restrictive foramen ovale. Balloon atrial septostomy may be used to temporarily relieve significant obstruction at the atrial level if immediate surgical intervention is not possible.

**Preoperative Management and Timing of Surgical Intervention**

Infants presenting with obstructed TAPVR represent a surgical emergency. An intensive resuscitation period should be followed by expeditious surgical intervention. Immediate interventions include endotracheal intubation and mechanical ventilatory support. Pulmonary vasconstriction should be avoided. Although pulmonary vasodilatory measures such as administration of 100% oxygen and hyperventilation to a partial arterial pressure of carbon dioxide (PaCO$_2$) of $<30$ mmHg have been traditionally used, it is unclear whether they provide any significant benefit. Metabolic acidosis should be treated with sodium bicarbonate or tromethamine infusions. Function of the
failing heart is augmented with the administration of inotropic and diuretic agents. Maintenance of ductal patency with a prostaglandin E1 infusion may also be of some physiologic benefit.

ECMO has been employed in those infants with severe pulmonary hypertension or cardiac failure refractory to conventional medical measures, although prompt surgical intervention is the mainstay of therapy. A brief period of ECMO may assist in stabilizing these critically ill infants and prevent end-organ dysfunction before operative intervention if immediate surgical intervention is not possible.

Nonobstructed TAPVR patients are usually in stable condition. Therefore, these infants rarely need significant preoperative intervention or pharmacologic support. Nonetheless, the current practice in most centers is to perform elective corrective surgery within a few days of diagnosis irrespective of the patient's age or weight. The impetus for early surgery has been a heightened awareness of the extremely high mortality associated with uncorrected TAPVR as well as the possibility of subclinical venous obstruction and the substantial risk of progression to irreversible cardiac and pulmonary vascular disease while awaiting delayed repair.

Surgical Technique

Preparation for and Management of Extracorporeal Circulation

The following descriptions apply specifically to TAPVR repair in neonates and young infants, with the understanding that older children and even adults also infrequently undergo corrective surgery for TAPVR. Central venous and umbilical arterial pressure catheters are usually placed during the preoperative resuscitation period. High-dose fentanyl is an ideal agent for the induction of anesthesia because it reduces stress-induced increases in pulmonary vascular resistance. Access to the heart and mediastinal structures is gained via a median sternotomy. After partial thymectomy, creation of a pericardial well, and systemic heparinization, an arterial cannula is placed in the ascending aorta. A single venous cannula is then positioned in the right atrial appendage. Alternatively, bicaval cannulation may be used to decrease the time of necessary circulatory arrest. Care is taken to avoid any undue manipulation of the heart until the institution of CPB because the myocardium of hypoxic, acidic neonates with obstructed TAPVR is especially irritable and prone to ventricular fibrillation. Immediately after the commencement of CPB, the patent ductus arteriosus is dissected and ligated. During core cooling to a nasopharyngeal temperature of 18°C, the posterior pericardium is incised where it directly overlies the common pulmonary venous trunk. Once a core temperature of 18°C is achieved, the aorta is cross-clamped and antegrade cold cardiopulmonary bypass solution is infused into the aortic root. Topical cold is also applied to the heart. Blood is then drained from the patient into the oxygenator to initiate the period of deep hypothermic circulatory arrest. At this point, the single atrial venous cannula may be removed to facilitate repair. If bicaval cannulation is used, periods of CPB can be alternated with periods of circulatory arrest, as needed. Circulatory arrest is a valuable adjunct to surgical repair of supracardiac, infracardiac, and mixed types of TAPVR because it provides a completely bloodless and quiescent operative field for fashioning of as large a pulmonary venous-to-left atrial anastomosis as possible. However, for the repair of TAPVR to the coronary sinus, standard CPB with two venous cannulas and moderate hypothermia (28°C) often suffices.

Supracardiac Type

Ligation of the vertical vein may be accomplished just after commencement of CPB or after completion of the repair. It is best to ligate the vein in its extrapericardial portion to avoid narrowing the ostium of the upper pulmonary veins. Because the condition of TAPVR renders the heart untethered by the pulmonary veins, excellent exposure of the posterior-lying common pulmonary venous confluence is afforded by retraction of the heart to the left or by lifting the apex of the heart to the right shoulder by using a pledged suture placed on the apex. However, one must be careful not to distort the cardiac and pulmonary venous anatomy during these maneuvers as distortion can result in kinking of the anastomosis when the heart is replaced to its natural position.

A longitudinal right atriotomy is performed and the left atrium is visualized through the septal defect. An incision is then performed on the posterior wall of the left atrium extending it superiorly toward the left atrial appendage for construction of a wide anastomosis. The particular site of the incision is chosen to optimize the apposition between the posterior wall of the left atrium and the pulmonary venous confluence and vertical vein without causing distortion (Fig. 97.8). A generous corresponding transverse incision is made in the common pulmonary venous confluence and vertical vein, where they lie in direct apposition to the posterior wall of the left atrium and left atrial appendage. Division of the vertical vein may be performed to use the distal end of the vein as part of a wide anastomosis. It is important not to extend the incision to include any individual pulmonary venous ostia. A continuous 7-0 or 8-0 polypropylene suture is used for the pulmonary venous-to-left atrial anastomosis using small and precise bites. The foramen ovale is then closed with the use of an autologous...
Fig. 97.8. Technique for repair of supracardiac-type total anomalous pulmonary venous return via a vertical vein (A). (B) A median sternotomy is performed. The pulmonary venous confluence is visualized by lifting the apex of the heart to the right shoulder with the use of a pledged stitch placed on the apex. (C) An incision is performed on the posterior wall of the left atrium extending it into the left atrial appendage to correspond with an incision performed on the pulmonary venous confluence and the vertical vein. (D) The anastomosis is performed between both incisions and particular care is placed on not distorting the anastomosis. Panel (E) shows the completed anastomosis. Panel (F) shows the flow from the pulmonary veins into the left atrium.
pericardial patch with continuous 6-0 polypropylene suture through the right atrium; direct suture closure of the foramen may jeopardize the patency of the common pulmonary vein-to-left atrium anastomosis. The right atriotomy is then closed with a continuous 6-0 polypropylene suture.

After completion of the repair, the heart is filled with saline, air is vented through the cardioplegia catheter site, and the venous cannula is reinserted into the right atrium. CPB is resumed, with systemic rewarming to a core temperature of 34 to 35°C. During rewarming, atrial and ventricular pacing wires are placed. A right atrial catheter may be placed for intravenous access and a left atrial catheter may be placed for postoperative monitoring.

**Cardiac Type**

Repair of TAPVR to the coronary sinus is approached through a longitudinal right atriotomy (Fig. 97.9). After performance of a median sternotomy and institution of CPB with bivacal cannulation, the patient is cooled to 28°C. A segment of atrial septal tissue is excised between the dilated coronary sinus ostium and the PFO; the valve of the foramen ovale is removed in the process. An unroofing incision is then made in the superior wall of the coronary sinus such that drainage of pulmonary venous and coronary sinus blood is redirected to the left atrium. An autologous pericardial patch is sutured with continuous 6-0 polypropylene to the perimeters of the foramen ovale and the coronary sinus ostium to close the resultant interatrial communication.

TAPVR directly to the right atrium is also approached through a right atriotomy. The pulmonary venous ostia are visualized as they open into the posterior aspect of the right atrium, usually by the way of a single venous trunk from each lung. A large ASD is created by excision of a portion of the atrial septum surrounding the foramen ovale. An autologous pericardial patch is then sutured over the resultant defect to include the pulmonary venous ostia. The functional results of such a repair are that the interatrial communication is closed and pulmonary venous drainage is baffled to the left atrium.

---

**Fig. 97.9.** Technique for repair of cardiac-type total anomalous pulmonary venous return via the coronary sinus. (A) Inset shows the site of the longitudinal incision in the right atrium. A portion of atrial septum is excised between the coronary sinus and foramen ovale, removing the valve of the latter. (B) Site of the incision in the superior wall of the coronary sinus. (C) An unroofing incision is made in the coronary sinus, allowing redirection of coronary sinus blood flow into the left atrium. (D) A pericardial patch is sutured around the perimeters of the coronary sinus and foramen ovale such that pulmonary venous blood returning to the former is diverted underneath the patch, through the patent foramen ovale, and into the left atrium. RA, right atrium.
**Infracardiac Type**

TAPVR below the diaphragm is obstructed in the vast majority of patients; thus, patients diagnosed with this anomaly usually undergo an emergency operation in the neonatal period. A midline sternotomy, CPB, and deep hypothermic circulatory arrest are used as described earlier. During the period of systemic cooling, the apex of the heart is retracted anteriorly to facilitate dissection and long mobilization of the descending vertical vein. The anomalous vertical vein is routinely ligated. Division of the vein may allow further mobility to allow the confluence to reach the left atrium without tension. As opposed to the supracardiac variant, the common pulmonary venous confluence in infra diaphragmatic TAPVR lies predominantly in a vertical orientation. Hence, a lengthy vertical incision in the vein is often required, extending from the superior aspect of the confluence into the descending vertical vein. A longitudinal right atriotomy is performed and an incision is created in the posterior wall of the left atrium such that it parallels the pulmonary venous confluence. Superior extension into the left atrial appendage may be required for a wider anastomosis. The common pulmonary venous-to-left atrial anastomosis is fashioned in a manner similar to that used for the repair of supracardiac lesions, using a continuous 7-0 or 8-0 polypropylene suture. Pericardial patch closure of the foramen ovale and continuous suture closure of the right atriotomy are performed in an identical manner to that described for supracardiac repair.

**Mixed Type**

Mixed patterns of pulmonary venous drainage, in which one or more pulmonary veins do not enter into the common pulmonary venous confluence but instead connect with the systemic venous circulation independently, are treated by a combination of the techniques described in the preceding paragraphs. Direct suturing of pulmonary veins to the left atrium is discouraged due to the higher risk of delayed pulmonary vein stenosis. In the event that only a single pulmonary vein from one lobe drains separately, it may be left uncorrected with minimal adverse physiologic sequelae.

**Postoperative Management**

In those infants who present initially with an obstructed subtype of TAPVR, pulmonary pressures are elevated due to high pulmonary vascular resistance secondary to preoperative injury and the inflammatory effects of CPB. Persistent pulmonary hypertension is a major cause of early morbidity and mortality after repair of obstructed TAPVR. It is not uncommon to see significant pulmonary hemodynamic lability and pulmonary hypertensive crises in the postoperative period in these patients. Although pulmonary artery-monitoring catheters are not a standard requirement for the management during the first 24 to 48 postoperative hours, it is essential to institute prophylactic measures to maintain an acceptably low pulmonary vascular resistance. Such strategies include hyperventilation-induced respiratory alkalosis and careful titration of the inspired oxygen concentration to minimize pulmonary vasoconstriction. If pulmonary pressures remain elevated beyond two-thirds or more of systemic pressure, right ventricular end-diastolic pressures may rise higher than left atrial pressure, thereby reducing stroke volume. In these cases, acidemia may ensue and should be vigorously treated pharmacologically as well as with ventilator management.

A continuous narcotic infusion (usually fentanyl) is useful for sedation, providing postoperative analgesia and blunting stress-induced increases in pulmonary vascular resistance. A paralytic agent to inhibit skeletal muscle activity with the intent of obtaining complete control of ventilation, and minimizing oxygen consumption may be useful in the acute postoperative period. Milrinone is an ideal agent when inotropic support is required because it also produces pulmonary artery vasodilation. Rarely, a sodium nitroprusside infusion may be required for the management of difficult cases of pulmonary hypertension. Nitric oxide is often a useful agent in cases of difficult-to-manage pulmonary hypertension. ECMO has been infrequently used when maximal combinations of the foregoing noninvasive measures fail to improve pulmonary vasoconspasm and right heart function. Before ECMO is initiated, mechanical causes of refractory pulmonary hypertension, such as pulmonary venous obstruction or anastomotic stenosis, should be ruled out with echocardiography.

Usually, a progressive decrease in pulmonary vascular tone permits weaning of ventilation, inotropes, and pulmonary vasodilators within 24 to 48 hours after surgery. Pulmonary edema is a frequent complication after TAPVR repair, especially in nonobstructed cases in which there is long-standing preoperative right ventricular volume overload and in the presence of a diminutive left ventricle. Postoperative fluid management is critical, as is the judicious administration of diuretic agents such as furosemide. Due to the relatively small left-sided structures on TAPVR, the heart is very sensitive to small increases in preload. Measurement of left atrial pressures can be useful to guide fluid and inotropic management. If there is deviation from the expected postoperative course or the patient is refractory to the usual interventions, an echocardiogram should promptly be obtained to investigate the possibility of pulmonary venous obstruction or anastomotic stenosis.

**Results**

Historically, the surgical mortality for TAPVR repair had been extremely high, as evidenced by a 65% to 85% rate of early death for infants undergoing repair in the 1960s. With the advent of deep hypothermic circulatory arrest in the 1970s, the 30-day operative mortality decreased markedly to 12% from 18%. Further advances in noninvasive diagnosis, surgical technique, cardiac anesthesia, and perioperative cardiopulmonary support, as well as adoption of the routine practice of early surgical intervention, have resulted in mortality rates of <5% in many recently reported series. Although young age at operation, preoperative pulmonary venous obstruction, infracardiac type of TAPVR, and emergent operation have all been previously indicted as risk factors for early death after isolated TAPVR repair, management practices of this lesion have virtually eliminated most identifiable preoperative risk factors for adverse outcome in the current era. Associated cardiac anomalies such as pulmonary atresia or the need for a systemic-to-pulmonary shunt may increase perioperative risk. Refractory pulmonary hypertension and cardiac failure continue to constitute the majority of intraoperative and early postoperative deaths in most series.

The most significant cause of late morbidity and mortality after corrective surgery for TAPVR remains recurrent pulmonary venous obstruction, which develops in 5% to 15% of patients within the first 6 to 12 postoperative months. The predominant pathologic manifestations of this complication are anastomotic fibrotic stricture, discrete stenoses of the individual pulmonary venous ostia, and a poorly understood diffuse fibrotic process that may involve the entire length of a pulmonary vein. There have been no technical factors that have reliably predicted or prevented the more insidious occurrence of diffuse, fibrotic stenosis of one or more pulmonary veins. This process accounts for a large proportion of the 5% to 10% late mortality rate after TAPVR repair. Various surgical techniques for managing postoperative pulmonary venous obstruction have been proposed, including revision of the common
pulmonary vein-to-left atrium anastomosis, patch angioplasty of stenotic pulmonary veins, creation of a sutureless pericardial well, and suturing of individual pulmonary veins directly to the left atrium. Pulmonary venous stents have been used with mixed results. Lung transplantation recently has been proposed for treating patients who have no other surgical alternatives.

Junctional rhythms and various degrees of heart block can complicate TAPVR repair of the cardiac type. The internodal tracts and the atrioventricular node itself may be disrupted during suturing around the coronary sinus, particularly around its anterior margin. Although some patients do sustain spontaneous conversion to a normal sinus rhythm after a few days of external pacing in the early postoperative period, others may require implantation of a permanent pacemaker as a result of a persistent postsurgical rhythm disturbance.

**PARTIAL ANOMALOUS PULMONARY VENOUS RETURN**

PAPVR is a congenital cardiac anomaly in which one or more, but not all, of the pulmonary veins connect with the right atrium or one of its systemic tributaries. By definition, at least one pulmonary vein must drain normally into the left atrium. Whereas the lesion is reported to occur in up to 0.7% of autopsy specimens, the frequency of antemortem diagnoses is somewhat lower as a result of a relatively high number of asymptomatic cases. The initial pathologic description was presented by Winslow in 1739, but it was not until 1949 that the first antemortem diagnosis was reported by Dotter and colleagues using angiography.

**Pathologic Anatomy**

PAPVR results from involution of the right or left portion of the common pulmonary vein at a stage in embryonic development when primitive pulmonary-to-systemic venous anastomoses still exist. In approximately 80% of cases, the anomalous vein or veins arise from the right lung, whereas in only 10% of cases does the left lung represent the sole source of PAPVR. Most commonly the pulmonary veins from the right upper and middle lobes drain anomalously into the right superior vena cava or, less frequently, connect directly with the right atrium. The innominate vein, coronary sinus, azygos vein, portal vein, and inferior vena cava represent uncommon sites of systemic venous connection. The anomalous pulmonary veins may enter the systemic circulation as a common trunk or as multiple individual connections. An associated ASD is identified in at least 80% of patients with PAPVR. Although a high-lying sinus venous defect is the most frequent coexisting cardiac malformation, a secundum ASD is also seen. In addition, a host of associated complex cardiac anomalies has been described in patients with PAPVR; in such cases, these complex defects dominate the clinical picture.

**Scimitar Syndrome**

By definition, the scimitar syndrome involves PAPVR from the right lung to the inferior vena cava. Some or all of the pulmonary veins unite in a common trunk to descend in a gentle curve alongside the right heart border en route to the inferior vena cava, giving the radiographic appearance of a scimitar (Turkish sword). The conjoined anomalous veins may enter the inferior vena cava near the cavoatrial junction or in its subdiaphragmatic portion. The right pulmonary artery and lung are hypoplastic in more than one-half of cases. Other associated anomalies include systemic arterial supply to the right lung (especially the right lower lobe) from aortopulmonary collaterals, abnormal lobation and bronchial distribution, secundum ASD, pulmonary vein stenosis, and a variety of other complex cardiac malformations.

**Pathophysiology**

The hemodynamic consequences of PAPVR are very similar to those of a large, isolated ASD. Pulmonary blood flow is substantially increased, but pulmonary vascular disease per se usually does not supervene for several decades with the lesion. The chronic right ventricular volume overload eventually yields right ventricular hypertrophy, dilation, and failure. The onset of pulmonary hypertension heralds an end-stage manifestation of a long-standing, uncorrected left-to-right atrial shunt. For unclear reasons, the scimitar syndrome is associated with pulmonary hypertension at a younger age and more frequently than other types of PAPVR.

**Diagnosis**

The majority of patients with PAPVR remain asymptomatic throughout early childhood. Those who eventually develop symptoms usually do so in the third or fourth decade of life, with the most common complaints being easy fatigability and mild exercise intolerance. Younger patients come to medical attention as a result of an incidentally discovered cardiac murmur, abnormalities on a chest X-ray, or recurrent pulmonary infections. Patients with associated major cardiac anomalies present in infancy with hemodynamic features referable to these complex lesions; in most such cases PAPVR is an incidental finding.

The mainstay in the diagnosis of PAPVR has become two-dimensional echocardiography with Doppler color-flow mapping. As in TAPVR, this modality is highly accurate in delineating the anomalous pulmonary veins and ASD. CT and MRI have proven to be useful in recent years to further define the anatomy and the relationship between the anomalous vessels and the right atrium or SVC. Cardiac catheterization is reserved for cases in which there are associated complex lesions or pulmonary hypertension is believed to exist. The pulmonary-to-systemic blood flow ratio \(Q/Q\) is usually found to be >1.5:1.

**Surgical Management**

To avert the onset of the potentially irreversible complications of right heart failure and pulmonary hypertension, elective surgical repair should be undertaken in all patients diagnosed with PAPVR. In general, the surgical principles of PAPVR repair include separation of the systemic and pulmonary venous circulations, avoidance of creating obstruction to superior vena cava or pulmonary venous blood flow, complete closure of the ASD, and preservation of sinoatrial (SA) node function.

**Partial Anomalous Pulmonary Venous Return to the Low Superior Vena Cava or Right Atrium**

We use a combination of techniques depending on the anatomy of the anomalous veins. For PAPVR with veins returning into the right atrium or low SVC, we tend to use a technique very similar to the simple pericardial baffle procedure originally described by Kirklin and associates in 1956 (Fig. 97.10). The heart and mediastinal structures are approached through a median sternotomy. The right pleural space may be entered to verify the origin of the anomalous veins from the right lung. The superior vena cava is completely dissected from the cavoatrial junction to the level of the innominate vein to clearly define the presence of any pulmonary veins returning to the SVC. With care taken to avoid obstructing access to the anomalous pulmonary venous ostia, the superior vena cava is cannulated with an angulated venous cannula placed above the anomalous pulmonary veins. If the anomalous veins enter very high in the SVC, direct cannulation of the innominate vein may be used. A standard venous cannula is used for
Fig. 97.10. Technique for repair of partial anomalous pulmonary venous return (PAPVR) to the right atrium. Panel (A) illustrates the location of an oblique right atriotomy after dissection of the superior vena cava and anomalous pulmonary veins. (B) After intracardiac visualization of all pulmonary veins, a piece of autologous pericardium is used to baffle the orifice of the anomalous vein through the atrial septal defect and into the left atrium. Panel (C) illustrates the completed baffle. Care must be made not to allow the baffle to obstruct the entrance of the superior vena cava.

A vertical incision is made in the right atrium lateral to the right atrial appendage extending upward to a level below the SVC/right atrial junction to avoid injury to the sinus node artery. Such an incision affords excellent exposure to all pulmonary venous ostia and the ASD and avoids injury to the SA node. If the ASD is narrow or the atrial septum is intact, a surgical atrial septostomy is created. A baffle of autologous pericardium is sutured into the lumen of the superior vena cava and the right atrium such that blood flow from the anomalous pulmonary veins is redirected from the superior vena cava, across the ASD, and into the left atrium. Care is taken to avoid narrowing the lumen.
of the superior vena cava or obstructing the pulmonary venous ostia with the pericar­
dial baffle. The incision in the right atrium
and superior vena cava may be closed with a
pericardial patch to eliminate the possibility
of superior vena caval stenosis.

Partial Anomalous Pulmonary Venous
Return to the High Superior Vena Cava
Even though the simple pericardial baffle
 technique may be used for PAPVR to the
high superior vena cava, we favor the use of
the Warden procedure when the pulmonary
veins drain 1 cm or higher above the
cavoatrial junction (Fig. 97.11). We believe
that this procedure, described by Warden
et al. in 1984, decreases the risk of postopera­
tive obstruction of the SVC, pulmonary
venous obstruction, residual atrial shunts,
and SA node dysfunction. Cannulation and CPB are conducted similar to the simple pericardial baffle technique. A longitudinal right atriotomy is performed and the ASD inspected. It may be necessary to enlarge the ASD superiorly, especially in cases of a secundum ASD, in order to allow adequate baffling of the SVC to the left atrium. The SVC is transected distal to the uppermost pulmonary vein. Depending on the anatomy, the azygos vein may need to be ligated and divided. The proximal SVC, containing the drainage from the pulmonary veins is then sutured closed, either primarily or with the use of an autologous pericardial patch. A pericardial patch is used to baffle blood from the cavoatrial junction (now containing only pulmonary venous drainage) through the ASD and into the left atrium. The tip of the right atrial appendage is divided and anastomosed to the distal SVC, therefore, directing the superior systemic venous drainage into the right atrium.

**Scimitar Syndrome**

In general, pulmonary resection rather than vascular reconstruction is recommended for the treatment of PAPVR in the scimitar syndrome if the right lung has been destroyed by recurrent infections, when it does not contribute appreciably to gas exchange, or in patients in whom an anomalous pulmonary vein arises from only a single lobe. Conversely, a variety of vascular reconstructive procedures have been proposed to reroute the pulmonary venous drainage to the left atrium in patients with sufficient right lung function and adequate pulmonary arterial blood supply. The anomalous pulmonary venous trunk is often too short for direct reimplantation into the left atrium; therefore, most procedures involve redirecting the anomalous drainage from the right atrium, across an ASD, and into the left atrial cavity via a pericardial tunnel. Aberrant aortopulmonary collaterals may be successfully treated by either surgical ligation or transarterial embolization.

**Results**

The surgical mortality for PAPVR repair is <1%. However, the higher mortality after repair of PAPVR in patients with the scimitar syndrome is a reflection of the frequently associated pulmonary hypertension and multiple complex cardiovascular anomalies. Although the reported incidences of late superior vena caval obstruction, pulmonary venous obstruction, residual atrial shunts, and rhythm disturbances is low after PAPVR repair, no single surgical technique has demonstrated a distinct advantage in further reducing these complications.

EDITOR’S COMMENTS

(continued)

seems to improve the postoperative sta-

bility of the patients and maintains car-
diac output better than if the vertical vein
is ligated and the vein used in the repair
as described by the authors of this chap-
ter. Initially, it was considered somewhat
illogical that leaving a vertical vein open
would significantly improve postopera-
tive cardiac output since any decompre-
sion of the vertical vein into the right side
of the heart would then be re-presented
to the left atrium. It appears that per-
haps the salient benefit of this approach
is permitting a larger capacitance to the
left atrium by essentially allowing the
venous capacitance to be part of the left
atrial capacitance and limiting left atrial
hypertension, which may improve cardiac
output even at the expense of what is a
left-to-right shunt. If the vertical vein is
left open there has been a reported signif-
ica nce of development of a late
left-to-right shunt that may need to be
addressed surgically, or by interventional
catheterization procedures.

The mixed types of TAPVR may rep-
resent technical problems in very small
infants because anastomotic techniques
for individual pulmonary veins may lead
to significant late stenosis. In addition,
patients who have all four pulmonary
veins entering separately into the right
atrium (although simple to repair by
excising the atrial septum and baffling the
veins to the left atrium) have a very high
incidence of late development of pulmo-
nary venous obstruction of the individual
veins and severe pulmonary hyperten-
sion. These patients must have continue-
d surveillance postoperatively, and if
pulmonary venous obstruction occurs,
prompt lung transplantation is the opti-
mal therapy.

Controversy continues regarding the
relative contributions of anastomotic
strictures to the late development of pul-
monary venous obstruction in TAPVR. It
is our impression that most pulmonary
venous obstruction is not related to an
inadequate anastomosis, but instead
to involution of tissue of the common
pulmonary vein or the individual pul-
monary venous entrances into the com-
mon pulmonary venous channel, which
occurs in the first 2 months after birth.
Thus, a widely patent anastomosis may
become restrictive with time. In situa-
tions in which the common pulmonary
venous channel and individual veins
are dilated with a restriction at the level
of the entrance into the heart, surgi-
cal revision can be undertaken using
sutureless techniques with good suc-
cess rates. This appears to be most com-
mon in patients who have cardiac forms
of TAPVR, in whom a wide anastomosis
of the left atrium is created by unroofing
the coronary sinus. In some of these
patients, continued involution of the
common pulmonary venous tissue can
cause restriction of this anastomosis and
require revision. Where individual pulmo-
nary veins are stenotic and the proximal
vein not dilated, operative intervention
has virtually no role in resolving severe
pulmonary hypertension. These patients
appear to have a diffuse process in the
pulmonary vein extending back into the
hilum of the lung, and even sutureless
techniques of vein repair do not result
in a significant drop in the pulmonary
resistance in most cases. If there is mixed
dilation of some veins and not others,
th en sutureless repair techniques may
be attempted before consideration for
lung transplantation. Nevertheless, these
patients have not responded to interven-
tional catheterization techniques or sur-
gical therapy in most cases and should
be referred early for consideration of lung
transplantation. Very high mortality with
conservative measures in these patients
and the inability to stent veins to relieve
obstruction in the more proximal vessels
have been noted. The use of stents in pul-
monary veins after repair of total anom-
alous pulmonary venous return or in
patients with congenital pulmonary vein
stenosis has been associated with recur-
rent obstruction very rapidly following
stent implantation or balloon dilation of
the pulmonary veins. Thus, stent implan-
tation probably has no role in the chronic
treatment of pulmonary vein obstruction
but may have a role as temporary decom-
pression in patients who have been listed
for definitive therapy with lung transplan-
tation. Even with consideration of lung
transplantation, these patients develop
severe pulmonary hypertension and often
have a progressive downhill course before
a lung donor becomes available.

An additional problematic group com-
prises patients with scimitar syndrome.
Although the authors recommend that all
patients with PAPVR and significant left-
to-right shunts undergo operative repair,
scimitar syndrome repair has been asso-
ciated with a high incidence of pulmonary
venous obstruction despite an initial suc-
cessful baffling of the venous return to the
left atrium. These patients then develop
pulmonary venous obstruction and often
hemopty sms from the right lung, which
has little pulmonary blood flow other than
bronchial supply. In addition, the aber-
rant aortopulmonary collaterals that
enter the lung through the diaphragm and
inferior pulmonary ligament may cause
sources of bleeding; recurrent infection is
not uncommon. In these patients, pneu-
monicectomy of the affected lung can often
resolve the hemopty sis and improve over-
all ventilation perfusion match.

Patients with scimitar syndrome pre-
senting in infancy are a very difficult sub-
group of patients with this anatomy. Often
these children have hypoplasia of the
right lung with a significant shunt from
the aortopulmonary collateral vessels.
In addition, associated congenital heart
lesions are common. Even with complete
correction of the cardiac defects, peris-
tent pulmonary hypertension is common,
and the mortality for operative interven-
tion in these infants is significant. For
these reasons, some authors advocate
lung removal in these patients or medi-
cal management alone if possible. Some
infants who have significant pulmonary
hypertension in association with scimi-
tar syndrome in infancy, often associ-
ated with other intracardiac shunts, may
be palliated by interventional occlusion
of significant aortopulmonary collateral
vessels into the right lung coming through
the diaphragm. Elimination of this addi-
tional source of left-to-right shunting may,
in fact, improve pulmonary hypertension
and failure to thrive in some of these chil-

The significant incidence of pulmonary
venous obstruction after cardiac repair in
isolated scimitar syndrome has led other
authors to suggest that these patients
do not undergo operative therapy. Reim-
plantation of the pulmonary veins into

(continued)
the back of the right atrium with baffling to the left atrium or direct anastomosis into the left atrium may be complicated by kinking of the pulmonary veins when the lung expands. Dr. John Brown and his colleagues have shown good success with direct anastomosis of the scimitar vein into the left atrium using a right thoracotomy approach with a low incidence of any turbulence or potential obstruction at intermediate follow-up. The encouraging results with this technique have led many centers, including ours, to preferentially use reimplantation through a thoracotomy approach if the patient does not have a significant additional intracardiac defect that would require cardiopulmonary bypass or a sternotomy approach such as an ASD. Most recently, we have used a technique similar to that described by Brown and associates for reimplanting the scimitar vein directly into the left atrium in patients who have a reasonable size right lung and significant left-to-right shunt, but who do not have an associated atrial or ventricular level defect that would require the use of cardiopulmonary bypass. We have divided the scimitar vein at its entrance into the inferior vena cava and, then used a short segment of PTFE graft to anastomose the vein to the left atrium. The graft functions as a stent of the anastomosis to prevent late stricture formation which has been the most frequent complication after direct anastomosis of pulmonary veins to the heart. Long baffles created from the entrance of the pulmonary veins at the level of the diaphragm along the right atrium into the left atrium have been associated with progressive stenosis. This is primarily because the veins take a right-angle course as they enter the inferior vena cava, and a baffle vertically into the atrium creates an obstructive junction at this site that can progressively occlude. We, therefore, incise the right atrial wall between the pulmonary veins and right atrium and suture the opening in the vein and atrium together, enlarging the pulmonary venous entrance point into the inferior vena cava up into the right atrium. In this manner, the veins enter in a wider orifice, which therefore can be baffled to the left atrium without creating a right-angle juncture. In a short follow-up, this approach has resulted in good patency of the pulmonary venous confluence.

Repair of PAPVR remains a surgical challenge because of the potential for pulmonary venous anastomoses in the atrium to develop obstruction. Vigilance in assessing the results of operative intervention and catheter intervention to maintain patency of the anastomoses may be necessary in some forms of anomalous venous return to ensure good long-term outcomes. For PAPVR associated with a sinus venous ASD, we make incisions in the right atrium without extending the incision across the junction of the superior vena cava and right atrium. In this way, the sinus node artery is generally preserved. In most cases, with a cannula placed very high in the superior vena cava, one can examine the pulmonary venous entrance into the superior vena cava from below, and with gentle retraction on the superior vena cava, the suture line of the pericardial baffle can be accurately placed in the superior vena cava without actually opening the vena cava directly. This technique is useful if there is significant dilation of the superior vena cava-to-right atrial junction due to the anomalous venous return. In these cases, the floor of the superior vena cava can be patched closed, baffling the veins to the left atrium without creation of significant SVC obstruction. However, if there is only modest dilation of the vena cava, then a more elaborate approach may be necessary, including the use of the Warden procedure (dividing the superior vena cava above the entrance of the anomalous pulmonary veins, baffling the orifice of the superior vena cava and right atrium across the atrial septum into the left atrium, and then reconnecting the remaining superior vena cava to the right atrial appendage to reestablish flow to the right atrium). These techniques have resulted in very low complication rates with excellent results. It may be advantageous to leave the azygous vein open if possible, rather than ligation and division of the azygous vein routinely, because if any stenosis of the superior vena cava-to-right atrial anastomosis occurs, some decompression through the azygous system can be permitted with this technique.

TLS
INTRODUCTION

This chapter focuses on managing coronary artery anomalies in patients without other congenital heart defects. Most coronary artery anomalies in number, origin, and distribution are of intellectual interest only. However, there are a few that are clinically significant and may result in myocardial ischemia, left ventricular dysfunction, and sudden death. This chapter will discuss anomalous origin of a coronary artery from the pulmonary artery, anomalous coronary artery that runs between the aorta and the pulmonary artery, and coronary artery fistula.

Normally, two-coronary arteries originate from separate ostia in the right and left aortic sinuses of Valsalva. The left main coronary artery (LMCA) arises from the left aortic sinus and usually bifurcates into the left anterior descending coronary artery (LAD) and left circumflex coronary artery. The LAD courses in the anterior interventricular groove while the left circumflex coronary artery runs in the left atrioventricular groove. The right coronary artery (RCA) arises anteriorly from the right aortic sinus and courses in the right atrioventricular groove. The RCA usually gives rise to the posterior descending artery at its terminus.

In most people, each coronary artery ostia is centrally located in the appropriate sinus of Valsalva. However, in some individuals the ostium may be located eccentrically close to a valve commissure. One or both coronary ostia may arise above the sinotubular junction, which is usually a benign finding but becomes significant if an aortotomy is necessary for aortic valve replacement or for another indication. If this anatomy is not recognized prior to the operation, the coronary artery could be transected. Another type of anomaly occurs when both coronary arteries arise from the same aortic sinus with either a single ostium or two separate ostia (Table 98.1). If the aberrant vessel courses posterior to the aorta or anterior to the pulmonary artery, this is believed to be benign but it becomes clinically significant if either the aberrant LMCA or RCA courses intramurally between the two great vessels as this has the potential for myocardial ischemia and sudden death.

ANOMALOUS ORIGIN OF A CORONARY ARTERY FROM THE PULMONARY ARTERY

Anomalous origin of a coronary artery from the pulmonary artery is a rare congenital anomaly that is almost always fatal if not diagnosed and treated. While anomalous origin of the LMCA from the pulmonary artery (ALCAPA) is the most common, other coronary arteries may also arise from the pulmonary artery. The RCA may arise from the pulmonary artery and is associated with ischemia and sudden cardiac death but is approximately 10 times less common than ALCAPA. Extremely rare are instances where the LAD, the circumflex, or both the left and right coronary arteries arise from the pulmonary artery; these variants are almost uniformly fatal.

The most important congenital coronary artery anomaly in this class is ALCAPA. It is a rare lesion with an incidence of 1 in 30,000 to 1 in 300,000 people. If left untreated, there is an extremely high mortality rate of 90% by age 1 year. It is the most common cause of myocardial infarction in childhood. ALCAPA is also known as the Bland–White–Garland syndrome after Bland and colleagues reported on the clinical and autopsy findings in an infant with this anomaly in 1933.

Anatomy

In ALCAPA, the LMCA usually arises from the main pulmonary artery (MPA) but occasionally it will arise from the right pulmonary artery. When it arises from the MPA, it usually originates from the rightward aspect of the posterior (facing) sinus of the MPA (Figs. 98.1 and 98.2). It may also originate from the leftward aspect of the posterior (facing) and rarely from the anterior (nonfacing) sinus of the MPA (Fig. 98.2). An anomalous RCA usually arises from the anterior portion of the pulmonary artery.

ALCAPA usually occurs in isolation but there may be other associated defects, such as patent ductus arteriosus (PDA), ventricular septal defect (VSD), coarctation of the aorta, and tetralogy of Fallot.

Pathophysiology

Symptoms usually begin during infancy after ductal closure and the subsequent fall in the pulmonary vascular resistance. During fetal life, the systemic and pulmonary vascular resistances are similar and myocardial perfusion remains intact since the pulmonary arterial pressure is systemic. After the child is born but before ductal closure, the pulmonary artery pressure remains elevated, and the anomalous coronary artery remains perfused. Because of this, ALCAPA is rarely diagnosed in the first few days of life. After ductal closure, the clinical course is largely determined by the presence or absence of collaterals from the RCA to the left coronary system. If there is inadequate collateral circulation, myocardial ischemia and ventricular dysfunction will result from inadequate myocardial perfusion because the pulmonary artery pressure is now much lower than the systemic pressure and the left ventricle is being perfused with desaturated blood at a low pressure. If the pulmonary artery pressure remains elevated due to the presence of a PDA or VSD, then the left ventricular perfusion pressure may be adequate and ischemia may not occur. If ALCAPA is unknown prior to the closure of these defects, it will become apparent shortly after with the subsequent drop in pulmonary arterial pressure, usually with fatal outcomes.

If there is adequate collateralization, then the perfusion of the left coronary system is maintained. However, as the pulmonary vascular resistance falls, a left-to-right shunt develops from the RCA to the pulmonary artery. There is progressive dilation of the RCA and left coronary artery.
Section III: Congenital Cardiac Surgery

Table 98.1 Origin of Both Coronary Arteries from One Sinus

1. Left main coronary artery originates from the right sinus of Valsalva (either from the right coronary artery or separate ostia)
   - Left main coronary artery courses anterior to pulmonary artery
   - Left main coronary artery courses through interventricular septum
   - Left main coronary artery courses between aorta and pulmonary artery
   - Left main coronary artery courses posterior to aorta
   - Rarely, the left anterior descending coronary or the left circumflex coronary artery alone may originate from the right sinus
2. Single left main coronary artery arises from the left sinus and bifurcates into the left anterior descending coronary and the left circumflex coronary arteries. The left circumflex coronary artery crosses the crux and continues as the right coronary artery
3. Single right coronary artery from the right sinus, which crosses the crux, continues as the left anterior descending coronary artery and the left circumflex coronary artery
4. Right coronary artery originates from the left sinus of Valsalva (either from the left main coronary artery or as separate ostium)
   - Right coronary artery courses posterior to aorta
   - Right coronary artery courses anterior to pulmonary artery
   - Right coronary artery courses between aorta and pulmonary artery

Clinical Presentation

Clinical presentation is usually between 4 and 6 weeks of age after the pulmonary vascular resistance has fallen. However, infants may not present until closer to 2 to 3 months of age when symptoms have increased in severity. Presenting signs and symptoms are those of congestive heart failure, including sweating and discomfort with feeding, tachypnea, poor weight gain, and pallor. The discomfort with feeding likely represents myocardial ischemia. Children who do not present as infants may be diagnosed at several months of age due to a loud murmur of mitral regurgitation (MR) secondary to papillary muscle dysfunction and ventricular dilation. Rarely, older children, adolescents, and adults may remain asymptomatic yet others may come to clinical attention because of exertional chest pain, presyncope, or syncope. There have been reports of sudden death with exercise in these older patients. The symptoms associated with anomalous origin of the RCA from the pulmonary artery are less severe and presentation may be at a later age during childhood but myocardial ischemia and death can still occur.

Physical examination of the infant with ALCAPA may demonstrate signs of congestive heart failure, including tachypnea, tachycardia, and hepatomegaly. Left ventricular dysfunction due to ALCAPA can be difficult to distinguish from dilated cardiomyopathy, for which it is often confused. The left heart is usually enlarged, often with associated MR and a gallop rhythm. If the left ventricular failure has resulted in pulmonary hypertension, then there may also be evidence of right heart enlargement and an accentuated pulmonary component of the second heart sound on examination.

Infants with ALCAPA will typically have an enlarged cardiac silhouette on systems, with reversal of flow in the left coronary leading to a pulmonary-coronary steal. The left-to-right shunt is relatively small related to overall cardiac output but is significant considering coronary blood flow. Children with significant collateral circulation may survive past infancy; however, there is usually progressive left ventricular dysfunction. In a small percentage of children, the collateral vessels are enough to maintain adequate myocardial perfusion at rest and sometimes even during exertion allowing these patients to not present until adulthood.
chest X-ray, essentially due to the enlarged left atrium and left ventricle. It will look similar to dilated cardiomyopathy. In infants presenting with congestive heart failure, the electrocardiogram can be a useful diagnostic tool. Classically, these patients have developed lateral or anterolateral wall infarction with Q waves and ST segment elevation in leads I, aVL, and V4 to V6. While this electrocardiographic pattern can be found in other causes of myocardial infarction or cardiomyopathy, if this is seen in an infant in congestive heart failure, the diagnosis of ALCAPA needs to be strongly considered. As well, any infant presenting with dilated cardiomyopathy must be extensively evaluated to rule out ALCAPA. This diagnosis should also be considered in older children and adolescents with dilated cardiomyopathy because occasionally patients survive past infancy.

**Diagnostic Imaging**

Imaging by echocardiography with Doppler color flow often shows a dilated left ventricle with significant MR. The MR seen with ALCAPA is due to infarction of the mitral valve posterior leaflet and ensuing poor movement of the leaflet; fibrosis and fibroelastosis of the papillary muscle may also be present. Visualization of both coronary arteries is usually possible with echocardiography. An enlarged RCA is almost always present and should increase suspicion of this diagnosis. The origins of both coronary arteries should be identified, including the abnormal origin of the LMCA to the pulmonary artery. If visualization of the anomalous vessel is unclear, color flow Doppler may be useful to demonstrate retrograde flow from the coronary artery to the pulmonary artery. If there is uncertainty about visualization of both coronary ostia, then cardiac catheterization is mandatory to rule out ALCAPA.

Cardiac catheterization with angiography traditionally was utilized in diagnosing ALCAPA but it is now performed usually only if noninvasive imaging cannot adequately establish the diagnosis. When infants present with ALCAPA, elevated filling and pulmonary arterial pressures and a low cardiac output are noted utilizing cardiac catheterization. In older asymptomatic patients, only mildly elevated pulmonary arterial pressures, normal filling pressures, and cardiac output may be seen. A small left–right shunt may be present. A single dilated RCA arising normally from the aorta will be demonstrated using an aortogram. If significant collaterals are present, aortic root angiography will demonstrate the collaterals providing late, retrograde filling of the LCA with a blush of contrast subsequently filling the MPA. A step-up in oxygen saturation may be noted in the MPA if there is a large left–right shunt from the collaterals. If doubt remains regarding the diagnosis, a main pulmonary arteriogram with distal balloon occlusion may be helpful in demonstrating the anomalous LCA.

Magnetic resonance imaging (MRI) has emerged as a useful noninvasive diagnostic tool for defining congenital coronary anomalies. There have been case reports of using this method in diagnosing ALCAPA during infancy but no case series with this anomaly have been reported. However, studies have shown that magnetic resonance angiography has a similar sensitivity and specificity when compared with coronary angiography and may be helpful in delineating the proximal course of anomalous coronary arteries. Computed tomography (CT) scan has been used extensively for coronary artery delineation in adults. While there are many advantages of CT, including rapid acquisition time and high resolution, it is not useful in infants due to the radiation exposure and need for a slower heart rate with ECG gating.

**Surgical Management**

**Indications**

Surgical repair is indicated in all patients with ALCAPA. In infants who present with congestive heart failure, surgery should occur within the first few days of diagnosis as risk of continuing myocardial ischemia and death is very high. In an infant who presents with severe heart failure, surgery will likely need to be delayed for at least 24 hours to stabilize the patient using mechanical ventilation, inotropic support, and vasodilators, when necessary. Even in the sickest infants, Del Nido and colleagues reported that a two-vessel surgical repair is possible if left ventricular assist devices (LVAD) are utilized postoperatively. Other critically ill infants may need extracorporeal membrane oxygenation (ECMO). Since these infants are often quite ill, it is important that centers performing ALCAPA surgery have options such as LVAD and ECMO available or else the child should be transferred to a hospital with these capabilities. In older asymptomatic patients, surgery can be performed on an elective basis.

As the goal of surgery is restoration of a two-coronary system, simple ligation of the anomalous coronary should not be performed. Revascularization is possible even in those infants with severe left ventricular dysfunction and mitral insufficiency because significant recovery of function usually occurs. Even if severe MR is present, left ventricular aneurysmectomy and mitral valve repair or replacement are rarely indicated at the time of the initial procedure because the severity of MR almost always improves after revascularization.

**Surgical Techniques**

**History of Surgical Techniques**

The first successful operation for the correction of ALCAPA was surgical ligation of the anomalous artery at the pulmonary artery. Ligating the anomalous vessel prevents the left-to-right shunt, thus allowing the left ventricle to be perfused through collaterals from the RCA. However, due to the increased risk of late death after ligation, those children who have had a simple ligation of the anomalous coronary, establishment of a dual coronary artery system.
Anastomosis. Without cardiopulmonary bypass. Using flap to direct blood flow from the aorta to procedure of choice in many institutions. A different surgical approach is ligation when a left thoracotomy is used, heparin via a left posterior lateral thoracotomy may be accomplished either primarily or due to the risk of anastomotic stenosis or occlusion.

CABG was accomplished using the left subclavian artery, the internal mammary artery (IMA), and saphenous vein. The first successful left subclavian artery-to-left coronary bypass was reported by Meyer and colleagues in 1968. Unfortunately, the results of bypass grafting, notably those with saphenous vein grafts, have been disappointing. Takeuchi and colleagues subsequently described the creation of an aortopulmonary window and intrapulmonary artery baffle using a pulmonary artery flap to direct blood flow from the aorta to the anomalous coronary artery. Finally, the procedure of choice in many institutions has become direct reimplantation of the anomalous coronary to the aorta as experience with the arterial switch operation for transposition of the great vessels has increased.

Coronary Artery Bypass Grafting

Left Subclavian-to-Left Coronary Artery Anastomosis. In the current era, CABG is rarely utilized in patients with ALCAPA. It may be used, however, to create a dual coronary artery system after previous ligation or due to stenosis or occlusion after a previous surgical repair. Left subclavian-to-left coronary artery anastomosis may be performed via a median sternotomy using cardiopulmonary bypass or via a left posterolateral thoracotomy without cardiopulmonary bypass. Using cardiopulmonary bypass may be necessary for the stabilization of critically ill infants but subclavian artery mobilization may be difficult through a median sternotomy. When a left thoracotomy is used, heparin is administered followed by mobilization of the subclavian artery. The subclavian artery is then divided distally. After the pericardium is opened, the anomalous coronary is mobilized. A partial occlusion clamp is placed and the anomalous coronary ostium is excised using a small button of pulmonary artery to extend the coronary artery. However, if the anomalous left coronary originates far leftward in the posterior-facing sinus or on the anterior non-facing sinus, direct reimplantation may not be possible.

Left Internal Mammary Artery Grafting. The IMA is the conduit of choice in CABG. Due to the risk of occlusion and poor long-term results, the saphenous vein should not be utilized unless it is the only conduit available. The IMA can be successfully used for bypass grafting even in neonates and infants with some evidence for growth of the IMA after bypass grafting in children.

Direct Reimplantation

In most patients with ALCAPA, direct reimplantation of the anomalous coronary onto the aorta can be performed (Fig. 98.3) and is the procedure of choice. When the anomalous coronary ostium is located in the posterior-facing sinus, the procedure is fairly straightforward. Direct implantation is possible even if the ostium is located in the non-facing sinus by excising a large button of pulmonary artery to extend the coronary artery. However, if the anomalous left coronary originates far leftward in the posterior-facing sinus or on the anterior non-facing sinus, direct reimplantation may not be possible.

After induction of anesthesia and placement of monitoring lines, a median sternotomy is performed. The thymus is resected, the pericardium is opened and suspended in stay sutures. There is a risk of ventricular fibrillation due to myocardial ischemia and left ventricular dysfunction, so contact with the myocardium should be kept at a minimum until the patient is placed on cardiopulmonary bypass. This operation may be performed using either continuous low-flow bypass with moderate hypothermia (25°C to 28°C) or deep hypothermic circulatory arrest (18°C) in very small infants. Prior to cannulation, an aortic purse-string suture is placed distally near the innominate artery and another is placed in the right atrial appendage for a single venous cannula. Heparin is administered, the aortic and right atrial cannulas are inserted, and cardiopulmonary bypass is established. The left ventricle should be decompressed by the placement of a left ventricular vent via the right superior pulmonary vein. The pulmonary artery and epicardial course of the left coronary artery are visualized.

The aorta and both pulmonary arteries are fully mobilized. The ductus (or ligamentum) arteriosus is ligated to improve the mobility of the pulmonary artery. Tourniquets are placed around both the right and left branch pulmonary arteries.

![Fig. 98.3.](image-url) After institution of cardiopulmonary bypass and induction of cardioplegia, the pulmonary artery is transected above the sinotubular junction and the anomalous coronary ostium excised with a generous button of pulmonary artery wall.
to occlude the branch pulmonary arteries and prevent run-off of cardioplegic solution into the lungs. Another way to prevent run-off is compression of the origin of the coronary artery from the pulmonary artery during administration of cardioplegic solution. A cannula is inserted in the ascending aorta for administration of cardioplegia solution. The aorta is then cross-clamped and cold cardioplegia is administered via the aortic root. If circulatory arrest is utilized, the head vessels are then occluded with tourniquets, the circulation is arrested, venous blood is drained into the reservoir, and the cannulae are removed. After adequate arrest, the pulmonary artery is transversely opened just above the sinotubular junction (Fig. 98.3). The anomalous coronary orifice is identified. The pulmonary artery is divided and the coronary ostium is excised from the pulmonary artery using a generous button of arterial wall, similar to the procedure used in the arterial switch operation. The segment of the pulmonary wall that is excised extends the proximal end of the coronary artery, which allows the aortic anastomosis to be accomplished without tension. The aortic commissure may need to be taken down to excise the coronary button if the coronary ostium is located near a commissure. If the coronary artery arises anteriorly from the pulmonary artery or from a branch pulmonary artery, the coronary artery can be extended using a tube constructed from pulmonary artery wall to allow reimplantation (Fig. 98.4). Using cautery, the proximal portion of the coronary artery is mobilized cautiously to avoid any small branches. Similar to the arterial switch operation, the aorta is then opened transversely just above the sinotubular junction and the incision is carried posteriorly above the left posterior sinus (Fig. 98.5). The sinus is then incised vertically to accept the coronary button. The coronary button is carefully aligned with the aortic incision to avoid twisting or kinking. Using a continuous suture of 7-0 polypropylene (Prolene), the anastomosis is started at the most inferior aspect of the coronary button, which is attached to the most inferior aspect of the incision in the sinus. The suture line is carried to the top of the incision anteriorly and posteriorly. The aorta is closed using a continuous suture of 7-0 Prolene, which is tied to the coronary button suture as the anastomosis is completed (Fig. 98.5). After the aorta has been closed, cardioplegia solution is administered and the anastomotic site is inspected for adequate filling of the coronary and hemostasis.

In most cases, the pulmonary artery can be repaired primarily with a continuous suture of 7-0 Prolene (Fig. 98.6). The ductus (or ligamentum) should be divided to improve mobility of the pulmonary artery confluence and to allow reconstruction without tension. If there is tension or narrowing, the pulmonary artery should be repaired with a patch of autologous pericardium (Fig. 98.6). If a commissure was taken down during excision of the coronary button, the pulmonary artery should be reconstructed with pericardium and the commissure resuspended.

The patient is rewarmed and the aortic cross-clamp is removed. To minimize...
ischemia time, the cross-clamp may be removed prior to the pulmonary artery reconstruction. The left ventricle is inspected for adequate perfusion and function and the suture lines are inspected for hemostasis. Right and left atrial lines are placed to adequately monitor pressure and for drug administration. Atrial and ventricular pacing wires are also placed. After complete warming, the patient is separated from cardiopulmonary bypass. Careful attention to the electrocardiogram during reperfusion and after separation from bypass is necessary to evaluate for ischemia. Inotropic support may be temporarily needed due to preoperative left ventricular dysfunction.

**Modified Takeuchi Operation**

The Takeuchi operation, or intrapulmonary artery tunnel, is an alternative surgical repair strategy for ALCAPA. Takeuchi and colleagues originally described the creation of an aortopulmonary window using a portion of anterior pulmonary artery wall to form a baffle directing blood from the aorta to the anomalous coronary artery ostium. In the modified repair, the baffle is constructed using a polytetrafluoroethylene (PTFE, Gore-Tex) patch. If the ostium is located near a commissure or arises from a branch pulmonary artery, then creating a baffle may not be possible.

The procedure may be performed with either continuous low-flow cardiopulmonary bypass (25°C to 28°C) or deep hypothermic circulatory arrest (18°C). Cannulation is performed as for direct reimplantation. After induction of cardioplegia, a longitudinal incision is made in the anterior portion of the pulmonary artery (Fig. 98.7) and the ostium of the anomalous coronary is identified. Using a punch, a 5 mm diameter opening is made on the leftward aspect of the aorta above the sinotubular junction (Fig. 98.8). If there is any question regarding the placement of the aortic opening, then an anterior aortotomy should be performed, and the incision directly visualized to avoid damage to the aortic valve. Creating the aortopulmonary window above the sinotubular junction allows a downward angle of the baffle into the sinus if the ostium is located deep within a sinus. After a similar incision is made in the pulmonary artery directly opposite the opening in the aorta, these are anastomosed using a continuous suture of 7-0 Prolene, thereby creating an aortopulmonary window (Fig. 98.8).
Fig. 98.8. Using a punch, a 5 mm opening is made in the aorta on the leftward aspect above the sino-tubular junction. A similar opening is made in the pulmonary artery at the same level, and these are anastomosed to create an aortopulmonary window.

A 4 mm PTFE tube graft is split longitudinally and customized to an appropriate length (Fig. 98.9). This graft acts as an intrapulmonary artery tunnel, baffling blood from the aortopulmonary window to the anomalous coronary ostium. The suture line starts at the anomalous coronary and is continued inferiorly along the pulmonary artery wall to the aortopulmonary window. The suture line is completed by returning to the coronary artery and finishing the superior aspect of the baffle. After the baffle is created, the pulmonary artery can be repaired using a prosthetic patch or autologous pericardium to avoid supravalvar right ventricular outflow tract obstruction (Fig. 98.10).

The main complications of the modified Takeuchi operation include baffle leak, baffle occlusion, and supravalvar right ventricular outflow tract obstruction.

Postoperative Management

Regardless of surgical technique, the most common postoperative issues are generally related to the infant’s preoperative state: low cardiac output, left ventricular dysfunction, and hypotension. Weaning off of cardiopulmonary bypass can be difficult due to these issues. Optimizing the patient’s hemoglobin, electrolytes, acid–base status, fluid status, and providing adequate inotropic support are very important. In infants and children with severe preoperative cardiac dysfunction, temporary support with an LVAD or ECMO may be necessary postoperatively. The second most common issue postoperatively is bleeding and is more commonly seen in small infants and those who require mechanical support. In these cases, aprotinin has been used intraoperatively to assist with coagulation and is often continued as an infusion for up to 12 hours postoperatively. Platelets and fresh-frozen plasma should be used aggressively to replace ongoing loss. Patients with low cardiac output and/or bleeding issues may be candidates for delayed sternal closure for 2 to 3 days.

Results

Simple ligation of ALCAPA has been shown to have unacceptable early and late mortality rates. In general, survival after establishment of a dual coronary system is excellent. Bunton and colleagues in 1987 reported on 24 patients with ALCAPA. There were 11 cases of coronary ligation or ostial closure and 11 cases that underwent a Takeuchi repair; 2 cases had other procedures. There was a 27% early mortality and a 25% late mortality over an average of 10.5-year
follow-up period in those who underwent coronary ligation or ostial closure. In those who underwent a Takeuchi procedure, there were no early or late deaths in over an 18.5-month follow-up period; however, two of these patients developed right ventricular outflow tract obstruction (one required a second operation) and one patient was found to have baffle occlusion. Backer and colleagues reported the follow-up surgical results of 20 patients who underwent different procedures. Of the nine patients who underwent ligation, there were two early deaths and one late death. In the 10 patients who underwent creation of a dual coronary artery system or the one patient who had cardiac transplantation, there were no deaths reported. Five patients underwent left subclavian-to-left coronary anastomosis and two developed significant anastomotic stenosis. Vouhe and associates from France reported on reimplantation of the anomalous coronary in 31 consecutive children. There were three hospital deaths and two additional deaths within the first 3 months. There were no late deaths. The one risk factor identified for early mortality was a shortening fraction of <20%. Twenty-three survivors were studied more than 1 year after repair. All patients had normal left ventricular function, and in five of seven patients who had severe MR preoperatively, the severity had decreased to mild or none. The reimplemented coronary artery was patent in all patients. A report by Lange and colleagues in 2007 reviewed the long-term results of 56 patients with ALCAPA who underwent either subclavian artery anastomosis or coronary artery transfer. Patients who had a Takeuchi procedure or a left mammary artery graft were excluded. There were similar early mortality rates of 14% for both surgical groups but no mortality in those undergoing repair in the more recent era. Late mortality in each group was also similar with one patient in each group. At final follow-up (mean 14.5 years for subclavian artery group and 8.7 years for coronary transfer group), 95% of patients had normal left ventricular function and 84% had MR less than grade 2. In 2011, Imamura and colleagues evaluated long-term outcomes in children who required ECMO after ALCAPA repair compared with those who did not. They reported on 26 consecutive patients who underwent surgical repair with 21 patients in the not requiring ECMO and 5 patients needing ECMO postoperatively. Twenty-three patients underwent coronary reimplantation, two patients had coronary artery ligation, and one had a left subclavian artery-to-left coronary artery bypass graft. There was no early or late mortality in either study group. One patient in each group required cardiac transplantation. In the ECMO group, all five patients needed reoperation: one underwent heart transplantation, three required mitral valve replacement (one underwent this procedure twice) for severe MR, and one underwent mitral valvuloplasty initially and then required atrial septal defect closure and pulmonary stenosis repair. At a mean follow-up of 7.8 ± 5.9 years, nearly all patients had normal left ventricular function and no more than mild valve regurgitation, excluding those with mitral valve regurgitation.

Special Considerations

Mitral Regurgitation
The ideal approach for managing MR during initial repair remains controversial. In general, MR is present at the initial presentation, often to at least a moderate degree. Even in patients with severe MR, in the majority MR improves significantly after coronary reperfusion alone. This is likely due to improvement in left ventricular dysfunction and decrease in left ventricular size postoperatively. Because of this, most centers have avoided mitral valve repair at the time of ALCAPA repair. Further, valve repair at the time of initial surgery can result in longer ischemic times and can be technically more difficult to perform in an infant heart compared with a later time when the child is bigger. However, some authors do recommend routine annuloplasty at the time of initial repair, whereas others propose annuloplasty or mitral valve replacement only with severe MR. In summary, we believe that early surgical repair of the mitral valve is generally not necessary. If valve repair in the setting of severe MR is needed later, it is likely to be more successful and easier to do technically. However, if severe MR persists late postoperatively, causes of ongoing myocardial ischemia should be investigated.

Late Presentation in the Adult
As discussed previously, it is rare for adults to present with ALCAPA. Surgery is indicated in all cases but generally can be done electively. The surgical choice is coronary bypass grafting using the left internal thoracic artery; this is generally a low-risk procedure that all adult cardiothoracic surgeons can perform with a low mortality rate.

ANOMALOUS CORONARY ARTERY COURSE BETWEEN AORTA AND PULMONARY ARTERY

Anatomy
A coronary artery that courses intramurally in the wall of the aorta between the aorta and pulmonary artery can result in myocardial ischemia and sudden death, notably in
children and young adults. When there are two separate ostia, either the RCA or LMCA may arise from the inappropriate sinus of Valsalva and subsequently course between the great vessels (Fig. 98.11). When the two ostia are in the same sinus, the ostium of the anomalous coronary artery is frequently small and elliptical (or “slit-like”) with an acute-angle take-off from the aorta. A similar situation may be found if there is an acute-angle take-off from the aorta creating a “slit-like” orifice that easily collapses, presence of an ostial ridge, and/or proximal intramural course that gets compressed within the aortic wall between the great arteries. Because of these malformations, the risk of ischemia increases with vigorous exercise when there is a significantly greater cardiac output and oxygen demand placed on the heart. It is unlikely that ischemia occurs every time the patient exercises; rather, it appears due to the collective effect of several smaller ischemic events over time that may lead to an unstable myocardium more prone to lethal tachyarrhythmias.

### Pathophysiology

When the anomalous coronary courses intramuscularly between the aorta and pulmonary artery, it is associated with increased incidence of sudden death. The greatest danger of sudden death is during or just after maximal exertion. Both anomalous LMCA from the right sinus and RCA from the left sinus are associated with sudden death but the former carries a higher risk. Based on autopsy studies of anomalous aortic origin of a coronary artery (AAOCA) patients, sudden cardiac death is hypothesized to occur from decreased anomalous coronary blood flow resulting in myocardial ischemia and/or ventricular tachyarrhythmias. This diminished blood flow is likely due to an anatomical malformation of the anomalous vessel, which may include one or more of the following: acute-angle take-off from the aorta creating a “slit-like” orifice that easily collapses, presence of an ostial ridge, and/or proximal intramural course that gets compressed within the aortic wall between the great arteries. Because of these malformations, the risk of ischemia increases with vigorous exercise when there is a significantly greater cardiac output and oxygen demand placed on the heart. It is unlikely that ischemia occurs every time the patient exercises; rather, it appears due to the collective effect of several smaller ischemic events over time that may lead to an unstable myocardium more prone to lethal tachyarrhythmias.

### Clinical Presentation

The true prevalence of an anomalous left or right coronary artery between the aorta and pulmonary artery is unknown but estimates range from 0.1% to 0.3% of the general population. Making this diagnosis challenging is that there are no characteristic physical findings in patients with this coronary anomaly. The physical examination is almost always normal. There may be an innocent murmur in children. This is often what prompts the referral to a cardiologist where an echocardiogram is obtained, leading to the diagnosis. Many patients with this anomaly are asymptomatic and may remain so throughout their life while, in others, the initial presentation may be sudden death. When symptoms are present, they most commonly include chest pain, palpitations, dizziness, presyncope, or syncope during or just after with exertion. Because of this, the diagnosis must be considered in any patient with exercise-induced complaints suggestive of myocardial ischemia or in those presenting with aborted sudden death or sudden death.

### Diagnostic Imaging

Anyone presenting with presyncope, syncope, or chest pain during or just after exertion should undergo further evaluation. A resting electrocardiogram should be obtained to evaluate for ventricular hypertrophy, arrhythmias, and evidence of previous myocardial infarction.

Echocardiography with color Doppler should be performed to confirm normal intracardiac anatomy and to evaluate heart function, especially focusing on areas of abnormal wall motion signifying possible history of ischemia. Close attention should be paid to the proximal coronary anatomy and the coronary artery origins. Identification of both coronary artery origins is often possible in many patients by two-dimensional echocardiography, especially when combined with color Doppler flow mapping to identify the anomalous origin. In patients in whom the anomalous vessel courses intramusurally within the aortic wall, the anomalous vessel may appear to arise normally where it exits the aorta using traditional two-dimensional imaging alone; color Doppler imaging can be very useful in helping show the direction of blood flow within the aortic wall, thereby delineating an anomalous vessel from one that arises normally.

When the coronary artery origins cannot be adequately delineated or to confirm the diagnosis, then other noninvasive techniques, such as MRI or CT scan, are frequently used. Occasionally, transesophageal echocardiography will be utilized to visualize the coronary anatomy; however, this is a more invasive options and is usually not the first choice in children. While cardiac catheterization with coronary angiography still remains the gold standard for detecting anomalous coronary arteries, it is being replaced by noninvasive imaging as described above. Coronary angiography may be necessary in adult patients to first evaluate for other coronary disease prior to undergoing surgical intervention.

After diagnosis, most patients will undergo further evaluation for myocardial...
ischemia at rest and stress. This usually includes an exercise stress test often accompanied by some form of imaging, such as nuclear perfusion imaging and/or stress echocardiography. However, because ischemia is intermittent in patients with AAOCA, using a single exercise test on which to base management decisions may not be reliable. In a study performed at our institution evaluating children with anomalous coronary artery, 9 of 16 patients who had a preoperative exercise test had presented with cardiovascular symptoms but only 1 had an abnormal exercise test. Further, there have been reports of patients with normal exercise tests who have subsequently experienced sudden death.

**Surgical Management**

**Indications for Surgery**

Surgical intervention is indicated in any patient with this diagnosis who has signs and/or symptoms of myocardial ischemia or ventricular arrhythmias. Further, most would agree that surgery is indicated in asymptomatic patients with anomalous left coronary artery from the opposite sinus of Valsalva because of the high risk of sudden death. The management of asymptomatic patients with anomalous RCA has not been defined; this controversy is even greater in the management of children and young adults who appear to have a higher risk of sudden death than those identified later in adulthood.

**Unroofing Procedure**

This has become the procedure of choice for patients with anomalous coronary artery with anomalous coronary artery from the wrong sinus of Valsalva with an interarterial and intramural course. After the median sternotomy is performed, the pericardium is opened, and the anatomy is inspected. The aorta is cannulated close to the innominate artery and a two-stage venous cannula is inserted via the right atrial appendage. After cardiopulmonary bypass with moderate hypothermia is established, a left ventricular vent is placed via the right superior pulmonary vein. The ascending aorta is cannulated for the administration of cardioplegic solution. The aorta is cross-clamped and cardioplegic solution is administered. After adequate arrest, a transverse aortotomy is performed and the coronary ostia are identified. If the anomalous coronary ostium arises close to the aortic valve commissure, it may be necessary to take down the commissure (Fig. 98.12). The slit-like ostium is opened longitudinally starting at the anomalous coronary ostium and continued into the correct sinus. A segment of the common wall between the aorta and coronary is excised and the intimal surfaces are approximated with interrupted sutures using 8-0 Prolene. If the aortic commissure was taken down, it is resuspended with a pledgeted suture (Fig. 98.13). The aortotomy is then repaired and the cross-clamp removed after deairing. As the patient is rewarmed, evidence of myocardial ischemia should be evaluated using the electrocardiogram. The patient is then separated from cardiopulmonary bypass in the usual manner.

**Creation of a Neo-Ostium**

An alternate technique for when the anomalous coronary passes intramurally below the aortic valve commissure is to create a neo-ostium in the correct sinus (Fig. 98.14). A probe is passed through the intramural segment of the anomalous coronary into the correct sinus. The coronary is opened at the location where it exits the aorta and a neo-ostium is created. The intima is sewn to the aortic wall with interrupted sutures. This technique avoids the takedown and resuspension of the commissure.

**Other Techniques**

When there are two separate coronary ostia with an interarterial but not an intramural course, coronary artery translocation with reimplantation has been utilized. This is similar to reimplantation done for the arterial switch procedure and was described above for the ALCAPA repair. The coronary artery is excised with a button of aortic tissue and usually reimplanted above the commissure in the correct sinus. Another technique for the potential prevention of compression of the coronary artery between the aorta and pulmonary artery was translocating the MPA to the left pulmonary artery or translocating the right pulmonary artery and bifurcation anterior to the aorta, thereby leaving the coronary circulation intact. This technique may be utilized when the anomalous coronary course is not intramural but the ostia are close together. Combining coronary artery patch angioplasty using pericardium in addition to translocating the MPA to the left pulmonary artery has also recently been proposed. CABG utilizing saphenous vein or IMA grafts may be appropriate in the older adult; however, concern about long-term graft patency in the child, adolescent, or young adult makes this a less desirable surgical option.

**Surgical Results**

No data exist regarding long-term neo-ostium patency rates in the unroofing procedure. However, short- to mid-term results have overall been reassuring with no reports of ostial stenosis by echocardiography. One study by Romp and colleagues described a patient who developed severe aortic...
insufficiency after commissural takedown and resuspension, ultimately requiring aortic valve replacement 44 months after the initial operation. In a study by Brothers and colleagues at our institution that evaluated children in the short- to mid-term after the unroofing procedure, subclinical evidence of postoperative myocardial ischemia was found in one-half of the patients with anomalous RCA and one of eight patients with anomalous left coronary artery. This was despite patent neocoronary ostia by echocardiography and with the patients remaining asymptomatic during testing. The clinical implications of these findings in the long-term are unknown, and further evaluations are needed over the next several years. In a recent study, Mainwaring and colleagues from Stanford University reported on mid-term surgical results on a series of 50 patients who underwent repair of anomalous coronary artery. The different repairs included unroofing, unroofing plus coronary bypass, coronary artery reimplantation (those without intramural component), and pulmonary artery translocation (those with a single coronary ostium without an intramural component). There was no operative or late mortality at an average of 5.5 years of follow-up. All patients who were symptomatic prior to surgery were now symptom-free and most had a normal, unrestricted activity level.

While coronary artery reimplantation has been utilized by some, one study by Rinaldi and colleagues reported that two patients required emergency bypass grafting. In an analogous procedure utilized for transposition of the great arteries, long-term follow-up studies have demonstrated coronary obstruction in up to 8% of patients with a recent report by Pedra and associates noting proximal eccentric intimal thickening by intravascular ultrasound in a majority of patients evaluated at least 5 years after the original surgery.

**CORONARY ARTERY FISTULA**

A coronary artery fistula is defined as an abnormal communication between a coronary artery and a cardiac chamber or any of the great vessels (e.g., coronary sinus, vena cavae, pulmonary artery, or a pulmonary vein). Coronary fistulas that end in right-sided structures, such as the right atrium, right ventricle, or pulmonary artery, are described as coronary arteriovenous fistulas while those that terminate in left-sided structures are called arterio-arterial fistulas. Coronary artery fistulas are usually congenital. They make up 0.2% to 0.4% of congenital heart defects but account for

---

**Fig. 98.13.** The walls of the coronary artery and aorta are anastomosed with interrupted sutures of 8-0 polypropylene (Prolene), enlarging the ostium and preventing compression by the great vessels. The commissure of the aortic valve is resuspended with a pledgeted suture.

**Fig. 98.14.** A neo-ostium is created by opening the anomalous artery in the correct sinus as it exits the aortic wall. The intima is sewn to the aortic wall with interrupted sutures.
nearly half of all congenital coronary anomalies. They can be in isolation or together with other congenital heart disease. Acquired fistulas are the result of cardiac surgery, cardiac catheterization (including coronary angioplasty, other transcatheter procedure, endomyocardial biopsy), or from a complication due to Kawasaki disease.

Anatomy

Coronary artery fistulas may arise from either the right or the left coronary artery with occasionally both coronary arteries affected. Most arise from a coronary artery with an otherwise normal distribution. The fistulous connection may arise in the midportion of the coronary artery with a normal vessel continuing beyond the fistula or as an end artery at the termination of the vessel. In the portion of the vessel proximal to the fistula, the coronary is dilated and elongated, usually in proportion to the size of the shunt across the fistulous connection. The portion of the vessel distal to the fistula most often returns to a small diameter.

The most common sites of termination are the right ventricle and the right atrium. Fernandes and colleagues described 93 patients with coronary artery fistulas. A single fistula was present in 83 patients with the other 10 having multiple fistulas. The most common site of origin was the RCA with the right ventricle being the most common termination site. Fifty-six patients had isolated coronary fistulas and the others had additional cardiac lesions. In a review of 286 patients, Lowe and colleagues found the RCA to be the site of origin in just over half of the patients and the left coronary artery system in approximately one-third. The right ventricle was the most common site of drainage (39%), with the right atrium (including the coronary sinus and superior vena cava) and the pulmonary artery as the drainage sites in 33% and 20%, respectively. In the remaining 8%, the site of drainage was the left atrium or left ventricle.

Pathophysiology

Coronary fistulas result in a left-to-right or left-to-left shunt. When they drain to the right side of the circulation, there is usually a small-to-moderate sized shunt. However, when it drains into a left-sided chamber (i.e., left-to-left shunt), an aortic run-off develops with similar physiology as aortic regurgitation. The effects of the shunt are related to the amount of blood flow from the fistula to the chamber and into which chamber the fistula drains. It can also be affected by myocardial ischemia resulting from “steal” from the coronary circulation.

Clinical Presentation

In general, patients with coronary artery fistulae are asymptomatic and are therefore rarely diagnosed in infancy or childhood. Many patients are diagnosed serendipitously during a murmur evaluation. When symptomatic, the most common complaints are shortness of breath with exercise and fatigue. Angina is uncommon, even though there may be coronary steal. Ventricular dysfunction and congestive heart failure may occasionally be present and is much more common in the adult. In an older patient, atrial fibrillation may be caused by a coronary artery fistula to the right atrium, leading to right atrial enlargement.

On examination, a continuous murmur is often auscultated. The murmur may be confused with that of a PDA but is heard lower on the sternal border than would be typical for a PDA. Cardiomegaly may be present as well. Similar to aortic regurgitation, a wide pulse pressure may be appreciated in large left-to-left shunts.

Natural History

In congenital coronary arterial fistulas, the fistula is likely present early in life and gradually increases in size over several years. Despite progressive enlargement of the coronary arteries, spontaneous rupture is rare and is usually due to aneurysmal dilatation and weakening of the vessel wall due to a congenital defect or atherosclerosis. Bacterial endocarditis may occur secondary to turbulent flow. The spontaneous closure of small fistulas has been reported.

Diagnostic Imaging

A normal electrocardiogram is found in about one-half of patients or may show evidence of ventricular volume overload. Atrial fibrillation may be noted in older adult patients who have right atrial fistulous connections. If coronary steal is present, evidence of myocardial ischemia in the affected region may be noted.

Chest X-ray films are usually normal but may show cardiomegaly or evidence of congestive heart failure. Giant aneurysms of the involved coronary artery can sometimes be noted.

Two-dimensional echocardiography is useful to demonstrate the enlarged coronary artery, the origin of the fistula, the chamber into which it drains, and any cardiac chamber enlargement and/or hypertrophy. The actual fistula may be demonstrated best by color Doppler.

MRI is an additional noninvasive imaging technique to diagnose and provide detailed anatomy of the coronary arterial fistula; in time, it may take the place of cardiac catheterization, but currently it is still used as an adjunctive imaging modality.

Coronary catheterization with selective coronary angiography remains the gold standard to define the coronary anatomy and the hemodynamic significance of the fistula. These results help in planning the surgical repair. Often, an experienced interventional cardiologist can successfully coil embolize the coronary artery fistula without the morbidity associated with cardiopulmonary bypass and sternotomy. However, the indications for coil embolization have not been well-defined so most patients undergo surgical closure as the preferred therapy.

Surgical Management

Indications for Surgery

All patients with symptomatic fistulas should undergo closure. Patients with very small fistulas may not require surgical closure; however, because the natural progression of the fistula is to enlarge, these patients should be closely followed. Asymptomatic patients with moderate-to-large fistulas should undergo elective surgical closure.

Surgical Techniques

Coronary artery anatomy must be clearly defined by coronary angiography before surgical closure. Each operation should be individualized based on the anatomy. Often, the fistula can be ligated or oversewn at its origin or termination without the use of cardiopulmonary bypass; however, cardiopulmonary bypass should always be available.

Through a median sternotomy, the coronary anatomy is visualized and carefully inspected, noting the site of the enlarged vessel. The fistula may be ligated without the use of cardiopulmonary bypass when it is located at the distal end of the coronary artery and there is no viable myocardium distal to the fistula (Fig. 98.15). This is performed by placing a ligature around the coronary artery immediately proximal to the fistula, thus temporarily occluding the fistula. The heart is observed for signs of ischemia and the electrocardiogram is
monitored. If there are no signs of ischemia and there is adequate myocardial perfusion, the ligature is tied. To ensure complete closure, a second suture ligature should also be placed. Intraoperative transesophageal echocardiography is useful to verify whether the fistula is closed.

Cardiopulmonary bypass is indicated for several reasons, including: the fistula arises from the middle of a coronary artery, the fistula is inaccessible, another cardiac lesion needs to be repaired simultaneously, or if the complete coronary course is inadequately defined. The aorta and both cavae are cannulated and bypass is initiated. If cardiopletic arrest is necessary, the fistula should be temporarily compressed during administration of the cardioplegia to prevent run-off through the fistula into the heart. If adequate arrest is not possible because of flow through the fistula, retrograde administration of cardioplegia solution may be necessary.

There are a variety of techniques that may be used to close the fistula. If the fistula terminates in the mid-portion of the LAD, the fistulous communication can be closed by placing multiple pledgeted sutures beneath the coronary artery, while avoiding distal perfusion compromise (Fig. 98.15). If distal perfusion of the coronary bed is affected fistula closure, coronary bypass grafting may be necessary. Another technique that can be used when the fistula arises from the mid-portion of the coronary is to longitudinally open the coronary on the epicardial surface and oversew the origin of the fistula from within the coronary artery (Fig. 98.16). The coronary artery can then be closed primarily.

If the fistula terminates in the right atrium or right ventricle, it may be closed directly from within the cardiac chamber (Fig. 98.17). A right atriotomy is performed after cardiopulmonary bypass and the termination site of the fistula is identified from within the chamber. The use of cardioplegia may be helpful for localization. The termination site may be closed primarily or with a pericardial patch (Fig. 98.18).

**Surgical Results**

The operative mortality for coronary artery fistula repair is quite low with outstanding late results. Few patients appear to have recurrence of the fistula. Lowe and colleagues reported on 56 patients who underwent closure of isolated coronary artery fistula. There was no early or late mortality but two patients had perioperative myocardial infarctions. Finally, Mavroudis and colleagues reported on 17 pediatric patients with an average age of 5.5 years. Eight underwent fistula closure utilizing cardiopulmonary bypass with one of these patients requiring distal IMA bypass graft. There was complete closure in all with no recurrences without any operative or late deaths reported.

**CONGENITAL OSTIAL ATRESIA OF THE LEFT MAIN CORONARY ARTERY**

**Anatomy**

Congenital atresia of the LMCA ostium is a rare congenital coronary anomaly with <50 cases reported in the literature. As defined by Musiani et al., in this disease, there is no LMCA ostium; instead, the LAD and circumflex coronary arteries, which are located anatomically in the correct position, end blindly, and receive blood flow solely retrograde through the RCA, usually through at least one collateral vessel. These collateral vessels are generally inadequate to perfuse the left side of the heart and these patients are almost always symptomatic. While there is no coronary orifice from the left sinus of Valsalva, there may be a dimple on the inner aortic surface, a blind pouch, or no marking at all. This lesion is not the same as a single RCA; in the single coronary artery, blood flow occurs in a centrifugal, or antegrade, manner and most patients with this condition are asymptomatic, unless there is underlying atherosclerosis or congenital heart defects. Left main ostial atresia usually occurs alone; however, there has been associations noted with supravalvar aortic stenosis, VSD with pulmonic stenosis, right coronary ostial stenosis, and PDA and aortic regurgitation.

**Pathophysiology**

The main pathophysiology underlying congenital left main ostial atresia is collateral vessel flow from the RCA. There is blood flow from the RCA to the left coronary artery system through collateral vessels that are smaller in size than the left-sided coronary arteries. Therefore, there is not enough blood flow through these small
Fig. 98.16. (A) When the fistulous communication arises from the mid-portion of the dilated coronary, the coronary may be opened longitudinally and the origin of the fistula oversewn from within the coronary. (B) The coronary artery is closed primarily.

vessels to perfuse the myocardium, which leads to ischemia and the potential for sudden death.

**Clinical Presentation**
Clinically, there appears to be early-, middle- and late-onset presentations with congenital atresia of the LMCA ostium. However, no matter what age the presentation, nearly every patient reported in the literature was symptomatic. The difference in age at presentation likely has to do with the extent of the collateral circulation as well as the presence or absence of other congenital heart defects. The early-onset patients, generally infants and young children, present with clinical signs and symptoms similar to ALCAPA or dilated cardiomyopathy. These patients generally present with feeding difficulty, failure to thrive, emesis, and dyspnea. In one patient, a holosystolic murmur was present due to severe MR from infarcted papillary muscles. They are also more likely to have an associated heart defect, suggesting that there is increased ischemia due to other congenital lesions that may cause increased oxygen demand. The older children and adolescents tend to present with syncope, dyspnea, angina, and ventricular tachyarrhythmias. The older adults are likely to have dyspnea and angina. Sudden death as the first presentation is present at all ages.

**Diagnostic Imaging**
Because symptoms are nonspecific and can be due to other reasons, diagnostic imaging is imperative in this diagnosis. In infants and children, chest radiography may reveal cardiomegaly with pulmonary congestion due to heart failure; in adults, the radiograph may be normal. The 12-lead electrocardiogram may show evidence of anterolateral Q waves, lateral T wave inversion, right bundle branch block, or ventricular tachycardia. A transthoracic echocardiogram should be performed and is likely to show a dilated left ventricle with poor function and MR. This is similar to the echocardiographic findings in ALCAPA. Close attention should be paid to the coronary artery ostia. Doppler color flow can be used to demonstrate retrograde flow from the RCA to the left coronary artery system without filling of the pulmonary artery. However, this may be difficult to demonstrate with echocardiography alone. A cardiac catheterization with coronary angiography is the gold standard and should be performed on any patient with the suspicion of ALCAPA or congenital atresia of the left main coronary ostium. Angiography should note direction of flow from the RCA to the left coronary system and attempt to delineate whether or not the PA is filled retrograde. If there is a question with diagnosis, selective RCA angiography should be performed, if possible.

**Surgical Management**
Because of the high risk of sudden death with this ostial atresia of the LMCA, surgery should be undertaken immediately after diagnosis. The majority of the cases reported in the literature have been treated with CABG. This includes both children and adults. While CABG in adults may be the procedure of choice, the use of this procedure in children is questionable as the long-term results of CABG in children, especially using saphenous vein grafts, is questionable. More recently, there have been reports of surgical revascularization that creates a dual coronary artery system, with the belief that, like patients with ALCAPA, long-term outcomes should be improved.

Varghese and colleagues described the use of an autologous pericardial patch to attain surgical revascularization in a single case of left main coronary ostial atresia. Under cardiopulmonary bypass, the aorta was transected and a dimple was noted where the normal left coronary ostium should be. The aorta was then incised vertically to the location of the ostium and the incision was extended down the LMCA and ended before the bifurcation into the LAD and circumflex coronary arteries. If there is an atretic membrane, it is removed. An autologous pericardial patch was then used to reconstruct the atretic LMCA ostium.

Bonnet and colleagues described the use of surgical revascularization of the left main coronary arteries, with two of the patients having LMCA atresia. In their technique, after standard cardiopulmonary bypass, hot-induction blood cardioplegia, followed by cold blood cardioplegia, and warm reperfusion were used to help attain myocardial preservation. The main PA was transected to visualize the aortic root and left coronary artery system. The aortic incision began on the anterior portion of the aortic root, extending toward the coronary orifice. In those lesions that were atretic or occlude, such as in LMCA ostial atresia, the LMCA was incised beyond the atretic portion. Then, the two incisions (aortic and coronary) were connected using an onlay patch, consisting of saphenous vein, autologous pericardium, or PTFE. This patch not only enlarges the LMCA but also extends onto the portion of the aorta that was incised, creating a “funnel-shaped” neo-ostium.

Finally, Kaczorowski and colleagues recently described the use of homograft patch ostioplasty in the treatment of LMCA ostial atresia in three children (Fig. 98.19). In all cases, bicaval cannulation was used and cardiopulmonary bypass was established. Two of the 3 children, who were...
initially thought to have ALCAPA, had their PA opened to evaluate for a coronary ostium; when none was found, an aortotomy was performed. Exploration in the aorta revealed no coronary ostium. In two patients, after identifying the blind-ending LMCA on the surface of the heart, an incision was made in the aortic wall, directed inferiorly to the aortic sinus and an incision was made in the LMCA until its division into LAD and circumflex coronary arteries. The ostium was enlarged using a pulmonary homograft patch that also joined the aortic sinus to the proximal LMCA. In one patient, the blind-ending LMCA was sewn onto the posterior aortic wall with anterior augmentation. Confirmation of coronary patency was achieved using coronary probes and with evidence of back bleeding. The aortotomy (and pulmonary artery in two cases) was closed and the patients were removed from bypass.

**Surgical Outcomes**

Long-term outcome data are missing in this population. Long-term results from CABG used for other coronary arterial abnormalities (e.g., ALCAPA), remain uncertain, although some reports using IMA grafts have shown good results. Postoperative mortality, at least in the short term, appears to be related to the extent of myocardial damage at the time of diagnosis and operation. It appears that if LMCA ostial atresia is recognized early and the patient has enough collateral vessels, then short-term results are encouraging after surgical revascularization, notably with those procedures that establish a dual coronary system.

**SUGGESTED READINGS**

Brooks HSJ. Two cases of an abnormal coronary artery from the heart, arising from the pulmonary artery: with some remarks upon the effect of this anomaly in producing cirrhotic dilatation of the vessels. J Anat Physiol 1885;20:26-29.

Roberts WC, Kragel AH. Anomalous origin of either the right or left main coronary artery from the aorta without coursing of the anomalously arising artery between aorta and pulmonary trunk: analysis of 32 necropsy cases. Am J Cardiol 1988;62:1263-1267.

Roberts WC, Shirani J. The four subtypes of anomalous origin of the left main coronary artery from the right aortic sinus (or from the right coronary artery). Am J Cardiol 1992;70:119-121.

Multiple operations have been devised for the treatment of anomalous left coronary artery in children and are well outlined by Dr. Gaynor in this chapter. Although each technique may be applicable in certain circumstances, we believe that reimplantation of the coronary is the most ideal technique and establishes a two-coronary system with the least risk of late stenosis or occlusion. Past experience with the Takeuchi operation has also been favorable; however, we have seen cases in which the baffle dehisced in the pulmonary artery and created a left-to-right shunt, which in addition allowed decompression of the coronary artery. Thus, the reimplantation technique prevents the possibility of any left-to-right shunt through the coronary, and in the worst-case scenario, if the coronary occludes, the patient would have a situation similar to coronary ligation but at least would not have an additional volume load on the ventricle.

As described by Dr. Gaynor, we have taken the approach of reimplanting the coronary ostium in the left coronary sinus of Valsalva in a more anatomic location. Other authors have used a punch to create an opening in the aorta for reimplantation of the coronary. However, when this is used, the opening must be made more distally on the aorta to avoid blind damage to the commissural attachments of the aortic valve. Thus, we believe that it is simplest to open the aorta transversely, make an incision down into the left coronary sinus, and use the same suture line to close the aortotomy incision. In this way, damage to the aortic valve can be avoided and excellent exposure is obtained. We have used absorbable suture for the suture lines in young infants to encourage growth.

An additional controversy with anomalous left coronary artery is the management of significant mitral valve regurgitation in these patients. As noted by Dr. Gaynor, in the majority of cases, mitral regurgitation resolves when a two-coronary system is reestablished with resolution of distal myocardial ischemia and ventricular dysfunction. However, there are very rare cases of infants who have significant myocardial damage at the time of presentation and situations in which the papillary muscles themselves have undergone infarction with progressive elongation and fibrosis. In these patients, mitral valve repair can be undertaken with good results, often with papillary muscle shortening. Valve replacement for this condition should be extremely rare. One technical note at the time of operation in patients with anomalous left coronary artery is the fact that there is often a thin-walled venous plexus in the area between the aorta and pulmonary artery that has to be mobilized for the exposure to the coronary for reimplantation. This troublesome area of venous collaterals may require meticulous cautery to avoid significant bleeding after the reimplantation is performed.

Coronary arterial fistulas are rare, but the majority of fistulas should be closed. The transcatheter coil embolization or occlusion device techniques have become increasingly popular, and these fistulas can be closed in the catheterization laboratory. However, in patients with a broad-based fistula proximal in the coronary artery, occluder devices will potentially compromise coronary flow and, therefore, surgical treatment is the procedure of choice. As noted by Dr. Gaynor, in the majority of cases, either direct ligation in the epicardial course of the fistula or suture obliteration beneath the coronary artery as the fistula dives into the myocardium can be performed with the patient off cardiopulmonary bypass, with excellent closure rates. More distal end artery fistulas at the distal ends of coronary arteries can often be difficult to close because the exact distal extent of the origin of the fistula is sometimes difficult to determine from the epicardial surface. Ligation and even suture obliteration of these distal coronary arteries may be the most satisfactory technique for ensuring that there is no recurrence of the fistula or residual flow. Even when from an epicardial inspection the fistula appears to be completely closed, intraoperative echocardiography is valuable because minor amounts of flow may still be present and complete obliteration is the goal in all cases. Not uncommonly, we have seen residual flow that requires additional sutures or ligatures for complete obliteration.

The situation of anomalous origin of the left coronary from the right or the right coronary from the left passing between the great vessels is becoming an increasingly recognized entity. Although in the past, these coronary anomalies were most commonly seen at catheterization, more recently, the techniques of echocardiography and ultrafast computed tomography have identified these coronary anomalies more frequently. They are especially frequently identified in children who are undergoing echocardiography for participation in sports or for some other nonassociated vague symptomatology. This has led to a situation in which many of these patients are being identified who are totally asymptomatic and brings up the question of whether all patients with these anatomies should undergo surgical treatment. The overall incidence in the general population is not completely known. These lesions have been associated with sudden death in athletes, especially when there is a slit-like origin of the anomalous coronary. We have, therefore, found it difficult not to recommend surgical intervention in patients with a slit-like orifice of these anomalous coronaries because it is unclear which patients will have sudden cardiac symptoms and potentially even death from coronary compression.

It is now apparent from increasing experience with the anomalous aortic origin of the coronary artery from the inappropriate aortic sinus that the risk of sudden death, especially in patients with anomalous right coronary from the left coronary sinus is extremely low. Although clearly asymptomatic patients with signs of ischemia with this lesion should undergo surgical therapy, it is difficult to justify surgical intervention in patients who are completely asymptomatic and have this lesion found on a routine screening echocardiogram. Unfortunately in many cases, patients with this anomaly will be restricted from active athletics, which then significantly compromises the patient’s quality of life. In some cases, repair of these defects has to be performed simply to allow the patient to have a more normal life style. However, as has been noted in the chapter, a study at The Children’s Hospital of Philadelphia has shown that even with complete repair of these defects subclinical ischemia can be identified in some cases. Therefore, the true value of surgical intervention for this condition is not well-defined.

Patients who have a single coronary artery with a branch crossing between

(continued)
the great vessels have an unknown risk for ischemia and sudden death. In most of these cases, there is no mechanism for the compression of the anomalous course of the vessel, unless there is a slit-like orifice. Certainly, in patients in whom the vessel passes intramyocardially through the septum, there has not been an incidence of sudden death, and most of these situations are benign variations in anatomy.

The value of translocating the pulmonary artery to the left to separate the great vessels is somewhat controversial, since the annulus of the aortic valve and the infundibulum of the pulmonary outflow tract is fixed and moving the distal vessel causes relatively little variation in the anatomy at the level of the coronary artery.

As imaging modalities are becoming more and more accurate, more abnormal coronary arteries are being picked up in childhood.

Some believe most anomalous origins of the right coronary from the left coronary sinus should be considered a normal variant and surgery should not be recommended.

The use of CABG and coronary reimplantation is less desirable than unroofing procedures. Bypass of an anomalous coronary, even with an internal mammary artery, may be associated with closure or stenosis of the bypass graft due to competitive flow through what is in most circumstances a situation of normal coronary flow. Thus, in the absence of proximal stenosis, bypass grafting should not be a primary therapy. TLS
The first pediatric heart transplant was performed by Dr. Adrian Kantrowitz on a small infant with tricuspid atresia in 1967. The child died soon after the procedure but this ushered in the concept of heart replacement for unreconstructable congenital heart disease. There were very few transplants in children from the late 1960s into the early 1980s. From the mid-1980s onward there was a steady increase in the number of pediatric transplants related in large part to the development of cyclosporine as an immunosuppressant as well as the successes of the group at Loma Linda University led by Dr. Leonard Bailey in children and that of Norman Shumway at Stanford University. Approximately 400 to 450 heart transplants are performed in children per year throughout the world. This number has been relatively static over the past 15 years. Survival in children is similar to that seen in adults at 5 to 10 years post-transplant but improves at 15 years (48% vs. 34%). A number of changes have occurred in pediatric heart transplantation over the past 20 years. Transplantation as primary therapy for any congenital heart disease (hypoplastic left heart syndrome in particular) is unusual. There has been a steady increase in the use of ventricular assist for children with end-stage heart failure, usually due to cardiomyopathy. This chapter will reflect some of these changes. Although “pediatric heart transplantation” should be limited by age, I will also include transplantation in adults with congenital diagnoses.

INDICATIONS
Heart transplantation in children has two basic indications—cardiomyopathy and congenital heart disease. On balance, these indications are approximately evenly split, although the congenital diagnosis predominates in younger patients and cardiomyopathy accounts for the majority of patients in the teenage group. The technical aspects of the procedure in cardiomyopathy are no different than that used in adults. The technical challenges lie in replacing the heart in a child with disordered anatomic arrangements of the great vessels (arteries and veins) and with anatomic derangements made so by prior corrective or palliative procedures. Hypoplastic left heart syndrome was a major indication for heart transplantation in the early 1990s in large part due to the poor survival following the Norwood procedure. Current survival with reconstructive first-stage palliation has been approximately 80% for the participants in the congenital registry of the Society of Thoracic Surgeons. In addition to this, transplant waiting time mortality may be as much as 20% to 25% in this group of neonates. It is impractical to consider transplantation for even half of infants with hypoplastic left heart syndrome in that at least 500 infants are born each year with this congenital lesion in the United States where less than 100 donors in this age group are available. Among those with congenital heart disease as the primary diagnosis, most have single-ventricle anatomy and may be at various stages of the reconstructive pathway from diagnosis to Fontan. Whereas a better understanding of the implications of early palliation for these patients has led to more successful outcomes with the Fontan procedure, the survival curves for those patients clearly declines at a much faster pace than the normal population or even the overall survival curve for children with congenital heart disease. These patients present with need for special consideration as far as the technical aspects of the transplant, the presence of significant elevation in pulmonary vascular resistance, the presence of preformed antibodies, and the presence of multiple small aortopulmonary collaterals. There remain a significant number of young adults who survived atrial switch procedures for transposition of the great arteries. Many (all?) of those patients will ultimately develop heart failure. This group will be out of the age range for pediatrics, but a clear understanding of the anatomy involved is necessary for a technically successful outcome.

CONTRAINDICATIONS
Absolute contraindications to heart transplantation include ongoing malignancy, multiscystem organ failure refractory to intensive treatment for heart failure, uncontrolled infection, and significant psychosocial issues. The presence of renal or hepatic dysfunction depends in large part on the degree and whether the patient might be candidate for combined or staged transplantation of either the liver or kidney. Elevated bilirubin has consistently been a marker for poor outcomes in heart transplantation. Renal dysfunction may be particularly problematic as both cyclosporine and tacrolimus (the primary drugs of immunosuppressant regimens posttransplant) have significant nephrotoxic side effects. The availability of effective mechanical support in children has broadened the recipient pool to some degree as those patients with significant organ dysfunction can be stabilized with ventricular assist devices and made better candidates.

Elevated pulmonary vascular resistance has been a classic risk factor for heart transplantation. The availability of multiple drugs to treat this in both the acute and chronic setting has altered the approach to this. As a baseline, the pulmonary vascular resistance should be <6 to 8 Woods units and the transpulmonary gradient should be <15 mmHg. It is often difficult to obtain accurate values of one or both of these because of congenital or acquired anatomy, resulting in multiple sources of pulmonary blood flow and difficulty accessing the pulmonary vasculature at the time of the cardiac catheterization. Patients deemed to be at high risk due to elevated pulmonary vascular resistance should be extensively studied to evaluate their response to a variety of pulmonary vasodilators. A lack of response acutely should be followed by long-term treatment with pulmonary vasodilators such as bosentan or prostacyclin in combination with inotropic support and then re-studied. Occasionally, an open lung biopsy may be of use to evaluate the presence of coexisting pulmonary parenchymal
ventricular end-diastolic pressure may benefit from ventricular assist device implantation for several weeks and then reevaluated. Failing these measures, heart-lung transplantation would be an alternative, recognizing that the long-term prognosis following this transplant procedure is significantly worse than isolated heart transplantation.

**DONOR ASSESSMENT/ MANAGEMENT**

After the usual criteria for donor acceptance have been met (blood-type compatibility, absence of transplantable disease), size match and organ function are then considered. Size match is of particular concern for small infants as very small donors are unusual. Accepting a heart from a donor three times the weight of the recipient will generally work out well, realizing that it may be necessary to open the left pleural space, remove some pericardium, and leave the sternum open for a few days posttransplant. For older children and teenagers, the range is usually 20% above and below the recipient weight. Many surgeons are of the opinion that a larger donor is preferred for patients with borderline elevated pulmonary vascular resistance; there are little data to support that position. Blood-type compatibility has been challenged in infants up to 1 year of age with results that mimic earlier results, albeit with more a complex immunosuppressive regimen.

The assessment of donor heart function is typically done with echocardiography only. The donor should be on only a modest degree of inotropic support with satisfactory blood pressure and evidence of good cardiac output clinically. Evaluation of the cardiac markers of ischemia (myocardial fraction of creatine phosphokinase and cardiac troponin I) should be routine. Donor hearts with borderline systolic function may be resuscitated using intravenous infusion of triiodothyronine. The basis of this is evidence that brain death is associated with reduction in cortisol and thyroid hormone production. Vasopressin is often necessary in the treatment of diabetes insipidus; the use of this drug will often allow a reduction in inotropic support. There are no absolute guidelines for the upper limit of inotropic support allowable for a donor heart to avoid posttransplant primary graft dysfunction, but generally one should avoid those requiring high doses of two or more.

**POST-TRANSPLANT COMPLICATIONS**

**Graft Failure**

This is the most common cause of early posttransplant deaths, especially in those transplanted at \(<1\) year of age. Graft failure may be related to poor preservation, poor donor selection, early rejection, pulmonary hypertension, or technical issues. Support for graft failure posttransplant is usually ECMO. Intra-aortic balloon counterpulsation is generally ineffective in children with fast heart rates and a compliant aorta. Ventricular assist is feasible with current small devices available. Pulmonary hypertension as a cause of early graft failure usually presents with elevated central venous pressure, tricuspid valve regurgitation, and low cardiac output. The pulmonary artery and right ventricular pressure may not be elevated because the donor right ventricle may not be able to generate high pressures. The usual measures of treatment would be sedation with neuromuscular paralysis, inhaled nitric oxide, and inotropic support. Occasionally, mechanical support is necessary. One must be certain that there are no technical problems with the pulmonary artery anatomy or anastomosis, particularly in the setting of prior palliative operations involving the pulmonary arteries.

**Rejection**

The incidence of acute rejection is lower in infants than in older children and teenagers. Nonetheless, surveillance is necessary in all age groups. A high index of suspicion should be maintained in patients with preformed antibodies going into the transplant procedure. The diagnosis of cell-mediated rejection is relatively straightforward using endomyocardial biopsy material. Antibody-mediated rejection, however, is significantly more difficult to diagnose. Although biopsy material can be stained for complement factors (C4d being the most common), this is not completely reliable. Evidence of poor cardiac function clinically and by echocardiography with a biopsy that is negative for cellular rejection should prompt this diagnosis. Treatment for acute cellular rejection is high-dose steroids (10 mg/kg methylprednisolone intravenously) daily for 3 days. Antibody-mediated rejection requires plasmapheresis as well as drugs aimed at reducing the production of antibodies.

**Bleeding**

These patients often come to transplant having had multiple prior operations with the anticipated adhesions. In addition, they may be taking anticoagulants or have disordered hemostatic mechanism due to long-standing heart failure. Additional use of blood products is anticipated.

**Other Complications**

Infection is a constant risk for these patients due to the immunosuppression necessary. Prophylaxis against *Pneumocystis jiroveci* is necessary using either sulfamethoxazole/trimethoprim daily or inhaled pentamidine monthly. Renal insufficiency related to marginal pretransplant renal function and calcineurin inhibitors posttransplant is relatively common to some degree and may occasionally require temporary dialysis. Seizures may occur in 5% to 10% of patients due to posterior reversible encephalopathy syndrome. Posttransplant coronary vasculopathy is a long-term complication, occurring in 35% of patients by 10 years posttransplant; this is much more common in adults, present in more than 50% at 10 years posttransplant. Lymphoproliferative disorder and other malignancies are present in approximately 10% of patients in long-term follow-up.

**OPERATIVE TECHNIQUES**

**General Comments**

As mentioned above, the technique of transplantation for patients with cardiomyopathy is the same as with adult transplantation and will not be presented further in this chapter. The focus will be on issues that are unique to congenital heart disease. The number of different combinations of congenital anomalies and their anatomic nuances preclude an encyclopedic description of each method of recipient preparation and donor implant. The principles presented for the conditions described can be adapted for each individual situation. The patients with single-ventricle anomalies provide the greatest challenges primarily because of the abnormalities in situs and venous anatomy as well as the obligatory pulmonary artery anomalies associated with the palliative procedures that these children have undergone in the past. Careful planning of the procedure by reviewing prior operative notes, cardiac catheterizations, and other imaging studies is crucial to conducting a safe operation. A computed tomography (CT) scan with contrast is particularly
helpful in providing landmarks for careful sternal re-entry. It is important to obtain sufficient donor tissue for whatever reconstruction is necessary, usually the superior vena cava and branch pulmonary arteries. In the setting of multiorgan retrieval where lungs in particular are being retrieved, additional length of aorta should be obtained to use if pulmonary artery reconstruction is anticipated. Alternatively, some of the native tissue that would otherwise be discarded with the recipient heart may be suitable for patches. Caval anastomoses (as opposed to an atrial anastomosis) have become the standard for transplantation with the exception of small infants where the risk of anastomotic narrowing of the superior vena cava is relatively high.

Hypoplastic Left Heart Syndrome

Although reconstructive surgery has generally supplanted transplantation as primary therapy for HLHS, there are circumstances where the risks of the Norwood procedure are prohibitive and the balance shifts toward transplantation. These risk factors are pulmonary valve stenosis or regurgitation, severe right ventricular dysfunction, severe tricuspid valve regurgitation, or syndromic infants (e.g., Turner syndrome). Small size (<2.5 kg) is another risk factor for the Norwood procedure, but finding a suitably small donor is problematic.

Donor Procurement

The major concern is to acquire all of the aortic arch and the proximal descending thoracic aorta to the level of the ligamentum arteriosum. This provides sufficient donor aorta for the arch reconstruction. At the time of donor operation, the innominate vein may be ligated to get better access to the arch vessels. After aortic clamping and cardioplegia administration, the innominate, left carotid, and left subclavian arteries are divided at their origins. The descending aorta is taken just beyond the ligamentum arteriosum. The rest of the procurement proceeds as per the usual technique.

Recipient Operation

The ductus arteriosus, branch pulmonary arteries, and aortic arch with its branches are dissected out extensively. When dissecting out the ductus arteriosus and during the distal arch reconstruction, care must be taken to avoid injury to the recurrent laryngeal nerve. Cannulation for arterial inflow may be performed by one of the three methods: via the main pulmonary artery with control of the branch pulmonary arteries, directly into the ductus arteriosus with ligation of the pulmonary artery end of the ductus, or via the innominate artery usually through a small graft sewn to the innominate. The last method provides the greatest flexibility for cannulation during the organ implant and potentially allows for regional perfusion during arch reconstruction so that no period of circulatory arrest is necessary. Bicaval cannulation is generally preferred and the patient is cooled to 18°C. While the cooling is proceeding, the donor heart is prepared by removing the cephalad aspect of the aortic arch leaving a “tongue” of aorta to reconstruct the arch (Fig. 99.1A). The recipient heart is excised, ligating the ascending aorta with a silk tie (Fig. 99.1B). The left atrial anastomosis is performed first. I prefer to perform

---

![Fig. 99.1.](image_url) Transplantation for hypoplastic left heart syndrome. (A) The recipient heart is removed leaving right and left atrial cuffs and dividing the main pulmonary artery between the bifurcation and the sinotubular ridge of the pulmonary valve. The ascending aorta is transected below the innominate artery and the underside of the aorta is opened beyond the insertion of the ductus arteriosus. (B) The donor heart should be retrieved with a segment of aortic arch all the way to the ligamentum arteriosus of the donor. The arch branches are removed leaving a “tongue” of aortic tissue for the arch reconstruction. (C) The transplant is performed with the left atrial anastomosis first, followed by the posterior right atrial anastomosis and then the arch reconstruction. (D) The pulmonary artery and anterior right atrial anastomosis are completed with the cross-clamp removed.
a portion of the right atrial anastomosis now because visualization will compromise coronary sinus blood return once the aortic reconstruction is completed and the clamp removed. At this point, either circulatory arrest or regional cerebral perfusion is initiated. Regional perfusion requires occlusion of the innominate artery proximal to the inflow graft sewn there and occlusion of the other arch branches as well as clamping the descending thoracic aorta 1 to 2 cm beyond the insertion of the ductus arteriosus. All the ductal tissues are excised and an incision is carried down into the aorta beyond the distal extent of ductal tissue. The remainder of the aortic arch is opened all the way to the distal ascending aorta (Fig. 99.1C). The aortic anastomosis is performed beginning distally and bringing the suture line all the way around the entire aortic arch. Following completion of this, the pulmonary artery anastomosis is performed in an end-to-end manner; the recipient MPA is often much larger than the donor. Finally, the transplant is completed with the anterior portion of the right atrial anastomosis (Fig. 99.1D).

Approximately 15% of all infants with HLHS have bilateral superior venae cavae (Fig. 99.2A). There are two methods of handling this. One is to take the donor innominate vein and sew the end of this to the end of the left superior vena cava. In this case, the right SVC will have to be sewn to the donor SVC. Another (preferred by me) is to perform the recipient cardectomy in such a manner as to leave the coronary sinus attached to the left atrial posterior wall, emptying into the recipient right atrium (Fig. 99.2B and 99.2C). The coronary vein branches have to be ligated or included in the left atrial suture line to control bleeding. This avoids an anastomosis to small, thin-walled vessels which would be at risk for stenosis.

The posttransplant management of these infants is similar to the care required for any infant undergoing major open heart surgery with the exception of a higher risk of pulmonary hypertension. Most of these infants have been waiting for a prolonged period of time with a significant left-to-right shunt imposed by the circulation associated with HLHS. Given the high risk, it is reasonable to preemptively treat with nitric oxide and neuromuscular blockade.

**“Congenitally Corrected” Transposition of the Great Arteries**

These patients have discordant connection on both the ventriculoarterial level and atrioventricular level, resulting in no net shunt or cyanosis, but an anatomic right ventricle serving as the systemic ventricle and the anatomic left ventricle serving as the pulmonary ventricle. The natural history of this lesion varies considerably, in part related to the associated cardiac anomalies. However, it is typical for the anatomic right ventricular function to begin to deteriorate as patients approach adult years. Tricuspid valve regurgitation is a complicating factor in this clinical deterioration. A typical patient will have had a prior operation—closure of ventricular septal defect with or without a conduit from the pulmonary ventricle to the main pulmonary artery. A pacemaker is often in place as well. Some patients will have had an “anatomic correction”—arterial switch + atrial switch. Although that operation restores “normal anatomy,” some patients will have progressive poor ventricular function of the anatomic left ventricle.

**Donor Operation**

This is the same as a typical cardiac harvest. It is helpful to retrieve as much length of the ascending aorta as possible.

**Recipient Operation**

The aorta is generally off to the left of the midline and anterior (Fig. 99.3A).
Cardiopulmonary bypass is initiated per the usual techniques. The aorta is transected relatively cephalad so that it is closer to the midline. The branch pulmonary arteries are mobilized so that the main pulmonary artery can be placed off to the patient’s left. It may be necessary to open the left pulmonary artery and close a portion of the right side of the main pulmonary artery to place this anastomosis in the appropriate position. The pulmonary artery anastomosis should be performed prior to the aortic anastomosis so that visualization is optimized (Fig. 99.3B). The remainder of the transplant procedure is conducted in the usual manner. Again, a long length of donor aorta may facilitate this connection.

Transposition of the Great Arteries—Status Post-Senning or Mustard Procedure

Most centers stopped performing the atrial switch procedures for transposition of the great arteries in the mid-1980s. Thus, the youngest patient presenting for transplantation with this anatomy will be approximately 25 years old. Nonetheless, these are transplants that should be performed by a surgeon familiar with congenital heart disease. It is often difficult to recognize deterioration in these patients based upon objective imaging data. The echocardiogram typically shows a dilated anatomic right ventricle with diminished systolic function for many years. Functional data such as VO$_2$ max may be useful. Symptoms of progressive heart failure are most important and indicative of impending problems. Cardiac catheterization is important to evaluate for pulmonary hypertension and any evidence of baffle stenosis, particularly in the patients post-Mustard repair. This will need to be relieved prior to transplantation if present, usually by balloon dilatation with or without stenting. Many of these patients will have pacemakers in place.

Donor Operation

No special alterations in the donor harvest are necessary. Additional length on the aorta and main pulmonary artery should be obtained.

Recipient Operation

Careful sternal re-entry is important as with any patient undergoing redo cardiac surgery. In this case, the right ventricle and/or the pulmonary venous atrium are very dilated and often pressed up against the back of the sternum. Injury to this will likely result in significant hemodynamic deterioration. The recipient cardectomy must be performed recognizing that the pulmonary venous atrium is now in a very anterior position (basically where the right atrium usually lies). Opening into this allows the surgeon to visualize the baffle so that it can be excised in its entirety. For the post-Mustard patients, this involves simply resecting the prosthetic patch (Fig. 99.4A). Occasionally, this is pericardium. This may make it difficult to identify borders as it is sewn to the interior of the atrial mass. Once this baffle is removed, it is obvious how best to proceed to provide a site for the left atrial anastomosis. The SVC and IVC will need to be cut off the atrial mass with as much tissue as feasible to allow for wide open anastomoses. Any stenosis in the SVC can be handled by either taking the anastomosis up higher or patching it. For the post-Senning patients, there are three layers to enter to get to the posterior left atrial wall (Fig. 99.4B and 99.4C). First, the anterior "right" atrial wall, entering the anterior pulmonary venous confluence. Next the anterior wall of the systemic venous pathway is in view. After penetrating that, one encounters the barrier created by the atrial septum sewn anterior to the left pulmonary venous orifices. The SVC and IVC should be removed with a cuff of atrial tissue followed by the removal of all barriers to the posterior atrial wall to get to the original left atrium so that the left atrial anastomosis is performed without any intervening tissue between the pulmonary venous orifices and the donor mitral valve. In the case of both the post-Senning and post-Mustard transplants, there will be a large amount of atrial tissue to trim away to prepare for the left atrial anastomosis. As with "corrected transposition," the pulmonary artery anastomosis may need to be moved to the

Fig. 99.3. Transplantation for “congenitally corrected” transposition of the great arteries. (A) The aorta is positioned to the left and anterior; occasionally, it is quite far out into the left side of the mediastinum. The main pulmonary artery is to the right and posterior to the aorta. (B) The recipient cardectomy has been performed; the aorta is divided distally, in a more medial position. The pulmonary artery anastomosis is placed partially into the left pulmonary artery, rather than directly into the recipient main pulmonary artery. (C) The completed transplant demonstrating the aorta now in a more normal position to the right of the pulmonary bifurcation.
left by incising from the orifice of the MPA into the LPA while closing off some of the right side of the MPA.

**Failed Fontan**

This is an increasing indication for heart transplantation in pediatrics. With improved survival of both early neonatal palliation of single-ventricle anatomy and the Fontan procedure itself, there are more children and young adults living with this circulation, some of whom develop complications requiring transplantation. Heart failure and protein-losing enteropathy are the two most common indications in this group.

**Donor Operation**

Pulmonary artery reconstruction or patch angioplasty and dealing with anomalies of the systemic venous return are the two anatomic challenges to transplantation in this group. The harvest should include as much of the superior vena cava as possible—at least up to the entry of the innominate vein—and branch pulmonary arteries. If the lungs are being harvested for transplantation, the pulmonary artery length will be limited. Taking some of the descending thoracic aorta will add to the flexibility of the transplant procedure.

**Recipient Operation**

This transplant procedure is perhaps the most challenging of what might be considered "standard" transplant procedures for congenital heart disease. It is challenging because of the multiple prior sternotomies, the native anatomy, the constructed anatomy, and the consequences of long-term cyanosis and of the Fontan circulation (chronically elevated central venous pressure). The cardiovascular structures may be densely adherent to the back of the sternum, creating potential havoc with sternal re-entry. The aortopulmonary collaterals complicate management of cardiopulmonary bypass as well as visualization of the anatomy with the heart opened and removed. Cannulation of the IVC may be difficult because of the location and nature of the conduit used to baffle the IVC to the pulmonary artery. There is generally no main pulmonary artery to identify, but rather a long confluent pulmonary artery between the hilar regions. The Fontan connections to the pulmonary arteries will have to be patched or taken down in such a way as to avoid creating stenosis there. Finally, these patients usually come to transplantation with very poor nutritional status related to protein losing enteropathy, some degree of liver dysfunction, and presensitized on an immunologic basis.

The illustrations for this show a post-Fontan recipient with associated bilateral superior venae cavae and thus bilateral Glenn shunts (Fig. 99.5A–99.5E). In this instance, the IVC is baffled to the pulmonary artery via an intra-atrial approach. Cannulation is performed high in the SVCs and as low as possible in the IVC. It may be possible to cannulate only the right SVC as there is an extensive network of venous connections in the facial and intracranial venous systems. In this case, the left SVC is snared to simplify the procedure. It is advisable to check the venous pressure above the snare to be sure that venous hypertension will not be an issue. The recipient cardiectomy is performed removing most of the right atrium and the entire cavopulmonary baffle. A cuff of right atrial tissue should be left on the orifice of the IVC to provide a bit more length for this anastomosis. The bilateral SVCs may be handled in couple of ways. Each of these will be presented separately.

The first method involves removing each SVC from its site of connection to the pulmonary artery with a plan of attachment to the donor innominate vein and right SVC. In most cases, the pulmonary artery defects left will require patching with appropriate material rather than directly oversewn. The transplant procedure is modified to allow
Fig. 99.5. Transplantation for "failed" Fontan. (A) This illustrates the heart of a patient with bilateral superior venae cavae and an intra-atrial lateral tunnel type of Fontan. Both superior venae cavae (SVCs) are anastomosed directly to the pulmonary artery. The IVC blood is directed via the intra-atrial baffle to the cardiac end of the SVC which is anastomosed to the underside of the right pulmonary artery. (B) In this illustration, the right and left SVCs have been disconnected from the respective pulmonary arteries which are then patched. A long segment of innominate vein obtained from the donor harvest is attached to the left SVC and the right SVC is then attached to the junction of the donor SVC and innominate vein. The undersides of the right pulmonary artery is patched and the inferior vena cava (IVC) is anastomosed directly to the donor IVC. The illustration shows the innominate vein draped over the aorta; this is usually better placed posterior to the ascending aorta. (C) An alternative is to use the mediastinal pulmonary artery segment connecting the SVCs as an "innominate vein." The right and left pulmonary arteries are transected just lateral to the insertions of the SVCs on each side. The left lateral end is either patched or oversewn. The lateral opening on the right side will be used to connect to the donor SVC. (D) If the entire mediastinal branch pulmonary arteries are not available with the donor heart, an interposition graft of the donor descending thoracic aorta (taken at the time of harvest) or a synthetic graft is placed between the distal right and left pulmonary arteries. An opening in this graft is created at the proposed site for the donor pulmonary artery anastomosis. (E) The transplant procedure is then performed connecting the donor main pulmonary artery to the opening created in the interposition graft. The donor SVC is connected to the segment of recipient pulmonary artery between the SVCs and the IVC is anastomosed directly to the donor IVC.

for an anastomosis between the innominate vein and the left SVC. This donor innominate vein is usually best positioned behind the ascending aorta rather than draped across the top of the aorta. The left SVC is in a somewhat posterior position as well. The right SVC is anastomosed directly to the donor SVC and the recipient IVC is attached to the donor IVC end-to-end. The donor main pulmonary artery is connected to the mediastinal pulmonary artery at an appropriate position from hilum to hilum. This is facilitated if there is a long segment of donor pulmonary artery available.

An alternative method is to leave the SVCs attached to the recipient pulmonary artery, as illustrated in Figure 99.5 series. This intervening segment of pulmonary artery between the SVCs becomes the "innominate vein" as it is detached from the more distal right and left pulmonary
arteries proximal to their hilar continuation. The new pulmonary artery segment is then reconstructed either by using the harvested donor branch pulmonary arteries left in continuity with the main pulmonary artery or with an intervening vascular conduit between the hilar regions. This conduit may be donor descending thoracic aorta or a synthetic tube graft. The advantage of leaving the SVCs connected to the recipient pulmonary artery is that it avoids the tedious nature of an anastomosis of a very thin-walled, fragile vein to another, risking suture line stricture. The disadvantage is that the reconstruction involves anastomoses to both branch pulmonary arteries in the hilar regions. If the donor aortic segment or synthetic tube graft is used for the pulmonary artery reconstruction, this can be done with the recipient heart out of the operative field simplifying this procedure. Circulatory arrest may also facilitate any of these steps in the reconstruction to avoid the field being obscured by pulmonary venous return from the extensive aortopulmonary collaterals generally present. The donor pulmonary artery anastomosis is then performed in an appropriate location in the mediastinal pulmonary artery segment. The donor SVC is connected to the underside of the new "innominate vein," and the IVC anastomosis is to the donor IVC. The order of connections is usually the left atrium, followed by the pulmonary artery reconstruction, the inferior vena cava, and finally the aorta. The cross-clamp can be removed at this point and the SVC anastomosis performed while rewarming.

In the presence of a "classic" Glenn shunt (where the pulmonary arteries are rendered discontinuous), the pulmonary artery reconstruction will nearly always require an additional segment of donor vascular tissue for an interposition graft. If the prior Fontan procedure was an atrio-pulmonary type, the most difficult part of the procedure may be sternal re-entry. An imaging study is crucial in these patients to identify what is lying directly behind the sternum. The right atrium in this situation is often enormous and stuck directly to the back side of the sternum. It may be necessary to begin cardiopulmonary bypass via femoral access prior to the sternotomy to avoid inadvertent entry into the right atrium which is much more difficult to control than even aortic entry. This leads to extremely long cardiopulmonary bypass times but is obviously preferable to the alternative.

**Situs Inversus**

These patients often have complex associated congenital heart disease, usually of a single-ventricle variety and will have had multiple prior procedures. Occasionally, this is associated with an isolated cardiomyopathy, but that is less common. In either instance, this entity is a significant technical challenge for transplantation. The likelihood of finding a suitable donor who happens to have situs inversus and an otherwise normal heart is extraordinarily unlikely given that it is estimated to occur at a rate of 2 per 10,000 in the general population. I have never encountered this in over 20 years of heart transplantation experience. Thus, techniques designed to modify the recipient anatomy to accommodate placement of a normal heart is necessary.

**Donor Operation**

Donor procurement depends on how the surgeon specifically plans to handle the systemic and pulmonary venous connections as well as the needs based upon associated anomalies and prior palliative procedures. To allow for the greatest flexibility, the harvest should include all the SVC and a long segment of innominate vein. If the patient has had a prior Glenn shunt or Fontan procedure, one should harvest as much mediastinal pulmonary artery or descending thoracic aorta as possible.

**Recipient Operation**

Cannulation directly into the SVC and IVC at points as far distant from the right atrium is necessary. The aorta should be cannulated in a distal location as well. The incision in the right atrium is near the atrioventricular groove, leaving sufficient amount of tissue for the modifications necessary for the implantation of the donor heart. The incision in the left atrium is also near the atrioventricular groove. As much of the atrial septum as possible should be left behind. The pulmonary artery is transected close to the bifurcation. The aorta is transected distally to move the anastomosis closer to the midline.

One acceptable technique for implantation of the donor heart is reminiscent of the Senning procedure for transposition of the great arteries (Fig. 99.6A–99.6D). The atrial septum of the donor is mobilized by dividing it at its caudal and cephalad portions. It is then reattached to the free wall of the left atrium anterior to the right-sided pulmonary veins. When an atrial septal defect is present, pericardium or prosthetic material may be used in addition to or in place of the atrial septal tissue. This directs the pulmonary venous return from the right lung to the left across the midline. The interatrial groove is then mobilized extensively. An atriotomy is placed anterior to the left-sided pulmonary veins. The left atrial anastomosis is thus placed on the left side of the mediastinum. It is usually necessary to perform the right atrial anastomosis next. A portion of the left superior aspect of the right atriotomy can be closed primarily to move more of this anastomosis to the right and to better match the size of the donor right atrial cuff. The recipient pulmonary artery is usually positioned to the patient’s right. This can be effectively moved to the left by mobilizing the branches or by extending the arteriotomy out onto the left pulmonary artery while partially closing the right side. The pulmonary artery anastomosis should be performed before the aortic anastomosis so that the pulmonary artery can be accurately seen. The aortic anastomosis is performed in the usual manner, but perhaps more distally so that it is closer to the midline.

There are other techniques that may be applied and may serve as better options, depending on the associated anomalies. The first of these is a modification of that described previously in which the atrial groove is dissected extensively and split so that two separate atria result. Frequently, the anterior portion of the atrial septum is too thin to precisely split; in that case, the septum should be devoted to the pulmonary venous atrium. These two atrial orifices are then transposed, moving the systemic (left-sided) atrium anterior and to the right and moving the pulmonary (right-sided) atrium posterior and to the left. The SVC and IVC need to be extensively mobilized—dividing the azygos vein above and mobilizing the subdiaphragmatic veins below. The atrial and arterial connections are then performed as described previously.

Another modification is based on the principle of devoting the atrial mass to the pulmonary venous connection and reestablishing systemic venous flow with bicaval communications. This may be the preferred technique when the patient has undergone palliation for associated single-ventricle anatomy. Cannulation in the SVC must be at or above the entry of the innominate vein and in the inferior vena cava below the diaphragm. The left-sided SVC is divided at its junction with the heart and just below the entry of the innominate vein. The cardiac end of the SVC is oversewn. The donor SVC is connected to the right side of
Section III: Congenital Cardiac Surgery

**Fig. 99.6.** Transplantation for situs inversus. (A) This illustrates a patient with “simple” situs inversus—no associated congenital heart disease. The SVC and IVC enter the right atrium on the patient’s left side and the left atrium is on the patient’s right side. (B) The recipient cardectomy has been performed leaving a large amount of atrial wall and septum behind. The atrial septum is mobilized by cutting the caudal and cephalad portions back. The dashed line is the proposed site for the left atrial anastomosis. (C) The cut edge of the atrial septum is sewn to the free wall of the left atrium anterior to the entry of the right pulmonary veins. The atrial groove on the left side is extensively dissected out, and an atriotomy is placed just anterior to the entry of the left pulmonary veins. The donor heart is then sewn in place starting with the left atrial anastomosis on the patient’s left side. The right atrial anastomosis is placed to the new right atrial opening into which both venae cavae have been directed. The pulmonary artery anastomosis will be moved out onto the left pulmonary artery somewhat because the recipient main pulmonary artery is often too far to the right. (D) The completed transplant.

the recipient innominate vein, placing this on the patient’s right side. The recipient IVC may be divided on the right side to assist with this. Leaving a flap of right atrial tissue attached to the IVC may be of assistance. Splitting the orifice to the IVC on the right side and sewing it to the pericardium to the right of it also moves the orifice closer to an appropriate anatomic location. The left atrial anastomosis is performed to a portion of the systemic venous atrium on the patient’s left side. The remainder of the transplant procedure is carried as per usual techniques.

It may be necessary to carry out the transplant procedure with a combination of these techniques to accommodate the anatomy with which the patient presents. In any event, it is a formidable challenge and one should be aware of the potential for obstruction in the various pathways created so that they may be dealt with either by interventional cardiac catheterization procedures or by reoperation.

**SUMMARY**

There are no anatomic contraindications to heart transplantation. Any anomaly has a suitable means of implantation of the donor heart, although it may be necessary to alter the recipient anatomy and donor procurement to meet the individual needs. In addition, heart transplantation can be successfully performed in the presence of situs inversus totalis. It is essential that a full anatomic evaluation of the recipient be performed in addition to a careful review of prior operative reports so that appropriate plans can be made for donor procurement as well as the transplant procedure itself. The surgeon should have thorough understanding of congenital heart disease and experience in the various palliative and corrective procedures employed therein.

**SUGGESTED READINGS**

Davies RR, Chen JM, Quaegebeur JM, Mosca RM. Transplantation for the "failed" Fontan. Prog Ped Cardiol 2009;26:21-29.

As greater experience has been gained in transplantation of the heart in pediatric patients, especially those with congenital heart disease, it is apparent that virtually all anatomic malformations are amenable to orthotopic implantation of a donor heart. Abnormalities of systemic and pulmonary venous return can generally be addressed either by relocating the vessels or adding additional length from donor tissues. In addition, experienced congenital heart surgeons can use prosthetic materials to reconstruct most venous connections so that orthotopic implantation of the heart can be performed. One remaining concern exists in patients who have dextrocardia associated with either normal situs or situs inversus. Although successful orthotopic cardiac transplantation has been performed in patients with situs inversus, patients with dextrocardia and normal situs represent a situation in which the implantation of the heart in the pericardial space may produce rotation of the apex toward the right and can distort the septal position and tricuspid valve. This is less of an issue if there is cardiac enlargement and the pericardial space is large enough that the apex can assume a more normal location after transplantation. However, in children with a relatively normal heart size in whom transplantation is performed with situs inversus or dextrocardia, it may be necessary to excise a portion of anterior pericardium on the left to allow the apex of the heart to sit in the left chest.

As cardiac transplantation becomes more commonly applied in children with congenital heart disease, the need for donor organs increases. The success of reconstructive procedures for congenital heart disease has created a fairly large population of children and young adults with complex cardiac reconstructions, a significant proportion of whom may ultimately require cardiac replacement. Thus, children, particularly those in the early teenage group, of ten present for cardiac replacement at a time when donor organs of suitable size for adult recipients are becoming increasingly infrequent. The use of assist devices such as implantable left ventricular or right ventricular assist pumps and total cardiac replacements needs to be extended to the pediatric population to permit survival while these patients are awaiting a donor organ. In most pediatric heart transplant centers, the average waiting time for donor organs has progressively increased, and many patients coming to transplant are on some form of assist.

ECMO has been the primary method of ventricular assistance in patients awaiting organ transplantation in the pediatric population until recently. Now, various pulsatile cardiac assist devices are becoming available for the pediatric population. Although the Thoratec and Heart Mate devices can be used in older children and adolescents, there is still a limitation on available devices in the United States for small infants and children. The new DeBakey Child Heart may permit fully implantable devices in smaller children, but it is not currently useful for infants and neonates. The availability of the Berlin Heart assist device in the United States has made it possible to bridge even neonates and small infants to heart transplantation over waiting times of several months. These devices have the advantage of multiple different sizes for the potential population of recipients. Nevertheless, all assist devices still have significant complication rates, with thrombosis, thromboembolism, and problems of anticoagulation being the primary issues.

Whereas 1-year survival after heart transplantation in children is approximately 80%, the results of the international heart and lung transplant registries suggest that 10-year survival of adult recipients will be approximately 30% to 40%. Thus, the long-term survival of patients after heart transplantation is still significantly lower than that of an age-matched population. It is, therefore, logical to attempt to preserve the native heart as long as possible if an adequate functional result is obtained in any patient with congenital heart disease. Cardiac transplantation can then be used as an additional palliative therapy after earlier palliative interventions have failed.

The approach to cardiac transplantation in infancy for children with hypoplastic left heart syndrome remains controversial. As more centers have achieved excellent results with staged palliative reconstructive operations, such as the Norwood procedure and ultimately Fontan reconstruction, it becomes increasingly difficult to justify the use of scarce donor organs for patients who have other surgical options. For these reasons, most centers, including ours, have abandoned cardiac transplantation as primary therapy for hypoplastic left heart syndrome. Reconstructive surgery with the Norwood operation has been extended to even infants of very low birth weight, and there has been no incremental increase in mortality with patients who have aortic and mitral atresia and an extremely diminutive ascending aorta. The early mortality of approximately 20% is comparable with the mortality on the waiting list for most centers that do primary transplantation for patients with hypoplastic left heart syndrome. Although the percentage of patients who will ultimately require transplantation after Fontan reconstruction is unknown, it is anticipated that the majority of transplants will not be required until patients reach the teenage years at which time better availability of organs may occur. A particular concern in centers doing high-volume infant cardiac surgery is the need for cardiac transplantation in patients who failed an early reconstructive operation and require ECMO support for postoperative survival. These patients may be salvageable if a donor heart were to become available within a reasonably short time frame. Because of the limited availability of infant organs, such salvage of these critically ill patients is not currently likely. It is perhaps in these patients that the limited available infant organs should be preferentially used. Several centers have shown satisfactory results if transplantation can be performed in a timely manner even in patients on ECMO support before transplant.

Because of the concerns of increasing waiting times for infants and neonates who may be unstable, there is increasing interest in the use of ABO-incompatible transplantation for these patients. The ability to use a non-ABO-compatible donor heart in infants extends the potential donors available and can potentially decrease the waiting time for some of the sickest patients. The early results with these techniques have been quite acceptable, with no increase in rejection episodes or early morbidity and mortality. The exact age at which ABO-incompatible transplantation can no longer be accomplished is not clearly delineated, but after 1 year of age, measurement of antibodies titer to other blood groups would appear to be appropriate.

One difficulty with transplantation of patients who have undergone staged reconstructive surgery for hypoplastic (continued)
left heart syndrome and have developed contraindications to continuing down the single-ventricle repair pathway is that often allograft tissue is necessary for reconstruction of the aortic arch and pulmonary arteries. It has been demonstrated that implantation of allograft tissue can result in significant elevations of panel reactive antibodies (PRA), which can increase the difficulty in cross-matching donor heart to a recipient and increase the risk of early rejection or chronic rejection episodes. Complex strategies including plasmapheresis and exchange transfusions may be necessary to permit transplantation with elevated PRA; clearly an increased incidence of rejection is a potential complication. The use of decellularized allograft material may decrease the risk of this complication; however, the routine use of the decellularized allografts has not been advocated for staged reconstruction due to the friability of this tissue at second- and third-stage reconstruction, making the surgery more difficult at the time of reoperation.

The optimal implantation technique for orthotopic heart transplantation remains controversial. Caval anastomotic techniques have been associated with a lower incidence of tricuspid regurgitation and better atrial function after transplant and therefore may be preferred in most cases. The late incidence of caval stenosis in children has not been identified but potentially can be treated with balloon dilation or stenting if it occurs. The use of separate pulmonary venous anastomoses has been raised in adult cardiac transplantation in the hope of improving left atrial and mitral valve function; however, the use of separate pulmonary venous cuff anastomoses may be associated with greater risk of arrhythmia.

The immunosuppression regimen after pediatric cardiac transplantation is variable from one institution to another. There is no clearly accepted superior technique for immunosuppression. The majority of centers use a triple-drug technique of azathioprine or mycophenolate mofetil, cyclosporine or tacrolimus, and steroids. Steroid-free regimens have been promoted in the hope of increasing late linear growth. In most centers, attempts are made to wean infant patients from steroids 6 months after the transplant, beyond the period when most early rejection and infection episodes occur. The use of tacrolimus for primary immunosuppressive therapy rather than cyclosporine in infants and very young children decreases the risk of hirsutism and gingival hyperplasia, which can impede feeding.

Controversy remains regarding the level of pulmonary hypertension at which orthotopic cardiac transplantation cannot succeed. Patients with significant transpulmonary gradients and elevations of pulmonary vascular resistance may have satisfactory results from orthotopic cardiac transplantation if the pulmonary resistance is reversible. Hemodynamic evaluation is important to assess in each patient before listing for heart transplantation. In some patients with an elevated transpulmonary gradient but in whom primary left heart dysfunction is present, heterotopic heart transplantation can permit the use of a heart transplant rather than a heart and lung transplant with acceptable outcome. The number of heterotopic heart transplants performed in children, however, is so few as to preclude any evaluation of long-term effectiveness of this therapy.
Clinical heart–lung transplantation began with Cooley in the late 1960s when the first heart–lung transplant was performed in an infant with atrioventricular canal defect and pulmonary hypertension. The child died of pulmonary insufficiency 14 hours after the operation. The first clinical success was not achieved until 1981 when Reitz performed a heart–lung transplant in a 45-year-old patient with pulmonary hypertension. As success was achieved in adult patients, heart–lung transplantation was performed in an increasing number of pediatric patients, from only a few in 1984 to as many as 40 in 1988. Successful clinical use of isolated lung transplantation in an adult by Cooper in 1984 established the possibility of lung transplantation alone for certain forms of cardiopulmonary disease. These techniques were ultimately extended to the pediatric population such that the use of heart–lung transplantation in children has gradually been restricted to children with irreparable cardiac defects associated with pulmonary disease while isolated lung transplantation (either single or bilateral) has become an accepted modality of therapy for children with pulmonary vascular disease or primary pulmonary disease with reparable cardiac defects. By 2012, approximately 1,200 children, the majority adolescent, have undergone single-lung or bilateral-lung transplantation. The number of heart–lung transplantsations in the pediatric population has declined significantly and is rare in the United States.

**INDICATIONS FOR TRANSPLANT**

General indications for heart–lung or lung transplantation in pediatric recipients are similar to those in adults. End-stage restrictive or obstructive parenchymal pulmonary disease or primary or secondary pulmonary vascular disease associated with correctable congenital heart defects can be considered for cardiac repair and lung transplantation if the cardiac repair is durable and not associated with significant inherent mortality. The presence of significant left ventricular dysfunction or cardiopulmonary defects that are uncorrectable are best treated by heart–lung transplantation.

Although general indications for lung transplantation are similar in adults and children, the types of pulmonary disease seen in children are different from those in adults. Obstructive pulmonary disease is extremely unusual in children as is pulmonary fibrotic disease. The great majority of lung transplants in children >5 years old are for cystic fibrosis. If present, fibrotic disease other than cystic fibrosis is often due to radiation fibrosis as a consequence of the treatment for leukemia and lymphoma. Younger children, under the age of 6, are transplanted for idiopathic pulmonary arterial disease and congenital heart disease with pulmonary venous stenosis. Neonates are only usually referred for significant surfactant abnormalities such as surfactant B or C deficiency for which there is no other treatment.

Children with cystic fibrosis represent the single largest group of pediatric patients who require lung or heart–lung transplantation. Most of these children are teenagers because the majority of cystic fibrosis patients survive to adulthood with intensive medical management and suffer from a slow decline. Indications for consideration of pulmonary transplantation in cystic fibrosis patients include increasing hospitalization for infection, progressive weight loss in older patients or lack of weight gain in younger patients despite nutritional supplementation, and increase in oxygen dependence or hypercarbia with gradual deterioration of pulmonary function. In general, a forced expiratory volume in 1 second (FEV₁) of <30% of predicted values is a relative indication for transplantation.

Cardiopulmonary diseases requiring transplantation in infancy are rare but include congenital diaphragmatic hernia, surfactant protein deficiencies, pulmonary vein stenosis or veno-occlusive diseases, and primary pulmonary hypoplasia.

The indications for transplantation in children with pulmonary hypertension are somewhat subjective because of the poorly defined natural history of pulmonary hypertension, either primary or secondary, in this age group. Generally, indications for consideration include progressive exercise intolerance, the onset of syncope, hemoptysis, angina pectoris, and significant right ventricular failure. These symptoms are often correlated with hemodynamic abnormalities, with elevations of right atrial pressure to >8 mmHg with a decreased cardiac index and a total pulmonary vascular resistance of >20 Woods units/m². When the product of right atrial mean pressure and pulmonary vascular resistance index is >360, poor survival is expected and transplantation is considered. Some children with significant pulmonary vascular disease may respond to vasodilators, including prostacyclin, and the use of chronic prostacyclin infusion may improve the stability of patients while they await suitable donor organs. The availability of increasingly novel therapies for pulmonary hypertension has decreased the need for lung transplantation in a significant number of patients. Most patients can now at least have significant palliation of their disease by medical management with transplantation reserved only for those patients who develop right heart failure or other major complications. In patients with Eisenmenger syndrome and a right-to-left cardiac shunt, the onset of severe polycythemia in association with hemoptysis, right ventricular failure, or progressive exercise intolerance may be considered a relative indication for transplantation.

A particularly difficult subgroup of patients comprises those with pulmonary vein stenosis and pulmonary veno-occlusive disease. These children are often extremely unstable with severe pulmonary hypertension. Because delivery of blood to the left ventricle is limited in these
patients, there has been a high incidence of death while awaiting organs, and therefore these children should be listed early in the course of their disease. It is important to recognize patients who have pulmonary vein stenosis or veno-occlusive disease that is not amenable to further surgical therapy. Despite the increased enthusiasm for the use of sutureless pulmonary vein repair in patients with pulmonary venous stenosis, there are no significant data that this approach has decreased the incidence of recurrent obstruction and in most of these patients the process appears to be a progressive disease. The lack of dilation of the pulmonary veins in the hilum of the lung in the presence of pulmonary vein stenosis is a marker that there are abnormalities of the veins that will not respond to surgical intervention. In addition, very small veins at the time of repair of total anomalous pulmonary venous return are associated with very poor long-term outcome and these patients may also be considered for transplantation. Patients who have stenosis of only one or two pulmonary veins or occlusion of one vein with other veins not obstructed yet in the presence of significant pulmonary hypertension are a very poor subset of patients for any surgical intervention. These patients who will not respond to surgical therapy should be considered for lung transplantation. Stenting of stenotic pulmonary veins may be palliative in some cases as a bridge to pulmonary or cardiopulmonary transplantation. Although it is possible to use chronic ventilation, nitric oxide therapy and even extracorporeal membrane oxygenation (ECMO) as a bridge to lung or cardiopulmonary transplantation in children, patients with pulmonary vein stenosis or pulmonary vascular disease are often unable to be adequately resuscitated with chest compressions while ECMO support is initiated because of the inability to get adequate blood flow to the left ventricle to provide cerebral blood flow during cardiac arrest. Heart–lung transplantation provides an option for patients who have uncorrectable congenital heart disease and pulmonary vascular disease. Typically, these patients become candidates once palliation is no longer successful, once exhibiting severe heart failure requiring inotropic support, or severe pulmonary hypertension requiring inhaled nitric oxide or infused prostaglandin.

Infectious complications are more common after cardiopulmonary and pulmonary transplantation than after solid-organ transplants. Of particular importance in pediatric recipients is the common occurrence of viral infections of the transplanted lungs. Children continue to be exposed to a wide range of viruses, including adenovirus and respiratory syncytial virus in addition to the influenza viruses. In addition, cytomegalovirus (CMV) infection is very common after pediatric lung transplantation because many children have not yet been exposed to CMV infection and active immunity is not present. An additional concern in children is the presence of Epstein–Barr virus (EBV). There is a higher incidence of seronegativity for this viral pathogen in children than in adults, and EBV infection can be quite subtle in early childhood, making diagnosis difficult. A significantly increased risk of associated lymphoproliferative disease in patients who have sustained an EBV infection after transplant has been reported and may progress despite decreased immunosuppression in these patients.

**CONTRAINDICATIONS TO TRANSPLANTATION**

Contraindications to transplantation are malignancy, multisystem organ failure, and sepsis. Other contraindications are primarily mechanical. Patients with severe scoliosis or restrictive chest wall mechanics may have chronic hypoventilation even if normal lungs are implanted. Significant associated metabolic diseases including renal insufficiency or uncontrolled diabetes are relative contraindications to transplantation, and patients with portal hypertension and biliary cirrhosis may also be considered poor candidates for cardiopulmonary transplantation alone. Patients who have had multiple prior surgical procedures with involvement of the pleural spaces require more complicated operations for implantation of donor organs. This is a particular problem in patients with chronic cyanosis, who may have multiple and extensive collateral vessels in the adhesions from previous surgeries that may be difficult or impossible to control at the time of transplant. Severe and even fatal bleeding complications have been noted in these patients in our series. High-dose steroid dependence is a relative contraindication to transplantation because of poor wound healing or sepsis. However, moderate doses of steroids have not been considered a contraindication in our experience. A long-standing history of noncompliance with medical interventions by the patient or family may be considered a relative contraindication to undertaking a procedure of such magnitude. Uncontrolled collagen vascular disease is also a contraindication to consideration for transplantation.

**SELECTION OF OPERATIVE PROCEDURE**

Historically, the majority of transplantations in children have been by the heart–lung en bloc technique. Whereas it is apparent that comparable results can be obtained with heart–lung or lung transplantation in many children, the need to maximize the availability of scarce donor organs and use the heart for other patients has produced a gradual decrease in the use of combined heart–lung transplantation for primary pulmonary diseases. Most heart–lung transplantation is now reserved for patients with uncorrectable congenital heart defects associated with severe pulmonary vascular disease. Heterotopic heart transplantation may be used in some children with elevated pulmonary resistance in whom improvement in pulmonary resistance can be anticipated with improvement in cardiac output. We use heart–lung transplantation for only those children with congenital heart disease who have a poor chance of long-term correction or those children with severe left or biventricular dysfunction. Pulmonary transplantation with preservation of the native heart is preferred in children with primary or secondary pulmonary vascular disease associated with normal ventricular function and a relatively simple or correctable congenital heart defect. Even children with severe right ventricular dysfunction are considered candidates for pulmonary transplantation alone if the right ventricular ejection fraction is >10% and tricuspid valve insufficiency is graded less than severe. Patients with repairable cardiac defects can receive cardiac repair and lung transplantation alone, and our experience includes children with atrial septal defect, ventricular septal defect (VSD), patent ductus arteriosus, vascular rings, atrioventricular canal defects, pulmonary vein stenosis, peripheral pulmonary arterial stenosis, and pulmonary atresia with non-confluent pulmonary arteries in addition to children with anomalies of pulmonary venous return.

An additional consideration in pediatric patients is the preference of single-lung versus bilateral sequential lung transplantation. In children with cystic fibrosis, bilateral lung transplantation is preferred to remove the infected lungs and decrease
the sources of potential sepsis. A similar consideration is given to patients with chronic bronchiectasis who may be best served by bilateral sequential transplantation and removal of infection sources in the lungs. Single-lung transplantation is a possibility in patients with pulmonary fibrosis and pulmonary vascular disease. Although there have been successful series of single-lung transplantations for primary and secondary pulmonary hypertension, these reports have suggested that the postoperative course is more complicated in such patients. The entire cardiac output is delivered to the transplanted lung if single-lung transplantation is used in the presence of severe pulmonary vascular disease. Thus, patients may be unstable in the postoperative period and have additional instability when infection, rejection, or bronchiolitis obliterans occurs in the transplanted lung.

We, therefore, prefer bilateral sequential transplantation in most children with pulmonary vascular diseases to improve postoperative stability and the distribution of pulmonary blood flow. In addition, the use of bilateral sequential transplantation in younger children and infants allows for maximum possible growth and development of the lungs. Single-lung transplantation is still considered in children with primary pulmonary hypertension in whom there is a relative contraindication to entering one pleural space, such as those children who have had multiple previous thoracotomies with cyanosis.

**DONOR SELECTION**

Donors for cardiopulmonary or pulmonary transplantation are sparse compared with donors for other organs. Only 10% to 15% of cardiac donors may be suitable or donation of heart–lung blocks or lungs. This rarity reflects the damage often done to the lungs during gastric aspiration either at trauma or with a sudden neurologic event. In addition, severe pulmonary edema from either neurogenic or cardiac cause can affect oxygen exchange of the potential donor lungs. General criteria for pulmonary donors includes blood type compatibility, normal gas exchange with an arterial partial pressure of oxygen (PaO₂) of >300 mmHg on 100% oxygen, and 5 cm H₂O positive end-expiratory pressure. A clear chest X-ray film showing no infiltrates or contusions, age younger than 50 years with no history of pulmonary disease and a <20 pack-year smoking history, and normal findings on electrocardiograms and echocardiograms are criteria for cardiopulmonary and pulmonary donors. Bronchoscopy should confirm normal airway anatomy and easily cleared secretions with no ready accumulation of further secretions. A history of pulmonary disease or prolonged smoking or asthma is a relative contraindication for donation. In addition, demonstrated aspiration of gastric contents, contamination of the tracheobronchial tree, or severe lung contusion is considered contraindication to donor use. In some cardiopulmonary donors, the requirement of very high-dose inotropic drugs in the face of suitable fluid management or significant ventricular hypertrophy or dysfunction on an echocardiogram is considered a contraindication to using the combined heart–lung block.

As in all organ donation, the presence of human immunodeficiency virus or hepatitis A or B is a contraindication for use of donor organs. Hepatitis C organs may be used in hepatitis C positive recipient and in some cases may be used if the severity of the condition of the recipient warrants the risk of hepatitis C transmission. Although it is generally advisable to match CMV-seropositive donors with CMV-positive recipients, successful transplantation is not precluded by CMV mismatching. CMV prophylaxis is routinely used after transplantation and CMV infection is usually adequately treated if it occurs. Occasionally lungs that initially are deemed inappropriate for transplant may, with aggressive donor management, be rendered usable. Careful evaluation of each potential donor is therefore important to maximize the availability of suitable donor organs. Size matching between donor and recipient is important in pediatric lung and heart–lung transplantation.

For heart–lung transplantation, it is desirable to have the donor weight within 20% to 30% of the weight of the recipient. Although it is possible in cardiac transplantation to use hearts of donors several times the body weight of the recipient, the fact that excess lung size may compress the heart limits the size discrepancy that is acceptable for combined heart–lung transplantation in children. Donor–recipient size matching is more liberal when double-lung or single-lung transplant is contemplated. Because the lungs have the capacity to expand to fill chest cavities of significantly larger recipients, it is possible to use smaller donor lungs. In addition, it is possible to use large donor lungs and use lobes or trim portions of the parenchyma on the lungs to allow them to fill the chest cavity without impinging on cardiac function. Bronchial size match between donor and recipient is better correlated with height and age than with weight. Thus, most patients are listed for lung transplantation with a size range of 3 to 4 inches above and below the size of the recipient. However, heights of twice the size of the recipient can be considered if lobes are to be used from larger donors.

**ORGAN PROCUREMENT**

Flexible bronchoscopy is preferable at the time of lung procurement. The presence of direct trauma to the lungs or pulmonary contusions should be evaluated by direct inspection before the heart–lung or lung block is removed. The donor receives methylprednisolone and antibiotics and is heparinized before organ procurement. The technique of organ procurement from pediatric donors is similar to that of adult donors except that the volumes of cardioplegic and pulmonoplegic solutions are adjusted for the weight of the donor. Cardioplegic solution is given for a total dose of 30 cm³/kg of donor weight and pulmonoplegia for 50 cm³/kg donor weight. Antegrade crystalloid cardioplegic solution and Perfadex (extracellular low potassium dextran) pulmonoplegic solution has been used in most centers for organ preservation. Prostaglandin E₁ (500 µg) is injected directly into the main pulmonary artery at the time of cross-clamp. Lungs are topically cooled with ice slush solution with both pleural spaces widely opened.

When a heart–lung block is harvested for a single recipient, the cardioplegic solution is administered into the aorta and pulmonoplegic solution directly into the pulmonary artery with venting of the heart by division of the left atrial appendage. Division of the inferior vena cava at the diaphragm permits evacuation of cardioplegia without distention of the ventricle. The trachea is mobilized above the level of the carina and minimal dissection of the carina and lateral trachea is done. The lungs are then gently inflated to a pressure of approximately 20 mmHg and the trachea stapled. The superior vena cava is ligated and divided and the esophagus mobilized in the superior mediastinum and stapled and divided. The aorta is transected at the level of the innominate artery, and the distal aorta in the posterior pericardial space is mobilized and ligated and also divided. If additional aortic length is necessary, the aorta is not transected, but the arch vessels are divided individually. With incision of the pleura at the paraspinal region, bilaterally, the entire heart–lung block is then excised and the esophagus then removed from the specimen. If the heart and lung are to be harvested separately, cardioplegic and pulmonoplegic solutions are administered as in the combined heart–lung
technique; however, the interatrial groove is developed and then the heart is eased by the division of the aorta and pulmonary artery, leaving the bifurcation of the pulmonary artery for the lung. The left atrium is then excised with a limited left atrial cuff, leaving as much as possible of the pulmonary venous confluence bilaterally for the lung implantation. The superior and inferior venae cavae are divided at the pericardial reflection. Many choose to use retrograde flush for the lungs at a dose of 5 to 10 ml/kg per pulmonary vein. The lung block is then excised as is the heart–lung block by the division of the trachea with gentle inflation of the lungs. The organs are then put in iced saline solution in sterile bags and transported to the recipient center on ice. Although some groups have used cardiopulmonary bypass for cooling of the entire heart–lung block, this technique is not widely used in the United States. Preservation times of >9 hours for lung transplantation have been successfully achieved with the use of these techniques.

**RECIPIENT OPERATION**

It is particularly important to take care in the removal of the recipient organs for heart–lung or lung transplantation to obtain absolute hemostasis in the mediastinum and pleural spaces and to avoid injury to the thoracic nerves including the phrenic, recurrent laryngeal, and vagus nerves. The bilateral thoracosternotomy or clamshell incision (Fig. 100.1) through the fourth intercostal space allows excellent exposure of the pleural spaces for takedown of adhesions and aids in obtaining hemostasis before implantation of the donor organs. When the clamshell incision is made, the incision needs to be carried as superiorly as possible in the midline so as to transect the sternum above the xiphoid to add stability of the sternal fragments when they are rewired after the procedure. Entrance in the fourth intercostal space is preferred; however, it is generally better to enter the chest more superiorly than inferiorly because the opening of the clamshell incision allows great exposure in the superior mediastinum. Many centers are now doing bilateral thoracotomies with separate implantation of each lung in patients who have adequate stability to undergo lung transplantation without the use of cardiopulmonary bypass. In implantation of heart–lung blocks, the sternotomy incision is generally preferred.

**HEART–LUNG TRANSPLANTATION**

The technical aspects of heart–lung implantation in children are similar to those used in adults. Cardiopulmonary bypass is used with bicaval and aortic cannulation while the lungs are excised bilaterally. Caval tapes are lowered around the cavae to eliminate venous return to the right atrium. The phrenic nerves are carefully protected on a pedicle of pericardium, which is mobilized before the organs are removed. The lungs are excised individually with the division of the mainstem bronchus, pulmonary artery and pulmonary veins after ligation, and division of the vessels. After the lungs have been removed, the heart is excised, leaving a cuff of right atrium and distal aorta for implantation of the new organs. A portion of the wall of the left pulmonary artery can be left in situ to avoid dissection around the recurrent laryngeal nerve on the left. After excision of the heart and each lung, the trachea is mobilized in the mediastinum behind the stump of aorta and divided approximately two rings above the carina. After meticulous hemostasis is obtained, the donor heart–lung block is placed in the mediastinum and the lungs passed behind

---

**Fig. 100.1.** The right and left lungs are removed sequentially with ligation of the branches of the pulmonary arteries and veins and stapling and division of the bronchus. The bronchial stump is left stapled, the bronchus is divided distal to the staple line, and the lungs are excised. The patient is on cardiopulmonary bypass, allowing removal of both lungs with the support of the circulation. As is illustrated, a cross-clamp can be applied, cardioplegia induced, and the cardiac repair performed before lung implantation. (Inset) The clamshell thoracosternotomy incision. The incision is carried transversely in the midline as high as possible to allow adequate sternum for sternal stability after rewiring with chest closure. The fourth intercostal space (ICS) is opened bilaterally and the incision carried out into the axillae. The incision in the chest can be carried more inferiorly because the trap door-like opening of the clamshell incision allows greater superior mobility than inferior mobility. It is, therefore, imperative not to enter the chest too high or dissection of the lungs will be impeded near the pulmonary veins and inferior pulmonary ligaments. PA, pulmonary artery; PV, pulmonary vein.
tinum is cut as short as practical; however, atrial anastomoses are used in small infants. To prevent distention of the heart and recovery of the heart, the arterial clamp is released, and air is aspirated from the veins before opening of the lungs for reperfusion. The same technique is then used for implantation of the right lung. On the right, the stump of the right mainstem bronchus is generally cut within two or three rings of the carina to have the shortest distance for revascularization of the anastomosis. Protection of the bronchial suture lines is accomplished with peribronchial tissues tacked over the anastomosis with absorbable suture if such tissue is available. However, with suitable trimming of the recipient bronchus, the suture line will be retracted into the mediastinal tissues such that good revascularization and protection of the anastomosis is available. We have abandoned the use of pericardial pedicle wraps or omentum for bronchial wraps in children, and the incidence of bronchial complications has not increased by using an unprotected anastomotic technique.

If cardiac repair is to be performed in association with bilateral sequential lung transplantation, the patient is cannulated for bypass, the lungs are removed as earlier noted, and the aorta is cross-clamped and cardioplegic solution administered. Closure of the intracardiac defects is performed through the right atrium if possible to prevent ventricular incisions in patients with significant pulmonary hypertension in whom right ventricular function may be depressed. After completion of the cardiac repair, reperfusion of the myocardium is permitted while the sequential lung implantation is performed.

SINGLE-LUNG TRANSPLANTATION

In children in whom only a single lung is required, the operation is performed either through a posterolateral thoracotomy on the transplant side or, more commonly, with the patient in a supine position and via a partial thoracosternotomy (Fig. 100.2). An anterior thoracotomy can be used, or the sternum can be crossed partially in the midline, allowing better access to the heart for cannulation and cardiopulmonary bypass. Closure of atrial septal and VSD can be readily accomplished with this technique. The patient is placed on cardiopulmonary bypass with caval cannulation through the right chest and direct aortic cannulation. With cardioplegia, the right atrium can be opened and the atrial septum patched or primarily closed and VSD approached across the tricuspid valve (Fig. 100.2). Explantation of the lung and implantation of the donor lung then proceeds as in bilateral sequential lung transplantation.

SPECIAL SITUATIONS

Congenital pulmonary vein stenosis is an extremely rare condition in children but is associated with high mortality and is usually not amenable to direct surgical repair. These children often present with severe pulmonary hypertension and it is not uncommon for transcatheter attempts at stabilization, including balloon dilation and stent implantation in the pulmonary veins, to have been performed prior to

the pedicles of pericardium containing the phrenic nerves. Anastomoses between the donor and recipient trachea, aorta, and right atrium are then accomplished with the patient on cardiopulmonary bypass. In older children, the tracheal anastomosis can be accomplished with a running suture; however, our preference is to perform a running anastomosis of the membranous portion of the trachea and interrupted anastomosis of the cartilaginous portion anteriorly. We have used absorbable sutures in children in hopes of permitting better growth of the anastomoses. The aorta and right atrium are both anastomosed with running suture. In most cases, separate superior vena caval and inferior vena caval anastomoses are not used, and the right atrium of the recipient is excised with the heart at the time of recipient preparation. In very small children, however, caval anastomoses may lead to purse stringing of the suture line and obstruction and, therefore, atrial anastomoses are used in small infants. To prevent distention of the heart during reperfusion and while weaning from cardiopulmonary bypass, a vent is inserted via the amputated left atrial appendage into the heart.

BILATERAL SEQUENTIAL LUNG TRANSPLANTATION

The child is positioned supine and the shoulders elevated on a rolled towel. With this positioning, the entire chest can be prepared down to the axillae and draped as a sterile field (Fig. 100.1, inset). The transverse thoracosternotomy (clamshell incision) is made in the fourth intercostal space. The internal mammary pedicles are divided bilaterally. Chest retractors are placed in each thoracotomy incision, and the thymus is divided in the midline or resected completely if exposure of the superior mediastinum is poor. The pericardium is opened and the heart is suspended with pericardial stay sutures. After heparinization, the aorta and right atrium are cannulated for bypass. We prefer to use cardiopulmonary bypass in all lung transplant procedures in children because of the ease with which bypass permits removal of the recipient lungs and the fact that after removal of both lungs, the airway can be irrigated with antibiotic solution if necessary to decrease septic secretions. In addition, the removal of both the lungs before implantation decreases the ischemia time on the second implanted lung.

Separate caval cannulation is used if heart–lung transplantation or cardiac repair is contemplated in addition to lung transplantation. With the child on cardiopulmonary bypass, the lungs are removed bilaterally by ligation of the pulmonary artery branches, pulmonary venous drainage, and stapling of the right and left mainstem bronchi. Care is taken to dissect around the bronchial stumps as minimally as possible. The donor lung block is then brought to the field, and the right and left lungs are separated from the combined lung block by the division of the bronchus approximately two rings from the take-off of the upper lobe orifices bilaterally. The pulmonary arteries are trimmed to appropriate length for suturing to the recipient and the pulmonary venous confluence is divided by dividing the remnant of the left atrium between the right and left pulmonary veins. The left lung is usually implanted first because traction on the heart may be necessary to aid in exposure and once the lung is implanted, the heart can then recover from any injury while the right lung is implanted. The bronchial stump on the left is cut as short as practical; however, generally the length of the left mainstem bronchus at implantation is longer than the right mainstem bronchus. The bronchial anastomosis between the donor and recipient is then created with running absorbable suture for the membranous bronchus and interrupted simple absorbable sutures for the cartilaginous bronchus. An end-to-end anastomosis of the bronchus without telescoping of one bronchus into the other is used to prevent stenosis or malacia of the anastomosis. If a significant size discrepancy between the donor and recipient bronchus is present, then minor telescoping of the bronchial anastomosis is accepted. The pulmonary arterial anastomosis is then created with a partial occlusion clamp on the pulmonary artery of the recipient and a running suture is used to complete the anastomosis. The venous anastomosis is created in a similar fashion. Just before completion of the venous anastomosis, venous return is permitted to the heart, the arterial clamp is released, and air is aspirated from the veins before opening of the lungs for reperfusion. The same technique is then used for implantation of the right lung. On the right, the stump of the right mainstem bronchus is generally cut within two or three rings of the carina to have the shortest distance for revascularization of the anastomosis. Protection of the bronchial suture lines is accomplished with peribronchial tissues tacked over the anastomosis with absorbable suture if such tissue is available. However, with suitable trimming of the recipient bronchus, the suture line will be retracted into the mediastinal tissues such that good revascularization and protection of the anastomosis is available. We have abandoned the use of pericardial pedicle wraps or omentum for bronchial wraps in children, and the incidence of bronchial complications has not increased by using an unprotected anastomotic technique.

If cardiac repair is to be performed in association with bilateral sequential lung transplantation, the patient is cannulated for bypass, the lungs are removed as earlier noted, and the aorta is cross-clamped and cardioplegic solution administered. Closure of the intracardiac defects is performed through the right atrium if possible to prevent ventricular incisions in patients with significant pulmonary hypertension in whom right ventricular function may be depressed. After completion of the cardiac repair, reperfusion of the myocardium is permitted while the sequential lung implantation is performed.

SINGLE-LUNG TRANSPLANTATION

In children in whom only a single lung is required, the operation is performed either through a posterolateral thoracotomy on the transplant side or, more commonly, with the patient in a supine position and via a partial thoracosternotomy (Fig. 100.2). An anterior thoracotomy can be used, or the sternum can be crossed partially in the midline, allowing better access to the heart for cannulation and cardiopulmonary bypass. Closure of atrial septal and VSD can be readily accomplished with this technique. The patient is placed on cardiopulmonary bypass with caval cannulation through the right chest and direct aortic cannulation. With cardioplegia, the right atrium can be opened and the atrial septum patched or primarily closed and VSD approached across the tricuspid valve (Fig. 100.2). Explantation of the lung and implantation of the donor lung then proceeds as in bilateral sequential lung transplantation.
referral for lung transplantation. In addition, interventional techniques have been used to stabilize patients while they are awaiting donor organs because this subgroup of children has the highest mortality under such circumstances. Because these children have often had stents implanted in the pulmonary veins, the implantation of the donor lungs is altered. At the time of lung implantation on cardiopulmonary bypass, it is necessary to excise the pulmonary venous confluence bilaterally including the excision of the stents, which often extend into the left atrium. This can be accomplished in either of two ways: (1) by implanting the right and left lungs with bronchial and pulmonary arterial anastomoses and then subjecting the patient to a period of aortic cross-clamping and cardioplegia while the pulmonary venous confluence is excised bilaterally and the pulmonary venous confluence of the donor lung is implanted directly into the left atrium with a running suture line bilaterally or (2) if possible by implanting both lungs and completing all anastomoses under a single period of cardioplegia. The anastomoses in lung transplantation in very small children are simple and often only require 15 to 20 minutes per lung implant, and therefore the total period of cardioplegia may not exceed 40 to 50 minutes for the entire procedure. We have used both of these techniques for implantation in patients with pulmonary vein stenosis with equal success.

In children in whom a patent ductus arteriosus is associated with severe pulmonary hypertension, it is advisable to place the patient on cardiopulmonary bypass and to divide and oversew the ends of the ductus arteriosus rather than ligate the ductus in situ. The elevation in pressure during ligation may result in enough pressure on the suture line to allow recanalization and division of the ductus ensures that recanalization will not occur.

A particular concern after cardiac repair at lung transplantation is the development of dynamic right ventricular outflow tract obstruction after the procedure. Many patients with elevated right ventricular pressure in the presence of shunt lesions such as VSD or a large patent ductus arteriosus may have severe right ventricular hypertrophy that creates dynamic outflow tract obstruction when the right ventricular pressure drops after successful lung transplantation. In severe cases, these patients may best be treated by patch augmentation of the right ventricular outflow tract, but in the majority of patients the avoidance of inotropic drugs postoperatively or use of beta-blocking agents may be sufficient to relieve the dynamic obstruction in the early postoperative period. In the majority of patients, this dynamic obstruction will resolve spontaneously after several days.

An unusual subgroup of children who may require lung transplantation comprises those with pulmonary atresia with VSD and nonconfluent pulmonary arteries. These children often have undergone multiple previous attempts at unifocalization operations to recreate a distal pulmonary vascular bed. Thus, many children will have had previous thoracotomies or median sternotomy incisions. In these children, typically the ascending aorta is markedly dilated and somewhat posteriorly located. Thus, the space available in the mediastinum for the placement of the pulmonary arteries is limited and placement behind the ascending aorta can result in compression of the right pulmonary artery by the dilated ascending aortic root. The operation is performed through the thoracosternotomy incision, as in bilateral sequential lung transplantation described earlier. The aorta is cross-clamped with the patient on bypass, and cardioplegia is administered. In this case, an incision is made in the right ventricular outflow tract to gain exposure to the VSD, which is closed with a polyester (Dacron) patch (Fig. 100.3). A pulmonary homograft conduit is then sutured to the superior margin of the ventriculotomy incision and augmented with a gusset of...
Fig. 100.3. Technique for cardiac repair and lung transplantation for pulmonary atresia with ventricular septal defect (VSD) and nonconfluent pulmonary arteries. With the heart on cardiopulmonary bypass and under diastolic cardioplegia, a right ventriculotomy incision is made vertically, avoiding major epicardial coronary branches. Through this defect, the VSD is exposed and patched with a polyester (Dacron) patch. Running or interrupted mattress sutures can be used for the placement of the patch, and in the posteroinferior aspect, care must be taken to avoid the conducting tissue if the defect is in the usually conoventricular location. Superiorly, the patch can be secured to the free margin of the ventriculotomy incision or to the conal septum. Care must be taken to ensure complete closure of the defect because reoperation for residual cardiac defects will be difficult in a patient on chronic immunosuppression.

LOBAR LUNG TRANSPLANTATION

Because suitably sized donor lungs are often not readily available, techniques have been devised to use lung grafts of reduced size (lobes) for smaller children. Cadaveric and living donor lobar transplants have now been performed with satisfactory results. The use of living donors for lobar lung transplantation has made donor organs more readily available for children with very unstable conditions who might not survive waiting for suitable cadaveric organs to become available. In addition, the use of cadaveric lobes from larger donors has expanded the donor pool for infants and children for whom identical-sized donors are rare. Because lung growth can continue to late childhood, we generally prefer to use lobes from pediatric cadaveric donors for infants and very small children in hopes that additional lung growth will continue. In older children, lobar transplants from adults may provide quite adequate alveolar volume even for continued growth despite the theoretical disadvantage of lack of additional donor lung alveolar growth. The indications for lobar lung transplantation and donor evaluation are similar to those for whole-lung transplant. Living donors, however, add additional concerns of donor evaluation. Both psychosocial and physiologic factors must be considered in these patients because the harvest of the lobe must result in the least possible morbidity to the donor. If bilateral lung transplantation is contemplated, the larger donor is generally preferred for donation of the right lower lobe because the total lung volume is lower in this lobe than the left lower lobe.

Technique of Donor Lobectomy

If lobes are used from larger cadaveric lungs, variations in lobar anatomy can be addressed at the time of dissection away from the operative field and the most suitable lobes identified for implantation into the recipient. In general, we prefer to use lower lobes for implantation because of the geometric advantages of the shape of the lower lobes bilaterally and the relatively consistent bronchial and vascular anatomy. Often the right upper lobe has multiple lobar arterial branches that require reconstruction to create a single pulmonary artery for anastomosis to the recipient. The right middle lobe is a relatively small amount of lung tissue for implantation and has variable venous drainage, which may complicate venous anastomosis and dissection. The use of a middle lobe from an adult to a young child or infant

polytetrafluoroethylene (PTFE) to allow a gentle take-off of the newly reconstructed right ventricular outflow tract from the right ventricle (Fig. 100.4). The remainder of the operation can then be performed with the heart reperfused and fibrillating or under continued cardioplegia. The lungs are then implanted sequentially as described earlier; however, the pulmonary artery anastomoses are performed last. After the bronchial and pulmonary venous anastomoses are completed, the pulmonary arteries are brought to the midline, either anterior or posterior to the ascending aorta. When brought anterior to the aorta, the pulmonary confluence is recreated in the middle with an absorbable suture posteriorly (Fig. 100.5). The reconstructed right ventricular outflow tract is then reconnected to the reconstructed pulmonary bifurcation with nonabsorbable suture because the homograft tissue is nonviable and growth is therefore not an issue (Fig. 100.6). After reconstruction, venous flow is returned to the lungs and air is evacuated through a vent in the left ventricle or atrium and from the ascending aorta to fully deair the heart before the patient is weaned from cardiopulmonary bypass.
Fig. 100.4. After closure of the ventricular septal defect, a pulmonary homograft of the largest size that will fit in the chest cavity to allow for adequate growth of the recipient is selected and secured to the superior margin of the ventriculotomy incision with nonabsorbable suture. A gusset of polytetrafluoroethylene (PTFE) is used to create a gentle take-off of the conduit from the right ventricle. Care must be taken to obtain adequate hemostasis of this suture line to avoid late pseudoaneurysm formation.

Fig. 100.5. If the aorta is large and posteriorly located, the pulmonary arteries are brought anterior to the aorta for reconstruction. The lungs are implanted bilaterally with bronchial and venous anastomoses and then the pulmonary arteries are brought anterior or posterior to the phrenic nerves to the ascending aorta and reapproximated in the midline.
might be associated with poor lung growth because the addition of alveolar number is unlikely to occur from an adult lung. For these reasons, we prefer to use lower lobes in most patients.

The technique of donor right lower lobectomy is shown in Figure 100.7. A posterolateral thoracotomy is performed and the inferior pulmonary ligament divided with electrocautery. Dissection in the fissure between the upper and lower lobes is created to identify the branches of the pulmonary artery to the right lower lobe and to define take-off of the right middle lobe pulmonary artery branch. The pericardium is opened around the inferior pulmonary vein and the venous drainage from the middle lobe identified to ensure that it does not enter the inferior pulmonary vein directly. After heparinization, a vascular clamp can be placed below the take-off of the right middle lobe pulmonary artery, leaving a stump of pulmonary artery adequate for anastomosis to the recipient. A vascular clamp can also then be placed on the inferior pulmonary vein at its entrance to the left atrium with dissection in the interatrial groove to allow a suitable stump of tissue for oversewing of the venous entrance in the donor and leaving an adequate stump of pulmonary venous confluence for anastomosis in the recipient. The vessels are then divided, and the remaining fissures are divided with the stapler. After division of the pulmonary artery, the bronchus to the right lower lobe is dissected as minimally as possible to preserve blood supply to the lobe. The middle lobe bronchus is identified, and the bronchus is divided with a scalpel. The donor lobe is then removed and taken away from the operative field for preparation and preservation. The pulmonary artery and left atrium are closed with running nonabsorbable suture, and the bronchus is closed with a stapler if adequate length is available or with simple nonabsorbable sutures. A pleural flap can be used to cover the bronchial stump if necessary.

The technique of donor left lower lobectomy is illustrated in Figure 100.8. Again, the inferior pulmonary ligament is divided and the pulmonary artery is dissected within the fissure to identify the lingular and lower lobe branches. The pericardium is opened around the inferior pulmonary vein and fissures are completed with a stapler. With the patient heparinized, a clamp is placed on the pulmonary artery proximal to the take-off of the superior segment of the lower lobe. Depending on the number and location of the lingular branches one or more may need to be sacrificed in order to have sufficient length of donor pulmonary artery to facilitate the anastomosis in the recipient. The pulmonary vein is clamped and divided, and then the bronchus to the left lower lobe is exposed behind the pulmonary artery. Once the lingular bronchus is identified, the
Fig. 100.7. Technique for dissection and excision of the right lower lobe for living donor lobectomy. The pulmonary artery is exposed in the fissure, and dissection is completed to allow identification of the right middle lobe (RML) pulmonary artery. Mobilization of the pulmonary artery is then performed so that a vascular clamp can be applied just distal to the take-off of the middle lobe vessel. The fissures are completed with staples and before placement of clamps. (Inset A) The pulmonary venous dissection is created by takedown of the pericardial reflection and isolation of the right lower lobe pulmonary venous confluence. Care must be taken to identify the middle lobe vein entrance into the upper lobe bifurcation or the superior aspect of the lower lobe and to protect this venous drainage if at all possible. Heparinization of the donor is then performed, a clamp is placed on the pulmonary artery and pulmonary vein confluence, and the artery and vein are divided. (Inset B) With retraction of the stumps of the pulmonary artery, the bronchus is identified and divided just distal to the take-off of the middle lobe bronchus. The donor lobe is then removed for preservation, and the vessels and bronchus are oversewn. PV, pulmonary veins.

The main bronchus is transected obliquely with care taken to include the superior segment bronchus in the donor lobe, leaving a 2 to 3 mm rim of bronchus above the take-off of the superior segmental lobar branch. Often the takeoff of the superior segmental bronchus is quite proximal and care must be taken to divide the bronchus so that the superior segmental bronchus is not separated from the basal trunk. The pulmonary artery is then oversewn with nonabsorbable suture, and the bronchial stump is closed with interrupted nonabsorbable suture and covered as in the right donor lobectomy as necessary.

Preservation of the living donor lobes is performed by infusion of pulmonoplegic solution in the pulmonary artery until the venous effluent is clear. Gentle inflation can be used during flushing to aid in evacuation of any residual blood. Prostaglandin E, may either be added to the pulmonoplegic solution or infused in the donor before lobectomy.

Because of the anticipated short ischemia time on donor lobes, gentle inflation and clamping of the bronchus during transport can be used, or the lungs can be left uninflated during the short period of transportation to the recipient.

Recipient Operation

The recipient operation for implantation of donor lobes is similar to the complete lung implantation technique. The short length
of the pulmonary venous confluence from single lobes makes it valuable to leave longer stumps of pulmonary veins in the recipient to gain length for the anastomosis. If proper organization and timing of donor and recipient operations is performed, it is possible to limit the ischemia time on each donor lobe to <45 minutes.

**POSTOPERATIVE MANAGEMENT**

Postoperative management and restriction of postoperative fluid administration are important after heart–lung and lung transplantation to attempt to attenuate the magnitude of reperfusion edema of the transplanted organs. Immediate postoperative issues are graft function, control of bleeding, and hemodynamic stability. Isoproterenol is often used in heart–lung transplant recipients to maintain the cardiac rate from 110 to 150 beats per minute. The isoproterenol may also lower pulmonary vascular resistance post transplant. The effects of immunosuppression agents such as cyclosporine and tacrolimus on renal function may be minimized by the use of diuretics and low-dose dopamine. Weaning of the fraction of inspired oxygen (FiO₂) is performed to maintain a PaO₂ of >70 mmHg and low amounts of positive end-expiratory pressure are used to prevent water accumulation in the lungs and atelectasis. We generally perform a fiberoptic bronchoscopic examination of the anastomosis 12 to 24 hours after lung transplantation to assess the blood supply and suction of any residual secretions before extubation of the patient. In addition, a thoracic epidural catheter for analgesia is placed prior to extubation.

It is generally advisable to keep children with severe pulmonary hypertension and congenital heart disease sedated and paralyzed for 12 to 24 hours after transplant.
to minimize hemodynamic instability. Patients who are chronically debilitated or have been chronically ventilated, pretransplant may require prolonged weaning after successful transplant procedures. If a patient had a tracheostomy preoperatively, this is usually replaced within 12 hours of surgery. Early reperfusion damage of the transplanted lungs, which is generally manifested by a diffuse pulmonary infiltrate on chest X-ray films, usually resolves after 5 to 7 days post transplant. Often, copious serous drainage from chest cavities may occur representing transudative fluid loss across the visceral pleura or exudative fluid loss from takedown of extensive intrapleural adhesions. Early mobilization is encouraged to aid in re-expansion of the transplanted lungs and surveillance cultures of sputum along with bronchoalveolar lavage cultures are performed as indicated. Immunologic staining of donor and recipient lung samples for common viruses has been performed to identify early potential viral infections of the transplanted lung. In our experience, most of the early graft dysfunction after lung transplantation is associated with positive viral cultures of the donor organs, which are particularly common in pediatric donors. It has been noted that patients after lung transplantation have a significant incidence of gastroesophageal reflux and aspiration, which may damage the donor lungs and increase the risk of late development of bronchiolitis obliterans. Therefore, in some centers, routine gastroesophageal reflux procedures are performed in the postoperative period to limit the risk of chronic aspiration.

The immunosuppressive regimen used for heart–lung and lung transplantation is similar to that used for pediatric heart transplants. No standardized regimen has been developed. We have primarily used tacrolimus and mycophenolate mofetil with steroids in our most recent pediatric experience. For lung transplant specifically, anti-thymocyte globulin has been used intraoperatively prior to reperfusion as induction immunosuppression with favorable results decreasing the incidence of acute cellular rejection. For heart–lung and lung transplants, ganciclovir administered for a 6-week period post transplant is used to prevent early CMV infection. Oral nystatin is used to reduce the likelihood of oral candida while on immunosuppression. It is yet unclear if there is any significant superiority of one immunosuppression protocol over another. However, we have used tacrolimus to make dosing and administration easier for children who may require multiple doses of cyclosporine to maintain adequate drug levels and for cystic fibrosis patients, who may have difficulty with gastrointestinal absorption. Common complications of cyclosporine include hirsutism, seizures and gum hyperplasia in addition to renal dysfunction. These complications are somewhat lessened by the use of tacrolimus. Steroids have been associated with the onset of diabetes but we have not noted an increased incidence of infection with steroid use. Although weight gain has been appropriate in small children who have undergone lung or heart–lung transplantation, bone growth may be somewhat decreased by the use of immunosuppressive regimens that include steroids.

**REJECTION SURVEILLANCE AND MANAGEMENT**

Bronchoscopy is used even in small infants and children for rejection and infection surveillance. Bronchoalveolar lavage fluid is sent for culture on a routine basis, and biopsy specimens are obtained either through a fiberoptic bronchoscope or though a suction catheter positioned in the distal airways under fluoroscopic guidance if the airways are too small to allow an adequate sized fiberoptic bronchoscope to pass into the distal airways. Significant documented rejection is treated by pulse steroids and increases in dosage of tacrolimus or cyclosporine as necessary.

Refractory rejection can be treated with cytolytic agents such as OKT3 if the patient does not rapidly respond to an increase in steroid dose. Echocardiography is used to evaluate cardiac function in children after heart–lung transplantation. Differential rejection of heart and lungs is well documented; however, cardiac rejection appears to be rare in the absence of associated pulmonary rejection. In addition, the incidence of cardiac rejection in cardiopulmonary transplant is lower than in cardiac transplant alone. Thus, in the absence of evidence for pulmonary rejection, cardiac biopsies are not routinely performed except when echocardiographic findings are concerning for rejection.

**RESULTS**

Early postoperative complications are uncommon. The incidence of airway stenosis is approximately 10% and can be treated conservatively with serial balloon dilation. True airway dehiscence occurs rarely and is managed emergently. Nerve injury resulting from the explantation of the native lungs is more frequent with phrenic nerve injury occurring approximately 15% of the time. It is managed conservatively in most cases and often resolves within 6 months of surgery. Recurrent laryngeal nerve injury occurs 10% of the time, rarely resulting in respiratory difficulty but potentially augmenting the possibility of aspiration.

Relatively few results of cardiopulmonary or pulmonary transplantation have been reported in children. However, the overall reported rates to the Registry of the International Society of Heart and Lung Transplantation show a significant increase in the number of pediatric lung transplants performed over the last decade, particularly in the 12 to 17 age range while there have been significantly fewer heart–lung transplants. For heart–lung transplant, there has been no increase in survival over the past 30 years. The average half-life survival in heart–lung recipients is approximately 3 years for those patients >1 year of age. For infants <1 year of age, however, only half of the patients survive >2 years. Excluding those patients who die within the first year post transplant, average survival is approximately 6 years. Survival is poorest in those patients transplanted because of complex congenital heart disease compared with pulmonary hypertension. Lung transplantation survival statistics in pediatric populations have improved significantly, particularly due to improved early survival. After the first year post transplant, survival in pediatric lung transplant has not changed significantly in decades. The half-life is best in older children at 12 to 17 year range surviving to 4.3 years. Early 1- and 5-year survival rates for recipients transplanted in the recent decade are 83% and 50%. As expected, the initial operative mortality is higher in children requiring pulmonary transplantation and cardiac repair and in patients with pulmonary hypertension. The long-term results are improved after initial operative mortality is excluded from the analysis.

The major obstacle to long-term survival after lung transplantation in children is the development of bronchiolitis obliterans, which may be a manifestation of chronic rejection. It is most commonly seen in older patients and in patients >5 years from transplant. The onset of bronchiolitis obliterans is associated with progressive dyspnea and reduction of oxygen saturation on room air plus a documented decrease in FEV₁ or in forced expiratory flow over mid-expiration (FEF₂⁰₋₇⁵). The clinical diagnosis of bronchiolitis obliterans may be considered if there is a sudden decrease in FEV₁ of 20% or greater from the maximum post transplant baseline level, unassociated with infection, acute rejection, or bronchial complication. Although some patients have had stabilization of the level of bronchiolitis obliterans with increased immunosuppression with
addition of an antilymphocytotoxic agent, such as OKT3, in other children a progressive decline in lung function has occurred that either required retransplantation or resulted in late mortality. In heart–lung transplant recipients, the onset of bronchiolitis obliterans may occur independent of the development of coronary graft atherosclerosis or chronic rejection of the transplanted heart. The majority of malignancies seen in pediatric transplant patients is related to post transplant lymphoproliferative disorder (PTLD), secondary to EBV, occurring in approximately 15% of patients within 5 years of transplant. PTLD is treated with reduction of immunosuppression and Rituximab with additional chemotherapy as needed.

**CONCLUSION**

Lung and heart–lung transplantation can be performed safely and successfully in patients who have no other therapeutic options. Donor availability remains limited and waiting list mortality high. Although results are encouraging, obliterative bronchiolitis remains a serious late concern that must be addressed for the future success of cardiopulmonary transplantation in children. As increasing experience has been gained in cardiac repair and lung transplantation and the use of reduced-size donor grafts, the technical limitations to cardiopulmonary and pulmonary transplantation have been largely eliminated. The immunologic issues related to late development of chronic rejection and bronchiolitis obliterans, however, make cardiopulmonary and pulmonary transplantation a palliative procedure for the majority of recipients.

**SUGGESTED READINGS**

PREOPERATIVE PLANNING

Severity of Leaflet Abnormality

Ebstein's malformation can be categorized according to the severity of apical displacement and hypoplasia of septal and anterior leaflets, as well as by the size of atrialized chamber. Echocardiography and magnetic resonance imaging (MRI) are typically used to categorize the malformation into types A–D, with type A describing very mild displacement of the septal leaflet, type B and C describing anterior leaflet displacement and varying degrees of tricuspid regurgitation. Functional RV beyond the tips of the abnormal leaflets may be small, thin-walled, and hypokinetic or dyskinetic. The preoperative assessment, timing of intervention, and techniques for TV repair are discussed. Although an “ebsteinoid tricuspid valve” may also accompany L-transposition of the great arteries, the management of this entity is not discussed in further detail.

Atrial Septal Defect

In patients with Ebstein's malformation and atrial septal defect, the direction of flow across the defect indicates relative compliance of the downstream ventricles. Gradual worsening of cyanosis heralds the decline in RV compliance and function. Catheter-based closure of the atrial septal defect in these patients may alleviate cyanosis but does not improve long-term prognosis related to ongoing RV volume overload and progressive RV failure.

Pulmonary Valve Stenosis or Atresia

Fetal or postnatal echocardiogram may demonstrate pulmonary atresia, but imaging may not reliably distinguish functional versus anatomic atresia in a fetus or infant with a patent ductus arteriosus (PDA) and significant left to right flow. The presence of pulmonary regurgitation suggests functional rather than anatomic atresia. The distinction is clinically relevant since the patient with anatomic atresia is dependent upon the PDA for pulmonary blood flow, whereas ductal closure may be the desired treatment for a neonate with functional atresia since interruption of the PDA restores antegrade flow across the pulmonary valve. Both functional and anatomic atresia are risk factors for mortality in neonates with Ebstein's malformation. Similarly, RV outflow tract obstruction is a risk factor for poor outcomes in non-neonates undergoing repair.

Right Ventricular Function and Mass

MRI can be used to estimate the volume and wall thickness of the functional RV in the evaluation of Ebstein’s malformation beyond infancy. A dilated and thin-walled RV may not tolerate isolated TV repair, and unloading maneuvers, such as cavopulmonary shunting, may be necessary adjuncts. In the evaluation of the neonate or fetus, Doppler estimation of the RV pressures allows risk stratification. Although low-RV pressure is almost universally present in children and adults with Ebstein's malformation, estimated RV pressures by echocardiography of <20 mmHg may be a sign of inadequate RV function in neonates.

Inducible Atrial and Ventricular Arrhythmias

Preoperative electrophysiologic studies are helpful at identifying the presence of accessory pathways or substrate for atrial or ventricular arrhythmias. Although ablation of accessory pathway can be performed in the catheterization laboratory, the presence of inducible atrial arrhythmias is an indication for intraoperative cryoablation–MAZE in a patient undergoing TV repair. The presence of inducible ventricular arrhythmias should raise consideration for intraoperative epicardial defibrillator coil placement, thus avoiding subsequent need for transvenous lead placement across the TV.

SURGICAL INDICATIONS AND TIMING

Operative intervention for Ebstein's malformation typically follows a bimodal distribution, with initial phase occurring in neonates and infants, followed by a phase that occurs in adolescence and adulthood. The indications for operation, the type of procedure performed, and the operative mortality vary significantly for these two groups.

Neonates

Prenatal diagnosis of Ebstein's malformation has allowed improvements in immediate postnatal management of this disease. Risk stratification prenatally can be performed by the assessment of RV size and function as well as by the measurement of RV pressures and direction and degree of flow across the PDA and right ventricular outflow tract. In severe forms of Ebstein's malformation, the RV pressure estimated by Doppler velocity of tricuspid regurgitation jet is low (<20 mmHg), suggesting poor systolic function of the RV. Presence of anatomic pulmonary atresia is a risk factor for mortality in neonates with Ebstein's malformation. Antegrade pulmonary blood
flow across a patent pulmonary valve may not occur in the presence of a PDA, resulting in functional pulmonary atresia. In a subset of patients with functional atresia and adequate RV systolic function, antegrade flow may resume following ductal closure. A patient with PDA and pulmonary regurgitation may present with extreme circulatory failure, and expeditious ligation of the ductus arteriosus abrogates the circular shunt. A sternotomy approach for ligation of the PDA allows access for cardiopulmonary bypass in case of circulatory collapse from inadequate right heart structures. A neonate with Ebstein’s malformation may present with circulatory failure or extreme cyanosis, warranting surgical intervention. In these patients, biventricular repair with TV repair alone carries a high mortality, and single-ventricle palliation with RV exclusion should be considered.

Adolescents and Adults
A patient who survives the neonatal period may remain relatively asymptomatic for years, even with significant tricuspid regurgitation. Indications for intervention include development of symptoms—specifically exercise intolerance, cyanosis, or arrhythmias. Timing of repair in the asymptomatic patient is controversial, but the presence of left ventricular compression, progressive right atrial (RA) or RV dilation by noninvasive imaging studies may herald onset of symptoms.

SURGICAL TECHNIQUES
Several techniques have been described for TV repair. Original procedures developed for this abnormality involved posterior tricuspid annuloplasty and transverse or longitudinal plication of the atrialized portion of the RV, thereby bringing the true annulus to the level of the functional annulus. A significant portion of these patients subsequently require TV replacement. The operation described by da Silva et al. termed “cone reconstruction” has been most recently adapted by many pediatric centers. The procedure bears similarities to the technique described in 1988 by Carpentier, but differs in the extent of mobilization and rotation of leaflet apparatus. The components of the tricuspid repair include leaflet reconstruction, RV reduction by plication or resection, RA reduction, and creation of atrial lesions to prevent arrhythmias. Augmentation of deficient leaflets and papillary muscle repositioning may be necessary as well.

Adjunct procedures include maintenance of a patent foramen ovale, creation of superior cavopulmonary shunt, and replacement of the pulmonary valve.

“Cone” Reconstruction of Tricuspid Valve
The goal of leaflet reconstruction is to utilize redundant valvular tissue from the anterior and posterior leaflets of the TV to re-create a new septal leaflet, which is appropriately located at the true annulus of the TV. The TV in Ebstein’s malformation may contain adequate surface area of leaflet material resulting from a large annular diameter and anterior leaflet circumference. Regurgitation results from maldistribution of leaflet material, such that the height of the posterior and septal leaflets is inadequate to coapt centrally with the anterior leaflet. The goal of the cone reconstruction is to redistribute existing leaflet tissue to the true annulus in the posterior and septal regions. Edge-to-edge reconstruction of leaflet material yields a circumferential leaflet of adequate height but smaller circumference, which allows for central coaptation. The leaflet reconstruction can be subdivided into discrete phases.

1. Detachment of leaflets and delamination of leaflet material. A circumferential incision is made in the anterior leaflet near its hinge point to the annulus, beginning at the anterosepetal commissure, extending clockwise onto the posterior leaflet and further onto the septal leaflet if present. Identification of the true annulus may be challenging due to tethering of leaflet tissue to the ventricle. In patients with type D malformation, there may be failure of delamination of the anterior leaflet tissue from underlying RV, giving an echocardiographic appearance of absent leaflet tissue. However, careful examination reveals distinct layer of leaflet tissue that can be delaminated from the RV mass. The distinction between leaflet and annulus is most obvious in the mid-portion of the anterior leaflet, and therefore, a circumferential incision is started at this point and carried in the clockwise and counterclockwise directions (Fig. 101.1). The hinge point to the annulus becomes easier to identify once delamination has been initiated on the anterior leaflet. Care must be exercised during delamination to avoid injury to the underlying myocardium or leaflet material itself. The leaflet detachment process is continued clockwise onto the posterior leaflet and septal leaflets, harvesting as much usable leaflet tissue as possible (Fig. 101.2). By delamination of fused leaflets, sufficient quantities of leaflet material can be frequently harvested to create a new TV without addition of prosthetic material.

2. Division of tethering secondary chords and muscle bundles. To allow adequate mobility of the leaflets for a cone-type reconstruction, the secondary chordal attachments and tethering muscle bundles must be mobilized down to the apex of the RV. These can be adequately visualized once the base of the leaflet has been detached from the tricuspid annulus (Fig. 101.3).

Fig. 101.1. Leaflet mobilization begins with detachment of the anterior leaflet at the level of the annulus. The circumferential incision at the base of the leaflet is carried counterclockwise to the level of the anterosepetal commissure.
Section III: Congenital Cardiac Surgery

Primary chordal attachments must be identified and preserved during this process, but inadequate excavation of tethered papillary muscles may result in residual regurgitation following repair. Repositioning the anterior leaflet papillary muscle toward the septum either by transection and re-implantation or suture approximation of the anterior and septal papillary muscles is an adjunct to papillary muscle mobilization, which prevents distraction of the tips of the reconstructed leaflets, improves coaptation, and may prevent dilatation of the RV cavity.

3. **Leaflet lengthening.** Once leaflet material has been harvested, reconstruction of the septal and posterior leaflets is performed by approximation of cut edges of septal and posterior leaflets, thus “lengthening” this leaflet tissue while reducing the effective circumference. Sewing edges of posterior leaflet to septal leaflet reduces the circumference of the new valve while increasing the height of its leaflets (Fig. 101.4). Edge-to-edge approximation is continued until sufficient leaflet height is obtained to reach the true tricuspid annulus without tension. By reconfiguring existing surface area of leaflet material, adequate zone of coaptation is achieved without augmentation with additional prosthetic material. The septal leaflet is approximated to the anterior leaflet at the commissure to create support for both of the anterior and newly constructed septal leaflet. Since the anterosetal commissure is maintained in its original position, edge-to-edge closure of the anterior leaflet and the new septal leaflet results in clockwise rotation of the entire valve apparatus, thus creating a funnel or “cone” configuration. The cone reconstruction converts a narrow but large-diameter TV into a smaller-diameter but taller-leaflet valve utilizing the same surface area of leaflet material. A subset of patients may have insufficient leaflet material to create a tension-free reconstruction up to the level of the true tricuspid annulus. Augmentation of septal leaflet with autologous pericardium or other leaflet substitute material may be necessary in these patients.

4. **Annular and ventricular remodeling.** Abnormally thin and dilated segments of RV must be excised or plicated during the reconstruction in order to optimize RV dynamics and prevent splaying of papillary muscles following cone reconstruction (Fig. 101.5). Identification of the right coronary artery and posterior descending coronary artery is critical to avoid injury to these structures during resection or plication of the RV. The section of RV that is usually remodeled includes the acute margin near the diaphragmatic surface. The goal of RV remodeling is to reduce the volume of the dilated ventricle as well as remove dyskinetic or akinetic regions of RV to improve ventricular efficiency. Reduction of RV volume also minimizes the distraction of papillary muscles and primary chordal attachments, which contribute to recurrent tricuspid regurgitation. The diaphragmatic aspect of the true tricuspid annulus is reduced by plication as an extension of RV plication or resection, as well as near the anterior leaflet (Fig. 101.6). The annulus is reduced to match the size of the newly reconstructed TV leaflets. Once the leaflets are attached to the neoannulus, reinforcement of the plicated annulus with a partial flexible ring prevents dehiscence, particularly in adolescents and adults (Fig. 101.7).

5. **Leaflet reattachment.** Following annular reduction and RV remodeling procedure, the reconstructed TV leaflets are attached to the neoannulus at the level of the true annulus. This reconstruction is reinforced by the placement of a prosthetic annuloplasty ring in the adolescent or adult patient. Injury to the atrioventricular (AV) node is avoided by the placement of a partial ring that spares the septal portion (Fig. 101.7).
1101

6. **Cryoaulation for prevention and treatment of atrial arrhythmias.** A rightsided cryoaulation–MAZE is performed for patients with documented paroxysmal atrial flutter and fibrillation or inducible atrial arrhythmia by preoperative electrophysiologic testing. However, we have expanded our indications for RA cryoaulation–MAZE to prophylactic application in all patients undergoing repair. Patients with chronic atrial fibrillation may benefit from bialtrial Cox-maze procedure. The lesion set most commonly utilized includes isthmus (1) between the inferior vena cava and the ostium of the coronary sinus; (2) between the ostium of the coronary sinus and the true TV annulus; and (3) between the anterior portion of the TV annulus and the edge of the atriotomy (Fig. 101.8). A fourth lesion between the foramen ovale and the atriotomy incision near the superior vena cava has been described, but in our experience increases the risk of postoperative sinus node dysfunction. If AV nodal conduction abnormality is present or suspected at the time of TV repair, placement of epicardial pacing leads is recommended to prevent subsequent lead placement through the reconstructed valve. Previously placed endocardial RV leads may be sutured within the annulus of the TV to avoid interference with TV function.

7. **Atrial septal defect closure.** A residual atrial level communication may be maintained as a mechanism for RV unloading. Superior cavopulmonary shunt is preferred if right heart failure is anticipated or encountered postoperatively (see below).

**Palliative Shunt and Right Ventricle Exclusion**

Neonates who demonstrate hemodynamic instability or severe cyanosis and require intervention are at high risk for mortality. They frequently demonstrate low-RV pressures suggestive of systolic dysfunction or have functional or anatomic pulmonary atresia. In these patients, a biventricular circulation is untenable not only because the RV is unable to support a full cardiac output but also due to compression of the LV from the massive RV. In these patients, exclusion and reduction of the RV along with an aortopulmonary shunt may provide stability for eventual single-ventricle palliation or biventricular conversion. Maintenance of the tricuspid valve tissue maintains the option for leaflet reconstruction, should the RV...

Fig. 101.7. The leaflet reattachment to the annulus is reinforced with the addition of a partial flexible annular ring.

Fig. 101.8. The right atrial cryoablation-MAZE procedure involves placement of lesions between (1) coronary sinus (CS) and true tricuspid annulus, (2) CS and inferior vena cava, (3) inferior vena cava and right atriotomy, and (4) right atriotomy and anterior tricuspid annulus. An additional lesion between the foramen ovale and the right atriotomy near the superior vena cava may be performed (not shown). CS, coronary sinus.

eventually be deemed suitable for biventricular conversion.

Superior Cavopulmonary Anastomosis

A superior cavopulmonary anastomosis may be necessary as an adjunct to tricuspid valve repair in patients with severely dilated and thin-walled RV as a means of unloading the right heart. Qualitative preoperative assessment of RV mass and systolic function by noninvasive imaging studies help guide the decision. Alternatively, hemodynamics can be assessed following tricuspid valve repair. Evidence of right heart failure (elevated central venous pressures, decreased cardiac output) in the operating room following separation from cardiopulmonary bypass would indicate a need for cavopulmonary shunting.

Tricuspid Valve Replacement

Prosthetic tricuspid valve replacement is reserved for patients who fail attempt at tricuspid valve repair. A biological prosthesis is preferred over mechanical due to the risks of thrombosis in the latter. The options for biological prosthesis include porcine and pericardial tissue valves. Porcine bioprosthesis has been preferred to pericardial prosthesis since the porcine leaflet material is thinner than the pericardial tissue; thus theoretically, it is better suited to function with the lower opening and closing pressures associated with right heart circulation. There are, however, no data to support this bias. AV nodal injury is prevented by implantation of the valve in the suprannular position near the septal aspect, leaving the coronary sinus on the ventricular side of the valve.

OUTCOMES

Early (hospital mortality) for non-neonates undergoing repair is between 3% and 6%. Long-term data are available regarding repair techniques other than the cone reconstruction. Actuarial survival and freedom from reoperation at 10 years are approximately 90% and 77%, respectively. Long-term results are beginning to emerge regarding durability of the cone reconstruction suggesting favorable results. Moderate tricuspid regurgitation at discharge is a risk factor for reintervention, and consideration should be given to early reoperation in these children to avoid sequelae of right heart failure. Sudden death due to arrhythmias has prompted more aggressive postoperative monitoring and management with antiarrhythmic agents, catheter-based ablation, and defibrillator implantation.

EDITOR’S COMMENTS

Until relatively recently, patients with Ebstein’s malformation of the tricuspid valve with atrial septal defect who survived infancy were managed medically for many years before any surgical intervention was recommended. The primary reason for delay in operative intervention was the fact that these patients remained relatively stable despite severe cardiomegaly on chest X-ray films and cyanosis from right-to-left shunting at the atrial level. It was believed that the only operative intervention would be valve replacement, and a high incidence of heart block was associated with valve replacement in the earlier surgical eras. Thus, operative intervention was delayed until the patient became old enough to accept a satisfactory-sized adult prosthesis with probable epicardial pacemaker placement.

The markedly improving results with valve repair for Ebstein’s malformation as pioneered by Danielson at the Mayo Clinic and recently by DaSilva in Brazil has changed the approach to patients with Ebstein’s malformation significantly. Because most valves can be repaired (approximately 90% in most series), earlier intervention may be recommended for patients with severe cardiomegaly and cyanosis. With earlier repair and with valve repair rather than replacement, the biventricular function can be maintained, and elimination of atrial level shunting decreases the chronic effects of cyanosis and markedly improves exercise tolerance in these patients. With current techniques, a low incidence of complete heart block has been noted. Nevertheless, as emphasized by the authors, arrhythmias are common after repair of Ebstein’s malformation of the tricuspid valve. Many of these patients may have accessory conduction pathways, and long-term antiarrhythmic therapy or ablation, either before valve repair or at the time of operation, may be necessary to control arrhythmias. Direct surgical approaches for controlling atrial arrhythmias at the time of valve repair have been advocated, and the results have been quite excellent.

The optimal valve replacement for patients who require replacement rather than repair is somewhat controversial. Mechanical valves in the right side of the heart require anticoagulation, and thrombosis may be more frequent than on the left side of the heart despite adequate warfarin therapy. Therefore, tissue valves have preferentially been used on the right side of the heart and have the additional advantage of permitting access for catheterization if necessary. Tissue valves, however, in young children have a significant incidence of degeneration even on the right side of the heart, and therefore valve repair should be undertaken if at all possible in all cases.

An infant with significant congestive heart failure with Ebstein’s malformation represents a continuing therapeutic dilemma. These patients often have abnormal ventricular function or obstruction to the right ventricular outflow tract, which accounts for the severity of the hemodynamic instability early in life. Thus, simple valve repair may not be possible in most of these infants, and the operative mortality with surgical intervention has been high. If infants do not respond to medical management, then the optimal operative approach remains controversial. As described in this chapter, in some patients who have only mild right ventricular outflow tract obstruction from leaflet tissue rather than at the valvar level, it is occasionally possible to close the entrance into the right ventricle with a patch to control the magnitude of tricuspid regurgitation and convert the patient to single-ventricle physiology. These patients, coronary sinus flow and Thebesian flow must still be ejected from the right ventricle, and therefore an unobstructed outflow tract to the pulmonary artery is necessary. Recognition of the distention of the small ventricle has led Starnes to modify his original procedure, creating a punch opening or fenestration in the center of the patch to allow decompression of the right ventricle. Even with these approaches, operative mortality is significant. As noted in this chapter, the most significant problem occurs in infants with Ebstein’s malformation and pulmonary atresia or significant pulmonary stenosis. These patients often are ill immediately after birth, and the right ventricle is markedly dilated and can cause abnormal ventricular function on the left side of the heart. If such patients can be identified in utero, then in utero listing for heart or heart-lung transplantation may be the most appropriate therapy. Operative intervention after birth in these rare children has been often unsuccessful, and in our experience heart transplantation may be the best option. As reparative techniques improve, however, some of these infants may be suitable for operative intervention if the right ventricle has adequate volume and function.

An increasing experience with repair of Ebstein’s malformation in neonates and infants has been reported by Knott-Craig. In his small series of patients who were unstable in the neonatal and infant period and did not respond to medical management, valve reparative techniques were successful in the majority of cases. Thus, it may be reasonable to attempt valve repair in the majority of these patients before converting them to single-ventricle physiology. Attempts to ablate the right ventricle have been unsuccessful because of the amount of inflow into the ventricle from the Thebesian veins, and therefore occlusion of the inflow into the ventricle without adequate outflow has not been successful. Attempts to reconstruct the right ventricular outflow tract and eliminate inflow into the ventricle have also not been successful because of the inability of the right ventricle to adequately decompress. Ventricular dysfunction is common in these patients with a thinned, poorly contractile right ventricle, probably secondary to in utero severe tricuspid regurgitation. Sano and his associates have been successful in complete excision of the right ventricular free wall in rare cases with pulmonary atresia and Ebstein’s malformation with patch closure or oversewing of the tricuspid valve inlet. These radical approaches of RV exclusion have been successful in isolated cases and may represent a reasonable alternative in patients who have significant RV dilation and RV dysfunction and abnormal

(continued)
ventricular septum that can bulge into the left ventricular outflow tract and cause left ventricular outflow tract obstruction. In these cases, removal of the free wall of the right ventricle may allow septal repositioning and improvement in left ventricular outflow tract diameter.

Drs. Emani and del Nido have appropriately emphasized the fact that closure of atrial septal defect to alleviate cyanosis in patients with Ebstein’s malformation may not actually improve long-term prognosis. It is a tempting in patients who present with increasing cyanosis to eliminate the right-to-left shunt with a catheter-based ASD closure. However, in the authors’ and our own experience, closing the atrial septal defect simply unmasks the underlying ventricular dysfunction in these patients and often worsens the tricuspid regurgitation. An important thing to remember in Ebstein’s malformation is that significant right-to-left shunting implies abnormalities of compliance of the ventricle rather than the magnitude of tricuspid regurgitation. Similarly, the authors have noted that patients presenting in the neonatal period with low-RV pressures may have a very poor prognosis from attempts at valve repair. If the RV pressure is low, these patients generally have had very abnormal ventricular function and compliance and these patients may represent the most severe form of the disease. Single-ventricle approaches are probably the best used in this subset of patients.

The most severe form (Type D) of Ebstein’s malformation can often still undergo complete repair using the cone technique. Nevertheless, as emphasized by the authors it is important when mobilizing an anterior leaflet in this severe subgroup of patients, not to significantly damage the ventricular myocardium. In some cases, the leaflet is essentially created from the endocardial surface and significant dissection of myocardial tissue is necessary to mobilize the leaflet. In patients who present with cyanosis with this type of lesion, ventricular function may be severely abnormal postoperatively. This can be a very high-risk subset of patients and postoperative RV failure, which is difficult to treat, can be a complication.

The authors note that valve replacement in Ebstein’s malformation is becoming increasingly less common. They suggest placement of the valve above the coronary sinus to avoid the area of the conducting tissue. If some valve leaflet tissue is allowed to remain in the area of the AV node, it is possible to place the tricuspid prosthesis in the normal anatomic location, which avoids subjecting the coronary sinus to right ventricular pressure.

Overall, the surgical approach to Ebstein’s malformation remains a technical challenge. Although repair techniques are evolving and the use of the bidirectional Glenn or cavopulmonary shunt permits more drastic reduction of the tricuspid annulus to achieve better competence, the wide variation in ventricular function, valve morphology, and age at presentation make this patient population medically challenging.

TLS
INTRODUCTION/BACKGROUND

Mitral valve repair in children is guided by the same surgical rules than in adults but the anatomical substrate differs greatly. They have been set by Carpentier more than two decades ago. The technical difficulties vary according to the anatomy and to the size and age of the patient. The indications for surgery and the timing of the surgery have to take into account a large number of issues and are, therefore, more complex than in adults.

This chapter will cover mitral valve repair in children, congenital and acquired, excluding the mitral valve in atrioventricular discordance, the mitral valve in univentricular hearts, and the mitral valve of the hypoplastic left heart syndrome. We have added in this edition the surgical approach to the repair of the residual or recurrent regurgitation the left atrioventricular valve in complete atrioventricular septal defects (AVSDs).

ANATOMY AND EMBRYOLOGY

Anatomy

The normal anatomy of the mitral valve in children does not differ from the adult one and has been described. Precise knowledge of the normal anatomy is essential to read the echocardiographic study, to understand the pathological anatomy and to plan the repair.

Embryology

The leaflet and chordal tissue derive from the endocardial cushion tissue lying on the inner surface of the atrioventricular junction. The anterior leaflet originates from the superior and inferior cushions, whereas the posterior leaflet derives from an infolding of the lateral wall. As the cushion tissue elongates and grows toward the ventricular cavity, the leaflets shape progressively into a funnel-like structure totally attached to the myocardium while perforations appear in the valve leaflet edges. The perforations grow and form the chordae tendineae. The ventricular layer of the cushions will generate the fibrous part of the mitral valve and the chordae. Simultaneously, the development of the papillary muscle takes place: The anterior and posterior parts of a horseshoe ridge within the left ventricle lose contact progressively with the ventricular wall. They will form the papillary muscles, increasing their size while keeping contact with the cushion tissue at their tip.

PATHOLOGY

Congenital Anomalies of the Mitral Valve

Congenital valve stenosis and congenital mitral valve insufficiency are presented together because they have identical pathology and associated lesions. They are frequently associated in the same patient and require similar surgical techniques for the treatment.

Cleft Mitral Valve

Very often isolated, the cleft mitral valve can be easily differentiated from a left atrioventricular valve in a partial AVSD. The cleft is centered on the aortic commissure between the noncoronary cusp and the left coronary cusp, and there is no suspension apparatus on the edges of the defect. The papillary muscles are normal. Lack of valvular tissue can be seen and is secondary to the regurgitation through the cleft. The defect is not stenotic and may generate only little regurgitation for a long time.

Accessory Valve Tissue and Valvular Tags

In these anomalies, often found in association with other valvar anomalies, the spaces between the chordae are filled with a network of myxoid, valve-like tissue. When there is continuity between the anterior and the posterior leaflet, the accessory tissue may generate a gradient directly related to the size of the perforations in the accessory tissue. When the accessory valve tissue is entrapped in the left ventricular outflow tract, the mitral valve may become regurgitant due to the traction exerted by the accessory valvular tissue on the anterior leaflet, opening the valve in mid systole; however, in such cases, the left ventricular outflow tract obstruction is the predominant hemodynamic lesion and is the most frequent mode of diagnosis. The accessory mitral valve tissue in isolation often does not generate significant gradient or insufficiency.

Lesions Associated with Lack of Valvular Tissue

Three major anatomical types have been identified, although there is a continuum between them. Their recognition is useful for the planning of the repair. The functional lesion can be either predominantly regurgitant or predominantly stenotic, it can be both stenotic and regurgitant, or the valve can have a normal function.

Parachute Mitral Valve

The parachute mitral valve can be found in isolation. It can be integrated in a Shone syndrome. There is a dominant papillary muscle with the orifice of the mitral valve overriding the tip of the papillary muscle. There is a spectrum of lesions for the chordae ranging from complete absence and fusion of the tip of the papillary muscle to the free leaflet edge to relatively normal looking chordae with good mobility of the leaflet. An accessory papillary muscle, usually very small is devoted to a short segment of the free edge, or even to the under surface of the leaflet tissue with or without second orifice (double-orifice mitral valve). The functional anatomy depends on the interaction between the amount and mobility of leaflet tissue, size of the fenestrations and the presence, length, and quality of the chordae. The parachute mitral valve has almost always a stenotic component.

Papillary Muscle to Commissure Fusion

This syndrome is a spectrum. It ranges from papillary muscle tip fused to the...
commisural area of the free edge to short, almost normal looking chordae. This anomaly can be limited to one papillary muscle only. The valve is generally more regurgitant than stenotic. When the papillary muscles are hypertrophied, the bulk of their mass is responsible for a valve predominantly stenotic.

**Hammock Valve (Arcade Valve)**

The suspension apparatus may have lost all resemblance to the normal anatomy. There is either no papillary muscle identifiable or multiple very small ones behind the posterior leaflet. The leaflets are suspended directly by a network of chordae directly attached to the posterior wall of the ventricle. This attachment is generally displaced toward the base of the heart with an excess of tension on the anterior leaflet and extreme limitation of posterior leaflet motion. The valve is most often predominantly regurgitant.

**Regurgitant Mitral Valves with Normal Anatomy Associated with Congenital Cardiac Lesions**

**Isolated Annular Dilation; Isolated Elongation of the Chordae and/or the Papillary Muscle**

There is no evidence of the congenital origin of these lesions. They are not found at birth unlike the previous anomalies described above. They are usually associated with significant volume loading of the left ventricle, that is large ventricular septal defect or large patent ductus arteriosus. Sometimes minor anomalies of the valvular tissue or the papillary muscles can give an indication toward a true congenital origin. The papillary muscle may have an ischemic aspect, and even rupture, this is mostly seen in neonates.

**ALCAPA**

The mitral regurgitation in patients with anomalous coronary artery from the pulmonary artery is of ischemic origin. The anatomy is normal. The functional classification is of systolic restriction of one of the segments of the posterior leaflet (Carpentier type IIb).

**Supravalvar Mitral Ring**

Quoted as a common cause of congenital mitral valve stenosis, the supravalvar mitral ring is an acquired fibrous construction attached to the posterior annulus of the mitral valve and from both commissures to the mid-height of the anterior leaflet. The supravalvar mitral ring is secondary to turbulent flow through the mitral orifice. The primary lesion of the mitral valve responsible for the turbulent flow can be obvious, stenotic, or regurgitant and can be very discrete and difficult to identify. The supravalvar mitral ring is prone to reoccur after surgical resection, unless the underlying anatomical anomaly has been identified and corrected. The supravalvular ring can be encountered very early in life. It has to be suspected every time the transvalvular gradient increases during follow-up or when the Doppler gradient is greater than what the anatomy depicted with the echocardiographic study would suggest; sometimes, it is only found at operation.

**Mitrail Valve Disease with Excess Leaflet Tissue**

They are Marfan syndrome, Loyes–Dietz syndrome, mitral valve prolapse, Barlow disease, Ehlers–Danlos syndrome, and mucopolysaccharidosis type I. All include elastic fibers alteration and myxomatous tissue proliferation of various degrees. Most are now well associated with chromosomal mutations.

**Acquired Mitral Valve Disease**

**Rheumatic Heart Disease**

Acute rheumatic fever (ARF) is an autoimmune disorder. The immune response to group A streptococcal M protein generates T cells and antibodies that cross-react with cardiac antigens. In some patients, the acute damage to the valves will induce chronic and evolving lesions secondary to the scarring process and/or the hemodynamic modifications. This is known as rheumatic heart disease.

**Acute Lesions**

Acute lesions are exclusively regurgitant. On inspection, the valvar tissue and the chordae are swollen but supple. Prolapse predominantly affects the anterior leaflet. This prolapse is usually related to large elongation of the marginal chordae that appeared stretched; chordal ruptures are rare. Multiple small nodules (2 to 3 mm diameter) can be seen on the free edge of either mitral leaflet. The annular dilation is secondary to the myocarditis.

**Chronic Lesions**

The healing of the spongiosa induces fusion of chordae as demonstrated by reduction in their number and increase of their thickness. The physiology of the regurgitation is always a combination of prolapse of the anterior leaflet, retraction of the posterior leaflet, and annular dilation. In the pediatric age group, the mitral valve is exclusively or predominantly regurgitant. The stenosis appears later and the age of apparition of the mitral stenosis varies greatly with the geographical origin of the population affected, suggesting different pattern of infection (i.e., age of first ARF episode) and influence of other factors (genetic mostly and alimentation).

**Infective Endocarditis**

Bacterial endocarditis of the mitral valve is rare. It is always a regurgitant lesion. At the Royal Children’s Hospital, Melbourne, in the last decade most patients had normal native mitral valve. It is very important for the surgeon to be able to differentiate intact valvar tissue, supple thin and resistant from infected tissue, thickened edematous and friable.

**The Left Atrioventricular Valve in Repaired Atrioventricular Septal Defect**

**Anatomy**

The anatomy of the left atrioventricular valve after complete AVSD repair has standard features: The superior and inferior bridging leaflets are partitioned transversally at the level of the crest of the septum. Their mobility is very limited at that level; it increases further away from the partition point. The superior and inferior bridging leaflets face one another through the zone of apposition made of by rough surface. The quality of the suspension apparatus to the free edge varies greatly from patient to patient. The zone of apposition between these two leaflets has often been closed with continuous or interrupted sutures at the time of the primary repair. In the most common configuration, the left lateral leaflet (LLL) or posterior leaflet is normally developed and the superior and inferior bridging leaflets separate from one another and delineate a triangular orifice at the inferior aspect of the left AV valve annulus. This orifice is covered with the LLL. It is triangular; the base hinges at the posterior aspect of the annulus and the tip faces exactly where the superior and inferior leaflets separate. Between one-third and one-fifth of the circumference of the reconstructed left AV valve belongs to the LLL. Two papillary muscles make the suspension apparatus. The anterior papillary muscle underneath the zone of apposition between the superior bridging leaflet and the LLL and the posterior papillary muscle...
underneath the zone of apposition between the inferior bridging leaflet and the LLL and their respective commissure. The leaflet has a broad base when it covers one-third of the annulus or a narrow base when it covers one-fifth. In that configuration, the LLL is tall and narrow and unstable.

In the least common configuration (6% to 10% of the complete AVSD), the LLL is diminutive or absent. Both superior and inferior bridging leaflets are supported by the anterior papillary muscle, while the posterior papillary muscle is commonly diminutive or more rarely absent. Both bridging leaflets reach the left lateral annulus where a true commissure can be seen. Most often, the diminutive posterior papillary muscle is supporting a second orifice in the inferior bridging leaflet.

Mechanism of the Regurgitation in Repaired Left Atrioventricular Valve

Valves with Normally Developed Left Lateral Leaflet

The regurgitation is related to the lack of apposition facing the tip of the LLL. The closure of the cleft does not restore a surface of apposition; in fact, the little apposition surface may be reduced and distorted by the cleft closure (Fig. 102.1). If the cleft closure has ruptured or partially ruptured, then the defect created and the doming of the combined bridging leaflets augments the regurgitation. If the regurgitation has been long-standing, the secondary lesion or dysplastic lesions on the edges of the cleft are severe with thickening, sometimes calcification and severe retraction of the leaflet tissue. However, it is almost the rule for the LLL to be thin and pliable with no secondary or dysplastic lesion. There is no restriction of leaflet motion and no prolapse.

Absent or Very Hypoplastic Left Lateral Leaflet

At the time of initial repair, the cleft closure is not performed or only partially executed in order to avoid the creation of a stenosis. Consequently, the regurgitation is always through the cleft, with retraction of the edges of the cleft and very few or no chordae attached to them (Fig. 102.2).

INDICATION AND PLANNING OF THE REPAIR

Echocardiography

The long axis view obtained from the apex or from subcostal view of the transthoracic study is best to grade the regurgitation, provide an accurate estimation of transvalvular gradient and define the precise amplitude of any prolapse or restriction. The short axis view gives a direct evaluation of the area of the mitral orifice, a precise localization of the regurgitant jet. It allows an analysis of the papillary muscles (presence, size, location, and symmetry). The transeosophageal echo is superior for the anatomical details of the suspension apparatus, the evaluation of the functional classification in relation to the anatomy (response to the question: how much prolapse/restriction and where?), but it is less useful to grade the severity of the regurgitation. The transgastric position allows for a short axis cut with precise measurement of the shortening fraction and an en face view of the mitral valve.

For mitral stenoses, the peak instantaneous and mean gradients across the valve have to be interpreted according to the quality of the diastolic function of the heart and the associated lesions (mainly $Q_i/Q_s$, the presence of an intra-atrial shunting and gradient across the foramen ovale/atrial septal defect). The overall impact of the gradient on the surgical indication has to be weighted with the pulmonary artery pressure but mostly the clinical tolerance.

Functional Classification

Transthoracic and transoesophageal echocardiography allows classifying the malformations according to the motion of the leaflets in one of the three following types:

Type I: Normal leaflet motion. The regurgitation results from a lack of coaptation between the leaflets.

Type II: Leaflet prolapse. The free edge of one or the two leaflets overrides the plane of the orifice during systole.
Type III: Restricted leaflet motion. The motion of one or the two leaflets is limited.
This can be secondary to short or stiff leaflet tissue or suspension apparatus (type IIIa) or the leaflet can be pulled away from the coaptation area by a paradoxical motion of the ventricular wall (type IIIb or systolic)

Other Investigations
Catheter study and angiography generate no additional information to the echocardiography and should not be performed.
Magnetic Resonance Imaging allows precise calculation of the ventricular volumes irrespective of the septal geometry; this may help for the decision-making with small left ventricle in mitral valve stenosis. The regurgitation fraction is measured accurately. Gradients and flows are demonstrated with MRL. In small patients, MRI does not help with the analysis of the valve anatomy.
Three-dimensional echocardiography is progressing rapidly with the exponential increase of computer power and miniaturization of the probes. The information generated are, however, of little use in small patients as the spatial resolution is still insufficient. Generally, the most obvious benefit is the ability to locate precisely the types II and III on the 3D en face view while they are quantified much more precisely on the 2D.

Indications
The indication for surgical intervention has to weigh several considerations.

According to the Mitral Valve Annulus
Large Mitral Valve Annulus (>30 mm in Female Patients and 32 mm in Males).
Using a wide range of mitral valve repair techniques, the probability of a successful repair of the valve is very high. A remodeling annuloplasty will not be outgrown and will not generate stenosis with the growth of the patient. The surgical indication is similar to the current indications in the adult population: The patients should be operated on as soon as the volume of the regurgitation is severe, irrespective of the severity of symptoms. The probability of repair is directly related to the experience of the surgical team but the repair of virtually all valves is an accessible goal.

Mitral Valve Annulus <18/20 mm
Biventricular repair should be considered only if the mitral valve annulus is not hypoplastic (Z value greater than −1.5). The repair is technically very challenging while the replacement is only possible with the use of surgical artifacts associated with significantly increased mortality. In these patients, the surgical indication should be differ as long as the patient can be managed with intense medical therapy, including transfusion. Aggressive medical therapy allows delaying the surgery for several months in some instances and can generate significantly more favorable operating conditions. However, the requirement for positive pressure ventilatory support more invasive than continuous nasal flow (either CPAP or other mode of pressure support) should trigger the surgical indication and so would a flat weight curve.

Intermediate Mitral Valve Annulus (>20 mm and Smaller than Adult Size)
In these patients, the mitral valve repair can be safely performed in anatomical position. Therefore, the timing of the mitral valve repair does not need to be delayed for fear of replacement in suprannular position. It is generally safe, however, to wait for a long time (up to several years) with a severe regurgitation, provided that adequate monitoring of the pulmonary artery pressure and ventricular function is achieved. Contrary to adult patients, in children, long-term ventricular function returns to normal in patients with decreased systolic function preoperatively.

According to Associated Lesions
Large Left-to-Right Shunts
These shunts can generate severe functional regurgitation that subsides with the treatment of the shunt. The mitral regurgitation should be addressed separately only if a prolapse of the anterior leaflet or a congenital valve can be identified. Similarly, modest mitral valve anomaly can generate severe gradient in this context. No or minimal intervention on the valve may only be required.

Aortic Valve Stenosis and Shone Syndrome
Whether to embark on a biventricular repair or a univentricular pathway in neonates with combined aortic and mitral valve anomalies is one of the most difficult problems in pediatric cardiology. The minimal size of the left ventricle required to survive a biventricular repair in isolated critical aortic stenosis is not a satisfactory criterion. The aim of a biventricular repair should be an excellent long-term functional result, which supposes normal ventricular function and normal pulmonary resistances. At the Royal Children’s Hospital, Melbourne, VIC, we limit this surgery to patients who have (1) no endocardial fibroelastosis on the echocardiographic study and intraoperatively, (2) a normal or very close to normal size left ventricle, (3) a normal size mitral valve annulus, and (4) the mitral and aortic valves can satisfactorily be repaired. In the early postoperative period, any difficulty to wean from the ventilator or an absence or minimal pulmonary pressure decrease with persisting reactivity should indicate a revision of the surgical strategy.
Mitral Valve Repair

Adapted to the Functional Classification

Correction of Type I

An annuloplasty is mandatory in all mitral valve repairs for regurgitation with the exception of some isolated type I without annular dilation, mostly cleft mitral valve. Attempts to perform mitral valve repair without annuloplasty have resulted in recurrence. To accommodate an adult size device, or a larger size annulus than what would be indicated from the area of the anterior leaflet, leaflet enlargement with glutaraldehyde-treated pericardium of the posterior leaflet, the anterior leaflet, or both are used (Fig. 102.3). When no annuloplasty device is available for the size of the patient or when the device is thought to be too small to allow for growth without stenosis, then a custom annuloplasty limited to the posterior annulus is indicated. The annuloplasty has to incorporate both trigones. For that purpose, we like to use expanded PTFE sheet folded once or twice to provide rigidity. The mattress sutures should not be tied too tightly to avoid corrugating effect (Fig. 102.4). In very small patients, we have found that the most effective annuloplasty allowing for growth was a compression of the annulus by the way of isolated mattress sutures tied over them (Fig. 102.5). In our experience, other means to allow room for growth have provided unreliable support of the annulus.

Correction of Type II

Correction of type II is rarely necessary in mitral valves with abnormal anatomy but is common in other types of valves. Multiple

Fig. 102.3. Remodeling annuloplasty using a complete ring. The ring has an adult size. When the surface of leaflet tissue does not cover an adult annulus area, the leaflet tissue can be augmented with treated autologous pericardium.

Fig. 102.4. Posterior annuloplasty in patients with less than adult size annulus. Band of polytetrafluoroethylene may be folded once for increased rigidity. It is secured from one trigone to the other.

Fig. 102.5. Technique of posterior annuloplasty suitable for very small mitral annulus. (A) Mattress sutures are applied in the posterior annulus as for any mitral valve repair and (B) tied to compress the posterior annulus.
techniques are available, to be used in isolation or in combination depending on the width of the prolapse (evaluated intraoperatively or on 3D echo), the height of the prolapse (based on the 2D echocardiographic study), and the aspect of the chordae. All techniques are efficient and reliable providing that the repair is adequate (restores a large surface of apposition between anterior and posterior leaflets) and avoids overcorrection.

The chordal shortening requires thin and flexible chordae. The correction generates significant shortening of the chordae and is only utilized when significant length of shortening is necessary (Fig. 102.6).

The chordal transfer, mostly between secondary chordae and the free edge, corrects a localized prolapse (Fig. 102.7).

Wedge resection (Fig. 102.8) and sliding plasty (Fig. 102.9) generate different degrees of correction of prolapsus to multiple chordae. They are very well adapted to prolapsus extended to a large segment of the anterior leaflet.

Artificial chordae: The use of artificial chordae should be restricted to the absence of available chordae of appropriate strength and quality in the area of prolapse. The insertion requires a rigorous technique to avoid overcorrection and large knots at the free edge (Fig. 102.10).

Papillary muscle shortening: Papillary muscle shortening is used rarely in infants and young children suffering from Barlow disease. It can also be used in the correction of scarred elongated ischemic papillary muscle (Fig. 102.11).

Correction of Type III
Successful correction of restricted leaflet motion and insufficient leaflet tissue is the essence of congenital mitral anomalies, especially in the first year of life.

Access to the suspension apparatus is the key to adequate mobilization of the latter. It can be done through the mitral valve orifice when it is sufficient. In very small patients, the mitral orifice is very small and does not allow for good access to the suspension apparatus. In these situations, the detachment of the posterior leaflet generates a good view of the papillary muscles. Adequate thinning, mobilization from the posterior wall, splitting and fenestration of the papillary muscles can then be performed safely with good exposure (Fig. 102.12A and B). The posterior leaflet is afterward reconstructed with the enlargement of the valvar tissue (Fig. 102.12C) when necessary.

The augmentation of the valvular leaflet tissue can be limited to the posterior leaflet

---

**Fig. 102.6. Chordal shortening: note the extent of the shortening achieved.**

**Fig. 102.7. Chordal transfer: only secondary chordae should be used and not the basal chordae.**
Chapter 102: Mitral Valve Repair in Children

The extension of the anterior leaflet should be done in the body of the leaflet, leaving a strip of valvular tissue close to the hinge point to avoid mechanical stress at this level. The height of the extension should not be greater than two-fifth of the height of the leaflet, leaving the area close to the free edge intact to allow for supple and efficient surface of coaptation. It should be symmetrical from trigone to trigone.

Resection of Supravalvular Rings and Accessory Mitral Valve Tissue

Resection of supravalvar tissue requires an excellent exposure of the leaflet tissue. The supravalvar tissue can sometimes be peeled off the valvular tissue. More often, there will be the need for a careful cleavage with blunt dissection. Perforation to the anterior leaflet may occur and should be closed with simple figure-of-eight suture (Fig. 102.14).

Resection of Accessory Mitral Valve Tissue

This requires rigorous surgical technique to delineate perfectly the mitral valve chordae from what can be resected without compromising the integrity of the suspension apparatus (Fig. 102.15). Various approaches to the suspension apparatus may have to be combined.

Repair of the Left Atrioventricular Valve in Repaired Atrioventricular Septal Defects

Patients with Normally Developed Left Lateral Leaflet

The secondary lesions in the area of regurgitation are mildly excised to reach pliable leaflet tissue. The cleft is closed with a long and narrow patch of treated autologous pericardium. This patch extends into the ventricular cavity to build a zone of apposition facing the tip of the LLL. The extremity of the patch is suspended either to adjacent marginal chordae and/or with artificial PTFE chordae (Fig. 102.16).

Patients with Absent or Very Diminutive Left Lateral Leaflet

The repair relies on the construction of a large zone of apposition on each side of the cleft using the leaflet tissue itself. The free edge after minimal debridement is suspended to the predominant PM with artificial chordae using the technique described before. To build some height to the coaptation area, a compression annuloplasty of the posterior annulus in front of the cleft is applied and generates redundancy to the leaflet tissue. If required, the superior and/or the inferior bridging leaflets can be...
Section III: Congenital Cardiac Surgery

Fig. 102.10. Insertion technique for ePTFE chordae: (A) a template is made from a short plastic tube cut at the required length and slid over the distal part of the stitch. The reference is an adjacent normal chordae to the free edge. (B) Here the secondary chordae facing the prolapse area is the reference. (C) The free edge of the leaflet is lowered to the contact of the papillary muscle. The artificial chordae is tied while the template is clamped. (D) The template is removed and the mattress suture is pulled to bring the knot in contact with the papillary muscle.

Fig. 102.11. Papillary muscle shortening can be used in combined anterior and posterior type II. It is useful when the papillary muscle as a whole has to be shortened, usually in chronic ischemic papillary muscle or in Barlow disease. (A) Section of papillary muscle is excised. (B) Apex of papillary muscle with attached chordae is sutured to the base of the muscle resulting in shortening.

RESULTS

The results have to be presented in two groups: the group of patients before 1 year of age and the one after 1 year of age, alternately with mitral annulus <18 mm or >18 mm. In the first group, the survival of the patient is the primary goal and it is best achieved through repair. After 1 year of age, the technical conditions approach the one of adults; the repair of all valves is an achievable goal and replacement of mitral valves is exceptional. Replacement does not influence long-term survival significantly with current anticoagulation protocols and mechanical prosthesis.

Congenital Mitral Valves in Neonates and Infants

At the Royal Children’s Hospital in Melbourne, VIC, 13 patients <1 year underwent initial mitral valve repair for regurgitation between 1996 and 2006. There were three reoperations with two reoperations requiring valve replacement. There was one early death in a neonatal Marfan syndrome and one late hospital death related to inappropriate orientation to biventricular repair for a patient with Shone syndrome.

During the same time span (1996 to 2006), nine patients <10 months were operated on for congenital mitral stenosis. The median age was 5 months (range: 1 week to 10 months). All had severe failure to thrive and severe pulmonary hypertension. The mean preoperative gradient was 13 ± 2.3 mmHg. The malformations included papillary muscle to commissure fusion (n = 6), parachute mitral valve (n = 2), excess tissue (n = 1), and supravalvar ring (n = 1) of whom one patient had Shone’s syndrome. Three patients had reoperations. The first patient had three reoperations, leading ultimately to MVR with a mechanical valve. The second patient (neonatal Shone’s complex and interrupted aortic arch) underwent reoperation (resection of supravalvar membrane) 2 years following initial intervention. There were no deaths. Other teams have similar results in this age group justifying early operation in severely symptomatic patients.

Congenital Mitral Valves in Patients Older than 1 Year of Age

Mitral Regurgitation

From the recent series available, repair should be expected in more than 90% of the patients with a risk for hospital mortality augmented with a patch of treated autologous pericardium (Fig. 102.17).
rate <10%. Results in the current era should be significantly improved compared with previous series stretching over a long time span. The expected reoperation rate should be <15% at 15 years.

**Mitral Stenosis**

The hospital mortality should be very low when the mitral stenosis is isolated. Mitral stenoses with associated cardiac lesions generate high mortality and reoperation rate but are rare in this age group. After mitral valve repair for mitral stenosis, residual gradient are frequent but often well tolerated and reoperations are indicated according to the level of pulmonary hypertension. Supravalvular mitral ring have a high recurrence rate.

**Rheumatic Mitral Valves**

Mitra! valve repair in the pediatric age group in units with significant experience is achieved in >90% of the patients with hospital mortality lower than 2%. Large variations in the reoperation rate are reported (45% to <10% at 5 years). These variations could be attributed to the quality of the follow-up, to the regional and national specificities including whether access to surgery is free or not but most importantly to the compliance to secondary anticoagulant treatment.

At the Royal Children's Hospital, Melbourne, VIC, between 1996 and 2005, 88 patients aged 6 to 24 years old had surgery for rheumatic mitral valve insufficiency. All had mitral valve repair initially. Freedom from reoperation at 70 months with 32 patients at risk is 78%. There were 15 reoperations in 13 patients of which 7 were replacements and 8 were further repairs. There was one early death and one late death.

**CONCLUSION**

In children with significant mitral valve disease, mitral valve repair in all is the objective. If mitral valve replacement is unavoidable, it should be delayed until it can be done at low risk. In that context, an imperfect repair represents a satisfactory palliation if the surgical indication cannot be delayed altogether.

**SUGGESTED READINGS**

Section III: Congenital Cardiac Surgery

Mitra! valve repair continues to be a surgical challenge in pediatric cardiac surgery. The wide range of anatomic abnormalities and the often palliative nature of valve repair in association with the extreme rarity of congenital valvular abnormalities result in only relatively small reported series of operations for these abnormalities. The results of valve repair in the pediatric population for more common adult diseases (such as rheumatic heart disease) are much more reproducible, and significant series of valve repairs with good results have been published. Patients with mitral regurgitation from either a congenital or acquired cause may respond to valve reparative operations as eloquently described by Dr. Brizard; however, the surgical technique has to be individually tailored to each anatomy. The effect of newer technology, such as three-dimensional echocardiography, on the preoperative assessment of valvular function and anatomy for guiding surgical repair is unknown; however, with the development of these techniques and more real-time imaging, better assessment of valve function may lead to improved outcomes in the future.

Dr. Brizard and his colleagues have had excellent results with valve leaflet augmentation extension procedures of both the posterior and anterior leaflets. Although we have had very limited experience with these techniques at the Children's Hospital of Philadelphia, the results have not been quite as good as those presented by Dr. Brizard and his group. In situations in which a restricted leaflet motion is present, it is not clear that augmenting the leaflet surface in its superior margin with these extensions will always result in better coaptation because the free margin is still tethered by the restricted motion. In augmentation of the anterior leaflet also, the chordal attachments at the free margin may be as important as the overall surface area in creating accurate valve function. Nevertheless, Dr. Brizard makes a very good point that these leaflet augmentation methods need to be accurately tailored to the valve anatomy, and excessive patching may actually cause problems.

An area of controversy concerns the supravalvar mitral ring. There is often confusion in the reported series of repair of supravalvar mitral ring between the anatomic entity described by Dr. Brizard and the patient with cor triatriatum sinister. Membrane-like structures dividing the left atrium with a stenotic central orifice can be completely excised with a very low recurrence rate. The acquired form of supravalvar mitral ring such as described by Dr. Brizard is distinguishable from cor triatriatum by the attachment of the supravalvar ring to the mid-portion of the anterior mitral leaflet. This may well be an acquired structure as noted; however, the pathophysiology of development of the lesions is not known. Although recurrence is a possibility due to abnormal flow characteristics across the mitral valve, there have been only a few reported cases of recurrence of supravalvar mitral rings in the literature. Perhaps, this is related to the extreme rarity of the condition or the fact that the underlying stenotic or regurgitant process, which leads to the development of the ring, is addressed at the time of the resection of the ring itself. There appears to be a slightly greater incidence of supravalvar mitral obstruction when there is a left superior vena cava entering the coronary sinus, perhaps creating abnormal flow characteristics across the mitral valve.

Although infective endocarditis of the mitral valve is usually associated with mitral regurgitation, large vegetations on the mitral valve can lead to primary mitral stenosis. The most common situation is a combination of regurgitation and stenosis. If the vegetation is obstructive, resection of the vegetation and valve repair can be performed; however, regurgitation can develop as additional healing of the valve occurs. In most cases, if there has not been extensive destruction of leaflet tissue, valve reparative techniques are preferable to valve replacement in infective endocarditis with the goal of maintaining the native valve for as long possible.

Cardiac catheterization is rarely necessary in the current era for the evaluation of valvular lesions on the left side of the heart. Nevertheless, catheterization to measure right ventricular pressure and pulmonary pressure and resistance may be necessary in some cases to determine optimal timing for valve intervention. Interventional catheterization with balloon valvuloplasty of even significant congenital mitral stenosis may be an effective palliative measure in some children. There are small reported series of balloon dilation of congenital mitral stenosis that resulted in adequate relief of valvular obstruction with only modest regurgitation and permitted palliation for sometimes many years prior to the need for surgical intervention.

As noted in Chapter 103 on Aortic Valve Repair, valve reparative procedures are certainly preferable to valve replacement in all children and young adults if a reasonably durable repair can be achieved. In the mitral position, even only modest improvement in stenosis can result in significant palliation. When valve reparative techniques have failed and there is significant pulmonary hypertension or increasing congestive heart failure, valve replacement may be warranted. It is not uncommon to perform multiple valve reparative procedures for mitral regurgitation or stenosis if necessary to avoid valve replacement until an older age when a prosthetic valve can be implanted without increased morbidity and mortality.

The situation of the Shone complex of aortic and mitral valve disease remains difficult. Many patients with this complex anatomy have significant aortic disease as newborns that require balloon dilation. The balloon dilation can then result in only temporary relief of stenosis or can cause significant aortic regurgitation. These patients may then require an autograft aortic valve replacement as a newborn or young infant. Often the nature of the mitral valve disease is not readily apparent until the relief of the distal aortic obstruction is achieved. In situations in which the mitral valve is abnormal in structure, it may be best to consider single-ventricle reconstruction for these patients. Nevertheless, decision-making continues to be difficult, and many patients have an intervention on the aortic valve before consideration is given to the single-ventricle pathway. If aortic regurgitation becomes significant, then it may preclude a single-ventricle reconstruction approach such as the Norwood operation.

There has been a recent interest in attempting to create biventricular repair in patients with certain forms of hypoplastic left heart syndrome. Many of these patients have critical aortic stenosis and endocardial fibroelastosis with secondary effects on the mitral valve with mitral stenosis. The group in Boston has suggested resection of endocardial fibroelastosis and debridement from mitral valve tissue to encourage left ventricular growth (continued)
and growth of the mitral valve. While there have been successes with these approaches, the long-term effects on ventricular function and the relative function of the mitral valve and pulmonary pressures and resistance have not been completely identified. Many of these patients continue to have relative mitral stenosis with some insufficiency and some may eventually require mitral valve replacement at a relatively young age.

As suggested by Dr. Brizard, mitral valve replacement in young children should be avoided if at all possible. While results with supra-annular mitral valve replacement in very small children are suboptimal, success can be achieved with careful implantation of the device. Many of these patients continue to have relative pulmonary hypertension due to lack of compliance of the left atrial chamber above the valve prosthesis, which can limit the functional result. In addition, the need for chronic anticoagulation in growing children makes follow-up difficult.

Mitral valve procedures in children should be considered palliative. In experienced centers such as the Royal Children's Hospital, Melbourne, VIC, the success of mitral valve reparative operations is enviable and a standard to which other pediatric cardiac programs should aspire.

TLS
Surgical management of aortic valve disease in children presents a difficult dilemma. On the one hand, early surgery protects the myocardium from volume and pressure overload, decreases the chance of fibrosis and remodeling, and is consistent with current surgical philosophy of early complete repair of all congenital heart defects. On the other hand, early valve replacement in children is suboptimal because of the lack of an ideal valve substitute that allows growth and does not need anticoagulation or frequent replacement. Autologous pulmonary valve has emerged recently as an attractive aortic valve substitute that fulfills these criteria but concerns persist over the long-term fate of the pulmonary valve in the aortic position.

The dichotomy created by the absence of the ideal valve substitute and the deleterious effects of long-standing ventricular volume and/or pressure overload associated with aortic valve disease has renewed interest in aortic valvuloplasty especially in children. Although several techniques, such as annular reduction, commissural resuspension, and cusp extension were used in the past, aortic valvuloplasty remained an evolving approach rather than a definitive treatment, due in part to incomplete understanding of the functional anatomy and geometry of the aortic valve. Recently, success in atriocentric valve repair, progress in myocardial protection, refinements in three-dimensional imaging of the aortic valve, and detailed analysis of valve anatomy and function have led to improved results of aortic valve reconstruction.

**ANATOMY AND FUNCTION OF THE AORTIC VALVE**

The three leaflets of the aortic valve are attached to the atriocentric junction. The collagenous condensation at the point of attachment of each leaflet has been termed the annulus fibrosis. There is, however, no true “ring” of annular tissue supporting the leaflets in a straight circular plane. The hemodynamic stresses on the leaflets, therefore, are counteracted at several structural levels. The margin of coaptation of a competent valve is more than a finite point of contact. It extends along the whole margin of the leaflet in length and several millimeters in depth. Beneath the apices formed by leaflet attachment, the so-called commissures, there are subcommisural or interleaflet triangles (Fig. 103.1). The wide base of these triangles follows the ventricular contraction pattern and allows optimal retraction of leaflets during systole. The sinusotubular bar marks the junction with the ascending aorta. It is thicker than the adjacent sinuses. It is circular with areas of increased collagen. It acts as a suspension post that supports the peripheral attachments (the commissures) of the valve leaflets. The parabolic shape of the leaflets resembles a suspension bridge. Their attachments to the sinusotubular bar are several millimeters above the level of coaptation. As these support poles stretch outward by as much as 16% to 44% during early systole, the leaflet edges (the cables) become straighter, aiding in the opening of the valve.

The aortic root is also a complex hemodynamic system. Its component parts change in size and shape during the cardiac cycle. Its distal portion is exposed to the aortic pressure. It expands to allow leaflet retraction. Its base is exposed to ventricular dynamics. It contracts during the peak of systole to decrease the distance between the leaflets and to reduce the stress forces applied to leaflets in early diastole. Moreover, the leaflet–sinus assembly behaves as an independent unit to store the diastolic pressure within. It allows the aortic valve to remain competent even if the interleaflet triangles are partly incised. The instantaneous changes in aortic valve orifice have been shown to precede movement of blood in the ventricle. The transformation of the aortic orifice from a closed position to a triangle and then to a circle without causing flexion deformity of cusp tissue is related to aortic root distensibility and the mechanism of leaflet suspension.

**PATHOLOGY AND FUNCTION OF THE ABNORMAL AORTIC VALVE**

**Aortic Valve Stenosis**

The **Congenital Bicuspid Aortic Valve**

In type I, there is no median raphe at the junction of two cusps. As a result, there are two rather symmetric aortic sinuses and leaflet base attachment. The valve orifice is central. The commissural triangle is rather well developed. The leaflets are suspended at the sinotubular bar and have adequate depth. In type II, which is more prevalent, a median raphe is present. The cusps are asymmetric and the fused leaflet is longer, shallower, and takes up more of the circumference of the valve. In contrast to the normal tricuspid valve, the leaflet edges are excessive and sagging. As a result, there is increased folding and crossing and a compensatory extension of the area of leaflet approximation from their edges (doming). The opening of the valve is eccentric due to discrepancy in leaflet sizes. The orifice also has an elliptical rather than a circular opening. The resultant distortion in blood flow pattern exaggerates turbulence and predisposes to degenerative changes. Frequently, there is commissural fusion that limits the leaflet movement and further exaggerates the eccentricity of valve opening and the decrease in its effective orifice diameter. The narrowed opening, often combined with annular hypoplasia, impairs the ability of the leaflets to escape systolic or diastolic pressure load, further exaggerating the stress on the valve. The subcommisural triangle is severely attenuated. It limits leaflet movement in early systole and the change in orifice configuration necessary for appropriate leaflet coaptation at the end of systole. The leaflet edges are suspended below the sinotubular bar. This, combined with redundant leaflet edges, results in shallow sinuses, decreases coaptation area,
abnormal flow patterns results in progressive scarring, thickening, deformity, and retraction of the leaflet edges and subsequent lack of coaptation (Type III).

**Aortic Regurgitation Secondary to Subaortic Fibromuscular Stenosis**

The abnormal blood flow pattern produced by the subaortic stenosis results in progressive deformity of the leaflet. Tethering of the leaflets by the subvalvar fibrous tissue, causing the obstruction, exaggerates the regurgitation (Type III).

**Regurgitation in Marfan Syndrome**

The pathology is progressive dilation of the aortic root wall due to fragmentation of its elastic support. The dilated sinotubular bar and valve sinuses stretch apart the commissural suspension and leaflet edges. The increase in hemodynamic stress due to changes in the leaflet suspension mechanism combined with enlarged aortoventricular junction leads to poor leaflet coaptation and central regurgitation (Type I).

**Regurgitation in Patients with Congenital Valvar Stenosis**

The continued trauma to the leaflet edges produced by hemodynamic stress and abnormal flow patterns results in progressive scarring, thickening, deformity, and retraction of the leaflet edges and subsequent lack of coaptation (Type III).

**Aortic Valve Regurgitation**

There are three types of regurgitant aortic valves. Type I is dilatation of the aortic annulus, sinotubular bar, or ventriculoaortic junction. Type II is leaflet prolapse. Type III is leaflet retraction and scarring. It is the most common pathology of the congenital regurgitant valve (Fig. 103.3).

**Regurgitation Associated with Ventricular Septal Defect**

There is discontinuity between the aortic media and the crest of the ventricular septum with consequent decrease in the support of the sinus wall and progressive prolapse and deformity of the involved cusp (Type II). The sagging leaflet edge loses coaptation contact with the other two leaflets and central regurgitation ensues. The noncoronary cusp is usually affected with perimembranous ventricular septal defects, whereas the right coronary cusp is involved with the subarterial, more anterior (supracristal) ventricular septal defect.

**Postballoon Regurgitation**

This condition is usually caused by leaflet(s) tear close to the fused commissure. The leaflet becomes flail and eccentric regurgitation results (Types II and III).
Aortic Regurgitation Secondary to Rheumatic Disease
There is cusp retraction secondary to inflammation and scarring. The hemodynamic sequelae result in progressive anular dilation and worsening of the regurgitation (Types II and III).

TIMING OF SURGICAL INTERVENTION
To achieve optimal short- and long-term results, surgical intervention should be timed appropriately. The decision relies on achieving the goals of valve surgery, which include relief of symptoms, restoration of exercise capacity, improved quality of life, and, most importantly, protection of the myocardium from chronic pressure and/or volume overload. Most of the reported guidelines for timing of valve surgery are based on studies in the adult population and on the premise that valve replacement is the only therapeutic option. These studies use mortality rates as a follow-up endpoint but fail to analyze myocardial performance and reserve several years postoperatively. They utilize as their database several single-center observational studies and very few prospective, randomized trials.

The introduction of and refinement in valvuloplasty techniques have prompted critical evaluation of these older guidelines for the timing of surgical intervention on the diseased aortic valve. The availability of a surgical alternative that avoids valve replacement or anticoagulation has liberalized the older rigid criteria. Although large-scale, long-term data on repaired valves are not available, there is unquestionable evidence that valvuoplasty extends the functional longevity of the native aortic valve in children and may safely delay the need for replacement, thus justifying earlier surgical intervention. Waiting for symptoms to appear or for ejection fraction to decrease prolongs the duration of ventricular pressure and volume overload and may lead to irreversible ventricular dysfunction.

Timing of valvuloplasty involves several two- and three-dimensional echocardiographic and Doppler-derived indices. For isolated aortic valvar stenosis, pressure gradients of 40 to 50 torr associated with progressive left ventricular hypertrophy or impaired exercise tolerance are indications for intervention. Measurement of effective valve orifice and the extent of valve pathology are also helpful in deciding the timing of surgery. In aortic valvar regurgitation, a diameter ratio of regurgitant jet to annulus of $\geq 0.4$ and the progressive increase in indexed end-diastolic left ventricular dimensions for two consecutive measurements, if they exceed a Z-score of 3, have been found to correlate with early ventricular dysfunction before onset of symptoms, and therefore constitute valid and rather objective indications for intervention. This is especially pertinent as isolated data have shown that patients with significant dilatation of the left ventricular cavity have an increased incidence of recurrent aortic insufficiency even with a successful valvuloplasty. However, in specific situations such as balloon-induced aortic regurgitation, there are probable benefits for delaying surgery if the residual pathology is not severe. Remodeling of the leaflets and enlargement of the annulus from increased blood flow during the waiting period may improve the long-term outcome of the valvuloplasty. Other parameters, such as changes in ejection fraction have also been used to time interventions; however, these have not been found to correlate objectively with optimal surgical outcome.

Techniques of Surgical Valvuloplasty
Most of the surgical techniques used for aortic valve repair were devised many years ago or have been used for a long time. Recent improved understanding of the valve pathology and pathophysiology and refinements in cardiopulmonary bypass and myocardial protection in children have made their successful application possible. In addition, several principles have evolved that helped in improving outcome. These include the following: (1) detailed pre- and intraoperative analysis of pathology is essential. This is best achieved by two- and three-dimensional echocardiography. Objective preoperative assessment, however, is rather difficult. Pliability of each cusp is estimated by the apparent change in the depth of the sinus, and areas of tissue deficiency or prolapse. (2) More than one technique needs to be performed to achieve both competence and relief of obstruction. The different steps in the procedure should be tailored to address the specific pathology types. (3) Reconstructive steps should be preceded by relief of obstruction as completely as possible. All areas of leaflet fusion or stenotic lesions should be relieved first even if that reduces leaflet support. Subsequent reconstructive steps of such leaflets should aim at restoring the normal morphology, function, and support.

Fig. 103.3. The different pathology types or congenital aortic valve regurgitation. (A) Leaflet prolapse. (B) Leaflet retraction. (C) Annular dilatation.

Regurgitation after Arterial Switch Operation
Regurgitation in these cases is related to disruption of the sinotubular mechanism and undue dilation of the aortic sinuses caused by the implantation of large coronary artery buttons or preoperative pulmonary artery banding. Delayed closure of ventricular septal defect associated with D-transposition of the great arteries also predisposes to long-term neoaoaic regurgitation following the switch operation (Type I).
(4) Repair of only one leaflet or cusp is inadequate and leads to early failure.
(5) Fresh autologous tissues such as pericardium or fascia lata cannot withstand dynamic stress when used for repair and tends to retract and scar with time; therefore, glutaraldehyde fixation is necessary.
(6) “Overcorrection” in cases of aortic valve incompetence might be needed, but excessive correction may lead to crowding and distortion of the repaired valve if the root is normal or smaller than normal in diameter.
(7) Centralizing blood flow through the valve decreases turbulence and extends the longevity of the repair; therefore, tricuspidization of the valve is advantageous when possible.
(8) It is essential to incorporate in the procedure the necessary steps that address the interaction between aortic root dynamics and valve mechanics, namely, maintaining annular and commissural flexibility and movement in order to avoid accelerated stress-induced valve degeneration. Mobilization of the subcommissural triangle and avoiding subtotal excision of the leaflets close to the aortoventricular zone are important to avoid the disruption of the delicate and complex relationship between the root and leaflet.

Techniques for Isolated Stenotic Valve with or without Annular Hypoplasia

**Unrolling and Thinning of Leaflets**
Patients with chronic stenosis, turbulence, and abnormal blood flow patterns have progressive leaflet thickening and distortion.

**Simple Commissurotomy**
The technique involves incising along the fused edges of the leaflets to allow improved mobility. Traditionally, the incision is extended up to the commissure but stops short of the aortic wall to avoid leaflet detachment and subsequent regurgitation. Although this technique results in larger valve orifice, it fails to address several pathologic features of congenital aortic valve stenosis and therefore has had poor long-term outcome.

**Extended Commissurotomy**
This approach attempts to improve on the results of simple commissurotomy. The incision along the edge of the fused leaflets is extended into the aortic wall in curvilinear fashion, splitting the inner media at the leaflet junction with the wall. The added extension results in a longer free leaflet edge, mobilizes the subcommissural triangle, and centralizes blood flow across the orifice (Fig. 103.5). However, it decreases leaflet support and may result in long-term progressive regurgitation if it is not combined with leaflet augmentation and suspension.

**Techniques for Regurgitant Valves with or without Annular Dilatation**

1. **Commissural reduction annuloplasty:** U-shaped pledgeted sutures are placed at one or more commissure(s) to plicate the aortic wall and reduce its total circumference. It is primarily applicable to valves with normal cusp mobility and moderately dilated annulus. Severe annular dilation cannot be repaired using this technique (Fig. 103.6).
2. **Circumferential reduction annuloplasty:**

   Annular reduction using a circumferential suture around the base of the valve leaflets at the aortoventricular junction can reduce the dilated annulus diameter and effect better leaflet coaptation. Alternatively, the use of external "subvalvar" prosthetic ring or band annuloplasty can also help to reduce root dilatation especially in patients with connective tissue diseases. The technique involves extensive dissection of the root down to the aortoventricular level, and adjusting its diameter over a dilator. Anatomically, however, there might be limitations to placing the circumferential band or suture at one plane, resulting in lack of symmetry of the annular constriction and consequent distortion of the valve. Similarly, placing a cylinder of prosthetic material around the whole valve apparatus reduces aortic root dilatation but could cause crowding and distortion (Fig. 103.7). The use of these different circumferential reduction annuloplasty techniques limits growth potential and results in future stenosis especially in children and young adults.

3. **Patch closure of discrete leaflet perforation:** Isolated perforation of the leaflet due to infective endocarditis or catheter intervention can be easily repaired using a small patch of autologous or bovine pericardium secured in place with multiple sutures. This simple approach is applicable only to cases where the rest of the valve apparatus is essentially normal. Continuous suture should be avoided to prevent purse-string distortion of the leaflet (Fig. 103.8).

4. **Plication of the prolapsing leaflet:** The free margin of the leaflet is plicated and resuspended to the aortic wall, or the prolapsed leaflet is pulled cephalad at both commissures and the redundant edge plicated above the level of both commissures (Fig. 103.9). These techniques are rarely successful when performed as an isolated step. Additional leaflet augmentation with a thin strip of pericardium and resuspension of the reconstructed leaflet at the commissures (see below) are needed to support the repair.

5. **Partial leaflet resection:** In the presence of restrictive fibrotic or calcified raphe, a triangular resection of the portion of the leaflet involving the raphe is made. Edges are approximated either primarily or using a triangular piece of pericardium (Fig. 103.10).

6. **Leaflet augmentation and resuspension** is the most versatile technique. After thorough mobilization of all aortic valve leaflets (see techniques for reduced mobility), a piece of autologous or bovine pericardium is fashioned (Fig. 103.11A). It is cleared completely from attached fatty tissue. The curvilinear longitudinal dimension GHI should equal the length of the leaflet free edge plus two 0.5-cm extensions on both sides (FA and EJ). The exact dimensions of the pericardial patch could be obtained from echocardiographic studies done on normal aortic valve in which the relationship between the intercommissural distance and the leaflet dimensions (depth and
Fig. 103.9. Leaflet plication: (A) Leaflet plication and fixation to aortic wall. (B) A suture is passed along the leaflet edge and tightened to effect reduction in free-edge length. (C) Commissural sliding in the distal aortic wall to decrease leaflet length and improve coaptation.

Fig. 103.10. Triangular resection and repair of redundant leaflet. (A) The leaflet is reconstructed primarily. (B) The raphe is resected and the edges resutured.
length) has been established. The patch is tailored to fit the deficiencies and irregularities of the leaflet edge. The longitudinal dimension (BCD) should be slightly straighter and shorter than the GHI (Fig. 103.11A). The width (CH) should provide enough additional depth to the leaflet so that the reconstructed leaflet free edge is in level with the sinotubular bar at the commissures but deeper (more caudad) at the center (C). The pericardial patch is sutured to the free edge of the leaflet using 5-0/6-0 polypropylene running suture starting at the leaflet center. The patch ends (or wings) are then sutured to the aortic wall with pledgeted suture, resulting in a rounded leaflet edge suspended at the sinotubular bar (Fig. 103.10B). The suspending sutures are placed in such a way as to enhance the sinotubular bar. The step is repeated for at least one additional leaflet. The heights (width) of the augmenting patches should equalize the depth of all sinuses (Fig. 103.11C and 103.11D). This allows effective leaflet enlargement and increases the surface of coaptation in the center of the sinuses. In bicuspid valves with fused but well-developed rudimentary commissure, the commissure is incised all the way to the aortic wall and the valve is converted into a tricuspid valve. The three leaflets are then augmented. An alternative approach to increase sinus depth and improve leaflet coaptation area is basal enlargement of the cusp with an autologous pericardial patch. An incision is made directly at the base of the cusp that needs enlargement. It is extended in both directions toward the commissures. The patch is trimmed to an oval form few millimeters larger than the defect created by the incision and its patch width is determined by the extent of the deficit in the coaptation surface. It is sewn into the leaflet using running and interrupted sutures to avoid purse-string deformation of the cusp. Resuspension of the leaflet edges at the commissure is then performed to allow normal coaptation plane (Fig. 103.12).

Additional Techniques for Aortic Valve Repair

1. Tricuspidization of quadricuspid valves: This technique is especially helpful in very young patients with regurgitant truncal valve where one cusp is rudimentary and dysplastic. The edges of the abnormal cusp are sutured to the adjacent leaflets edges resulting in three

Fig. 103.11. Technique of augmentation valvuloplasty. (A) The harvested pericardial patch. (B) Augmentation of the leaflet with patch. (C) Side view. (D) Final result.

functional leaflets and by providing support to the prolapsing and rudimentary leaflet, regurgitation is minimized (Fig. 103.13). Another approach is to excise the dysplastic leaflet and its corresponding sinus wall thus effecting a reduction in the circumference of the valve and improving coaptation. An additional subvalvar annuloplasty can be applied to the dilated aortic (truncal) root if further reduction in diameter is needed.

2. **Subtotal leaflet excision and reconstruction:** Excision of all the leaflets of the diseased valve and leaving a narrow strip of cusp tissue at the aortoventricular junction have been used. The leaflets

Fig. 103.13. Tricuspidization of aortic valve. (A) The rudimentary leaflet. (B) Conversion to three leaflets and commissuroplasty.
are then reconstructed by a continuous strip of glutaraldehyde-treated autologous pericardium, fashioned into three cusps and sutured to the leaflet remnants. The newly constructed leaflets are then suspended at the commissural area to prevent prolapse. This approach may impair the dynamic interaction of the aortic valve leaflets with the root and the left ventricle, leading to early failure of the repair.

3. Bicuspidization of tricuspid valves: This approach is rarely used. It is an easy surgical alternative in patients with tricuspid aortic valves and a large annulus when one of the three leaflets sags or prolapses, thereby causing significant regurgitation. Its use, however, is limited to patients in whom two of the three cusps are normal.

4. Leaflet creation: This technique is used when there is at least one relatively normal leaflet. The rudimentary part of the fused leaflet is partially detached from the annulus and used to reconstruct a normally functioning leaflet. The unguarded area of the annulus thus created is filled with a cusp made of pericardium (Fig. 103.14).

The choice of patch material for valve augmentation has evolved through the years. As mentioned earlier, fresh autologous pericardium does not withstand the hemodynamic stress. Treating the pericardium with a high concentration of glutaraldehyde (2%) resulted in a very stiff patch and predisposed to early calcification and stenosis. The use of low concentration of glutaraldehyde (0.6%) with a short fixation time (3 minutes) results in a more pliable patch material and decreases the incidence of restenosis. Fixing the pericardium on a curved structure such as a malleable retractor shapes the patch like a cusp (Fig. 103.15). Thin bovine pericardium, processed using infrared wave technology, provides a good alternative with minimal calcification or stenosis on short follow-up; however, it has failed to withstand the long-standing hemodynamic stresses that the aortic valve is exposed to. As a result, mid-term degeneration of the patch has resulted in relatively early recurrence of regurgitation. The newly introduced patch material made of decellularized intestinal mucosa (CorMatrix) has been used for reconstruction of the pulmonary and aortic wall. It is pliable, strong, and does not calcify. However, its longevity on the aortic side especially as a valve leaflet has not been objectively evaluated.

TECHNIQUES FOR DILATED AORTIC ROOT

As mentioned above, aortic root dilation is an important aspect of aortic valve disease. Higher freedom from recurrent aortic regurgitation has been observed where the valve repair was combined with root replacement, especially when the dilated aorta has an asymmetric configuration.

RESULTS

The techniques of aortic valvuloplasty are in evolution. Several series have reported results using one or more of the techniques mentioned here. None of these results, however, reflects the present knowledge of the surgical anatomy or the outcome of valve repair when these technical steps are used in combination.

Review of our total experience with these different approaches revealed a significant drop in pressure gradient across the valve, a decrease in aortic regurgitation as judged by grade and by ratio of the regurgitant jet to aortic annulus diameter, and a decrease in indexed left ventricular end-diastolic volumes.

Long-term postoperative follow-up revealed a progressive increase in pressure gradient in 42% of patients, associated with stiffening or calcification of the patch used for leaflet augmentation. When restenosis was analyzed further, it was apparent that patients who had valvar stenosis and annular hypoplasia had the highest incidence of restenosis. This increased incidence might have been due to the crowding of the hypoplastic aortic root when aggressive overcorrection was used early in our experience. Recurrence of regurgitation was not

![Fig. 103.14](image1) New leaflet reconstruction. (A) Removal of the scared and deformed leaflet. (B) Reconstructed leaflet. The middle cusp is made of pericardial patch.

![Fig. 103.15](image2) Fixation of the patch on a curved structure allows better configuration of the leaflet edges.
a problem in follow-up, and most patients maintained competent valves. Based on the initial follow-up results, we have adopted a selective approach to aortic valve disease in children. Patients with primary valvar stenosis and associated annular hypoplasia undergo Ross with Konno procedure. On the other hand, patients with primary regurgitation or annular dilatation are best managed early by using the described valvuloplasty techniques.

CONCLUSIONS

Aortic valvuloplasty as currently used has very low operative mortality. It provides an excellent alternative to valve replacement, especially in children and young adults, in whom anticoagulation and need for repeated valve replacements are serious drawbacks. It maintains the patient’s own valve and does not preclude other alternatives when deemed necessary. It is probably superior to the Ross procedure in patients who are very young or have significant annular dilation due to regurgitation or other causes. Its use in patients with aortic annular hypoplasia should be limited to avoid recurrent stenosis. The use of patch material not fixed with glutaraldehyde might provide a decrease in the incidence of restenosis.

SUGGESTED READINGS

There has been a resurgence of interest in aortic valve repair based on the pioneering work of Dr. Ilbawi and his associates. As very nicely summarized in this chapter, the complex geometry of the aortic valve requires multiple approaches to achieve a competent repair, and the procedure must be tailored to the individual patient’s anatomy and pathophysiology. The use of valve extension techniques as pioneered by Dr. Ilbawi has permitted the creation of trileaflet valves even in patients with bicuspid valves to achieve a more central orifice and improve the long-term outcome.

Valve reparative techniques may offer the option for earlier surgical intervention in patients with significant aortic stenosis and insufficiency. The indications for intervention, however, remain somewhat vague. In most cases, stenosis with a measured peak-to-peak gradient of >40 to 50 mmHg is a relative indication for surgical or balloon intervention, especially when there is associated left ventricular hypertrophy or strain pattern on electrocardiogram. Exercise testing with evidence for ventricular dysfunction is another relative indication. Symptoms are a late finding in aortic stenosis and should not be the indication for surgical intervention. Aortic insufficiency of a severe degree causing diastolic flow reversal in the descending aorta and significant progressive ventricular volume overload are indications for surgical intervention. Documented increase in left ventricular end-diastolic dimension on serial measurements that are greater than three standard deviations above normal despite use of afterload reduction therapy is a relative indication for surgery, as is a decrease in systolic performance on exercise. Exercise intolerance is another relative indication for intervention.

An increasing number of patients are coming to aortic valve repair or replacement after balloon dilation of aortic valve stenosis in infancy. In many cases, these valves can be repaired by the techniques described by Dr. Ilbawi’s group. However, many of these patients have relative hypoplasia of the aortic annulus, and the reparative techniques to alleviate the regurgitation may result in varying degrees of stenosis. Therefore, these valves may be best suited to a valve replacement rather than valve repair. Concerns about longevity and aortic root dilation over time of the autograft aortic valve replacement have led to an increasing use of valve reparative techniques as a temporizing measure. We use valve repair whenever possible if we believe a relatively durable (>5 year) good result can be anticipated. If the valve is significantly distorted or if valve reparative techniques will result in relative stenosis, we believe that the Ross operation may be a better choice. Nevertheless, patients with predominant aortic insufficiency can often have a quite durable valve repair, which may allow children to grow and provide more options for valve replacement in the future.

We consider valve repair a palliative procedure that will ultimately require reoperation and valve replacement; however, in small and growing children, female patients, and young adults it may be advisable to perform a valve repair of limited durability to allow the patient to grow into adulthood, when mechanical valve replacement may be a better option. In addition, the increasing interest in development of tissue-engineered valves lends hope that in the future viable valves can be developed that will alleviate many of the concerns with bioprosthesis or mechanical valve replacement.

The tissue used for valve leaflet extension is controversial. As noted, glutaraldehyde-fixed tissue tends to calcify and stiffen over time and may lead to valve degeneration and recurrent regurgitation or stenosis, requiring reoperation. Fresh pericardium tends to shrink and may lead to a relatively unstable early repair. The use of any nonautologous tissue such as homograft material, bovine pericardium, or CorMatrix* has not been examined at long enough follow-up to determine whether these tissues might provide a more reliable alternative. Nevertheless, the use of nonviable tissue for reconstruction is likely to result in degeneration over time, as in tissue valve prostheses.

The complex geometry of the aortic valve and the difficulty in assessing the valve function in the operating room make the use of newer imaging modalities for pre- and postoperative assessment important. Three-dimensional echocardiography is a new modality that may preoperatively identify the mechanism of valve dysfunction and guide the surgical intervention for valve repair. When three-dimensional echocardiography can be done in real time, it may significantly improve our ability to perform accurate valve repairs. Transesophageal 3D transducers are now available for adult size patients. Hopefully, smaller 3D transducers will become available for use in children in the future.

The complications of valve replacement as noted in Chapter 104 have led most pediatric centers to begin more aggressive repair of valves in all positions in the heart in the hope of providing reasonably durable palliation before anticipated later valve replacement.

TLS
INTRODUCTION

Left ventricular outflow tract obstruction (LVOTO) occurs in 3% to 5% of patients with congenital heart disease. Valvular aortic stenosis (VAS) makes up 50% to 65% of the cases of LVOTO in children. Bicuspid aortic valve (BAV) is the most common type of LVOT pathology and is seen in 1% of human hearts. One-third of BAVs will require surgical intervention during childhood and a second one-third will require replacement during adulthood. The remaining one-third will not require treatment during a normal life expectancy. The aortic valve is the second most common valve to require replacement in childhood superseded only by the pulmonary valve.

Aortic valvular pathology in infants and children poses numerous challenges to the pediatric cardiac surgeon. Without question, valvular repair is the goal of initial intervention because improvement of anatomy and physiology using native tissue allows growth and a potentially better long-term outcome. When reconstruction fails or is not feasible, valve replacement becomes inevitable. The timing of valve replacement and the type of prosthesis remains controversial. Few reports compare the outcomes of the Ross aortic valve replacement (AVR) and other valve substitutes (non-Ross) in children. The goal of this chapter is to address these controversial issues and draw from our institutional experience and review current literature to support our preference for the Ross AVR in children when possible.

Most infants and children with LVOT obstruction due to a BAV in North America will be subjected to an initial attempt at balloon aortic dilatation (BAD). The BAD procedure indiscriminately tears the valve at its weakest point. The stenotic neonatal aortic valve is usually dysplastic and visual identification of commissures can be difficult. There has been little outcome advantage for surgical aortic valvuloplasty (SAV) compared with BAD in neonates. Visualization of the anatomy is not a problem in infants beyond the neonatal period, and in these cases surgical valvuloplasty should be considered as the principal palliative measure.

We recently compared our last 20 years experience with SAV in infants >2 months of age with our last 10-year experience with BAD and found that survival was equivalent. However, SAV gave twice the initial gradient reduction, half the degree of early aortic valve regurgitation, and had 3 to 4 times the palliative durability of BAD. Ten and twenty year freedom from AVR following SAV was 80% and 70%, respectively. Freedom from AVR after BAD was 75% at 10 years and an additional 25% required balloon or surgical reintervention during the same time period.

BAD usually reduces the LVOT gradient but may produce important degrees of regurgitation in up to 20% of neonates and BAD has no advantage in risk of reintervention and mortality in this age group. Other types of LVOT obstruction in children, which involved subvalvar, supravalvar, or multilevel obstructions, are initially referred for surgical treatment. While this report will concentrate on AVR in children, treatment options for patients who have additional areas of LVOTO will be included.

INDICATIONS FOR INTERVENTION IN AORTIC VALVE PATHOLOGY

Infants and children with aortic valve pathology should be offered intervention if they have symptoms of congestive heart failure, angina, or syncope. An asymptomatic child should be offered intervention if the peak LVOT gradient is over 70 mmHg, the mean LVOT gradient is more than 50 mmHg, the aortic valve area is <0.8 cm²/m² of the body surface area, or if they have more than moderate regurgitation with LV dilation and/or dysfunction.

When surgical palliation fails or is not feasible, valve replacement becomes inevitable. Prosthetic valve selection for infants and children requires several considerations that include: aortic annular size, associated LVOT obstructive lesions, associated connective tissue abnormalities, presence and/or quality of the pulmonary valve, and the ability and experience of the operative surgeon.

Controversy over the prosthetic choice for AVR in children has dropped dramatically in the past 10 to 15 years because of the growth in popularity and excellent results obtained with the Ross AVR in many centers (Table 104.1). Mechanical, xenograft, and allograft valves in most institutions in the current era are reserved for children with connective tissue disorders or patients whose native pulmonary valve, if present, is unsuitable for translocation to the aortic position.

AORTIC VALVE REPLACEMENT USING AN ALLOGRAFT AORTIC VALVE

Fresh antibiotic-sterilized aortic allografts were among the first valves to be used for AVR by Ross and others in the early 1960s. Most were implanted as free-hand valves in the subcoronary position of the recipient’s aorta. Their initial function in most instances was satisfactory but within 2 to 6 years the valves failed by calcified stenosis and/or regurgitation.

Aortic allografts were rarely used in North America in the 1970s and early 1980s due to their lack of availability and xenograft and mechanical valves predominated. Cryopreservation techniques became the accepted mode of allograft preservation and storage in the early 1980s and availability of aortic allografts in various sizes for AVR was made possible. In many centers, the aortic root replacement with the allograft aortic root gave more predictable results with less initial regurgitation than did the free-hand sub-coronary

AVR, aortic valve replacement; RVOTR, right ventricular outflow tract reoperation.
XENOGRAFT AORTIC VALVE

have no growth potential and develop interstitial matrix decreasing allograft immunogenicity without weakening the tissue. Decellularized pulmonary allografts have been used by us and others in substantial numbers and their durability in children and adults is better than standard cryopreserved pulmonary valves. Decellularized aortic allografts have only been used in limited numbers by a few investigators and appear to be more durable than standard cryopreserved aortic allografts but the numbers of patients and length of follow-up is too short to draw meaningful conclusions.

XENOGRAFT AORTIC VALVE REPLACEMENT IN CHILDREN

Stented xenograft valves have had very limited use in the pediatric aortic position due to their bulk and large annulus to effective orifice area ratios. Stentless xenografts have a much better orifice area and hemodynamic efficiency. We have used stentless xenografts for aortic root replacement when the pulmonary autograft is unavailable or unsuitable and when anticoagulation for mechanical valves is impractical as encountered with young females who want to consider having children. However, due to rapid calcification and early dysfunction, xenografts are a poor choice in younger children. Xenograft pericardial valves usually fail by calcific obstruction and porcine valves usually fail by regurgitation. Third- and fourth-generation xenograft valves may prove more durable than prior generation xenografts.

MECHANICAL VALVES IN CHILDREN

Mechanical valves in the aortic position of children can be more durable than allograft and xenograft valves, but they have no growth potential and develop patient prosthesis mismatch (PPM) as the child grows. The smallest mechanical valve manufactured for AVR is 16 to 17 mm, and its effective orifice area is slightly over 1 cm². PPM is defined as an effective orifice area of <0.85 cm²/m² of body surface area. Mechanical valve size <23 mm will likely develop PPM as the child reaches adulthood. Mechanical valves can also suffer from pannus ingrowth that can obstruct the inflow and/or outflow of the prosthesis and lead to early prosthetic dysfunction. The development of left ventricular hypertrophy, secondary to PPM or pannus ingrowth, leads to increased LV mass, increased systolic and diastolic dysfunction, and shortened patient survival.

All mechanical valves at present require Warfarin anticoagulation that leads to bleeding problems in 1% to 2% of patients per year. Bleeding tendency can be a particularly troublesome issue for female patients with monthly menses and females who want to become pregnant. Warfarin is also teratogenic for the fetus. Anticoagulation monitoring and compliance is another important issue with teenage patients who are beyond parental control.

Potential for a thromboembolic event is a constant risk factor in mechanical AVR with and without Warfarin anticoagulation and such events occur in 1% to 4% of patients per year. Central nervous system thromboembolic complications, if not fatal, can be devastating for any patient regardless of age.

Quality of life in children with mechanical aortic valves is less than other valve prosthesis because of the need for monthly monitoring of anticoagulation, fear of thromboemboli and bleeding complications, and inability of the child to participate in active and/or contact sports due to anticoagulation and the attendant bleeding risk.

PROSTHETIC ENDOCARDITIS

Prosthetic endocarditis is higher for xenografts than for mechanical valves, homografts, or autografts. Mechanical and xenograft valve endocarditis frequently leads to septic emboli and the need for early prosthetic replacement. Table 104.2 is a literature survey of outcomes in non-Ross AVR in children and shows a higher early and late mortality, higher postoperative complication rate, and a reoperation rate of nearly 20%.

AUTOGRAFT AORTIC VALVE REPLACEMENT (ROSS) IN CHILDREN

Replacement of the diseased aortic valve by pulmonary autograft, a procedure initially described and performed experimentally by Shumway and Lower in the early 1960s and then performed clinically by Ross in 1967, has provided excellent hemodynamic results, both in children and in adults. In experienced hands, the Ross procedure has low morbidity and mortality (Table 104.1). The Ross AVR was slow to be accepted in North America until Elkins and Stelzer introduced it in the early 1980s. They modified the implantation technique to a full root replacement, which gave the Ross AVR more consistent results. Most American surgeons follow their lead and perform the Ross AVR as a root replacement. The Ross AVR is the only AVR, which can place a child or young adult back on a normal life expectancy curve.

ROSS TECHNIQUE IN CHILDREN

The Ross AVR is most often performed as an autograft root replacement as described previously. All patients have intraoperative transesophageal echocardiography (TEE). Standard techniques of cardiopulmonary bypass were used, with bicaval cannulation, moderate hypothermia to 26°C, and antegrade (when possible) and/or retrograde cold blood potassium cardioplegia. The autograft is harvested using standard techniques and leaving 2 to 3 mm of RV muscle attached to the pulmonary annulus. Only 3 to 5 mm of main pulmonary artery is beyond the pulmonary valve commissures is harvested.

After the aortic root is dismantled and debrided, and the tops of the aortic commissures shortened to achieve a near circular but modified aortic annulus, the coronary arteries are removed as large buttons and mobilized for 5 to 8 mm. After the autograft commissures are marked to enable equal distribution of sutures, pledgeted (3 × 7 mm) interrupted mattress sutures of monofilament or braided Dacron (Boston Scientific Corp, Natick, MA) are used to encircle the modified aortic annulus and these sutures are placed in mattress fashion through the autograft annulus. The proximal autograft suture line is fixed or reduced with a Dacron strip when the aortic annulus is larger than the autograft annulus and when annular growth is not desired. Annular reduction is indicated when the aortic valve annulus is more than 4 mm larger than the pulmonary valve annulus. Annular

AVR, aortic valve replacement; H, homograft/allograft valve replacement; M, mechanical valve replacement; RVOTR, right ventricular outflow tract reoperation.
reduction is performed using a 5 mm wide Dacron strip placed circumferentially around the aortic annulus and taking smaller bites of the Dacron, and wider bites of the aortic annulus, thus pleating the aortic annulus 1 to 3 mm per mattress suture along the left and noncoronary portions of the aortic annulus (Fig. 104.1).

The annular reduction is confirmed by placing an appropriately sized Hegar dilator through the reduced aortic annulus.

The autograft is oriented in an anatomic manner keeping the anterior wall anterior and suturing the left-coronary button in the middle of the posterior autograft sinus using 5-0 or 6-0 monofilament suture. The right coronary button is placed in the anterior autograft sinus after careful orientation and before completing the distal aortic anastomosis or left unattached until after the aortic root is allowed to distend.

The right ventricular outflow tract (RVOT) is then reconstructed with an appropriately oversized (6 to 10 mm larger than the autograft) standard cryopreserved pulmonary homograft, a decellularized pulmonary homograft (Synergraft, CryoLife, Inc., Marietta, GA) or a bovine jugular vein conduit (Contegra, Medtronic, Inc., Minneapolis, MN). The bovine jugular vein conduit is preferred for RVOT reconstruction in children <6 years because it has been more durable at our institution in this younger patient age group.

The distal autograft anastomosis is completed after RVOT reconstruction with a 5-mm Dacron strip incorporated into the distal suture line if growth is not desired. The ascending aorta in older or larger children is replaced to include a hemiarch if it is significantly dilated and replaced with a synthetic Dacron tube graft. The mean ascending aortic graft size is 25 ± 2.6 mm (range, 20 to 30 mm). A drawing of the heart after the operation is shown in Figure 104.2.

A TEE is performed intraoperatively in all the patients after cardiopulmonary bypass weaning in order to evaluate the competence of the Ross and RVOT valves. PI and AI have been minimal in our experience and never greater than mild.

**ROSS–KONNO MODIFICATION**

The Ross–Konno is reserved for patients with multilevel obstruction. If the aortic annular diameter is 4 mm smaller than the pulmonary annulus, then enlargement of the aortic root is accomplished by the Konno technique. This involves transecting the aortic annulus for 4 to 8 mm at the commissure between the left and right cusp or at a level just below the pulmonary annulus if the aortic valve is bicuspid. The autograft is carefully harvested leaving a 10 to 12 mm anterior lip of subannular free wall muscle for the Konno patch. The Konno patch is kept very short and an aggressive subannular myectomy is performed if subannular obstruction is encountered. The autograft is trimmed and sutured to the widened aortic annulus (root) placing the anterior tip of the retained RV free wall to patch the triangular defect created by transecting the aortic annulus and the proximal ventricular septum. Pledged interrupted mattress sutures are used for the Konno extension (Fig. 104.3).
Fig. 104.3. Ross–Konno procedure (A) The aortic annulus is enlarged by incising the interventricular septum (dashed line) between the left and right commissures. The length of the incision is frequently limited to just beyond the annulus. A myectomy will also increase orifice area, limiting the extent of ventriculoplasty incision. (B) The autograft is sutured to the margins with interrupted pledgeted sutures. A short apron is left on the autograft to fill the ventriculoplasty site. (C) Coronary buttons are reimplemented into the autograft. (D) Completed reconstruction.

Mavroudis and coauthors have described placing the Konno incision in the middle of the left sinus to reduce the incidence of acquired heart block (Fig. 104.4). We have used this modification on occasion but it requires more extensive mobilization of the left-coronary artery. Additionally, postoperative bleeding in this area if encountered would be difficult to control.

**OTHER METHODS OF ANNULAR ENLARGEMENT**

If a more limited aortic annular enlargement is required for AVR using any aortic valve substitute, the Nicks or Manouguian techniques can be considered. The Nicks annular incision is made at the commissure between the non- and left-coronary cusps and carried down to the mitral annulus.

**DISCUSSION**

There are several advantages of the pulmonary autograft that benefit both the adults and pediatric patients. These advantages
include superior hemodynamics and better regression of LV mass, better long-term survival, no risk of thromboemboli, no age or size limitation for infants and children, growth potential for infants and children, lower risk of endocarditis than other prosthetic types, excellent midterm durability of the autograft and allograft when compared with other prosthetic types, acceptable risk of reoperation, and no bleeding issues related to anticoagulation (Tables 104.1 and 104.2). All of these advantages translate to a better quality of life for children because the Ross AVR allows unrestricted physical activity, more normal psychological development due to lack of need for frequent blood draws to check anticoagulation status, and the Ross AVR allows for pregnancy in young women.

Even with all of these advantages, the early experience of the Ross operation was marred by some problems and disadvantages. Disadvantages include the increased technical difficulty of the Ross AVR. The harvesting of the pulmonary valve necessitates putting two valves at risk for a single-valve disease. Additionally, a prior Konno procedure is likely to have damaged the autograft annulus and exclude a Ross AVR. The most significant problems include a higher than expected rate of reoperation. Dilatation is specifically shown to occur at the valve annulus, sinuses of Valsalva and sinotubular junction (STJ) of the pulmonary autograft. This increase has been attributed to a variety of causes including secondary to passive dilatation due to exposure to higher blood pressure, mismatch of the pulmonary autograft and the aortic annulus or ascending aorta, an intrinsic abnormality of the pulmonary root possibly associated with congenital BAV disease, or normal somatic growth in the pediatric population.

There is no consensus on the rate and nature of autograft dilatation. Tantengco and colleagues noticed pathologic dilatation according to values during the first year after the Ross AVR, but without progression thereafter. Pasquali and colleagues demonstrated a significant increase in values of the annulus, sinus, and STJ over time. Kouchoukos and colleagues observed a consistent increase of the sinus and STJ dimensions over time, but not of the annulus dimensions; however, his measurements were not indexed to the patients’ body surface area. Horer and colleagues noticed that the annulus grows proportionally to somatic growth but the curves depicting the values of the sinus and the STJ increased over time. The rate of autograft dilatation calculated on serial echocardiographic assessments was reported by Takkenberg and colleagues at 0.5 mm/year in an adult population and by Pasquali and colleagues at 2 mm/year in a mixed pediatric and young adult population. Neo-aortic regurgitation and neoaortic root dilatation occur over time in some adolescents and adults; however, the correlation between AR and aortic root dilatation has varied between institutions. Kouchoukos identified dilatation of the STJ as an independent predictor for the progression of AR. Horer and colleagues determined that the aortic root dimensions immediately after the Ross AVR were larger than in normal healthy children but the annulus grows proportionally to the somatic growth of the child. They found in their series that AR develops slowly but significantly and was associated with a dilated STJ. Patients with BAV and dilated ascending aorta or patients with dilated aortic root and primarily aortic insufficiency have been considered the highest risk group for dilatation and neoaortic insufficiency in some series. Other studies have shown that no association exists between bicuspid valve disease and histologic changes in explanted pulmonary autografts. When the root dilatation leads to significant autograft valve regurgitation or when the dilatation rapidly progresses into an aneurysm, reoperation is indicated. These problems are uncommon in our experience (Table 104.1).

Because of the early experiences with root dilatation and/or AR many centers modified their Ross technique in an attempt to prevent autograft dilatation. Our institution currently reinforces the annulus and STJ with Dacron, replaces the ascending aorta if it is significantly dilated (z > +2), and aggressively manages perioperative and postoperative hypertension for up to 6 months. We reduce the aortic annulus if it is dilated. The aortic annulus and STJ should be at least 20 mm in diameter before we restrict its growth with a Dacron band or ascending aortic graft. The youngest patient in our pediatric Ross experience who needed aortic annulus reduction was an 8-year-old boy. We reduced his annulus to 20 mm. Elkins and colleagues describe that the only independent predictors for the development of moderate or greater autograft regurgitation were increased age at the time of the operation, autograft regurgitation at completion of the Ross AVR, and increased follow-up time.

Moritz and associates reduced the diameter of the aortic annulus and wrapped the pulmonary autograft with an absorbable mesh in a few patients as an attempt to prevent postoperative AI. Pacifico and colleagues described an operative technique in which the entire pulmonary autograft was wrapped with glutaraldehyde-fixed bovine pericardium to prevent dilatation. The Ungerleider technique of placing a Dacron sleeve...
around the autograft was recently introduced to address this concern in adults. Other techniques to prevent post-Ross autograft dilation have also been suggested. Excessive autograft length in the root technique may lead to late dilation at the STJ and above, as shown by de Kerchove and coworkers. They conclude that in the root technique the autograft is less likely to dilate if it is as short as possible and when the distal suture line is reinforced with a Dacron strip or extended with a Dacron graft. We adopted these modifications in 2000. These annular and STJ reinforcement techniques may not fully protect against autograft sinus dilation, but some data suggest a benefit from support at and above the STJ. We also advocate aggressive treatment of systemic hypertension during the first 6 months postoperatively.

A comparison of our freedom from reoperation before and after 2000 when we modified our technique and aggressively treated hypertension is shown in Figure 104.5.

**Ross Reoperation**

Acquired Ross root dilatation with or without aortic regurgitation was seen before 2000 in our Ross experience in 15% to 20% of our cases. Salvaging the Ross valve using a valve-sparing root replacement technique with reintervention of the valve has been possible in the majority of our Ross reoperations.

Other treatment options for Ross root dilation and AR include a mechanical valve Bentall procedure, re-replacement of the aortic root with a homograft, replacement of the aortic valve with supported or unsupported aortoplasty, separate replacement of the aortic valve and the ascending aorta, or valve-sparing root replacement.

The rate of pulmonary autograft replacement in our overall adult and pediatric series of 350 patients is 8% and 5% in children. The results in small children <6 years are not as good but an 81% freedom from any reintervention is still acceptable. Table 104.3 compares freedom from any reoperation in our Ross versus non-Ross children and shows a superiority of the Ross over non-Ross AVR.

Our good results with RVOT reconstruction in Ross AVR in children are in part due to excising most of the muscle from the proximal end of the allograft, oversizing the allograft by 6 to 10 mm expecting the allograft to shrink 15% to 25%, and treating all patients with low-dose aspirin and ibuprofen to lessen the inflammatory response of the recipient to donor tissue for 6 months postoperatively. With these modifications, we have an 88.5% freedom from replacement of the RVOT in our 112 children and 95% freedom from RVOT reoperation in our 350 combined pediatric and adult series.

**SUMMARY**

AVR in children is challenging. With the Ross procedure, the LVOT gradient is almost always completely eliminated and there is the expected regression of left ventricular mass that should improve the long-term prognosis.

When valve replacement becomes necessary we prefer the Ross AVR as a full root technique as described above.

Ross AVR in infants and children gives superior results in most high volume centers as compared with other prosthetic types (Tables 104.1 and 104.2; Fig. 104.6).

The Ross AVR is a challenging surgical procedure. Many of the early problems seen with the Ross root technique, that is, dilation and regurgitation can be prevented. When dilatation and/or regurgitation are encountered, the surgeon has another option of performing a valve-sparing root replacement.
replacement thus avoiding the worrisome complications of other prosthetic valves. The Ross operation has superior survival with less postoperative complications and gives a child a better quality of life. The Ross is the AVR procedure of choice in children requiring valve replacement.

**SUGGESTED READINGS**

The advent of balloon valvuloplasty for valvar AS and the development of the pulmonary autograft procedure for the replacement of the aortic valve and root (Ross operation) have dramatically changed the approach to children with congenital aortic valve disease. In most centers, surgical intervention by aortic valvotomy has become an unusual operative procedure and balloon valvuloplasty is the primary procedure of choice for aortic valve stenosis in newborns or infants. Dr. Brown and his group have shown an excellent series of surgical valvotomies and valvuloplasties that seem to have results superior to current balloon valvuloplasty results. In spite of this information, most centers will still perform balloon valvuloplasty in preference to surgical intervention because of the less invasive nature of the procedure. Pulmonary autograft valve replacement has permitted replacement of stenotic or regurgitant aortic valves earlier in life. In the past, patients with significant valvar disease often were managed medically for prolonged periods at the expense of ventricular function, because the options for valvar replacement were limited in children and suboptimal. Mechanical valve replacement in children is associated with the need for reoperation as the child outgrows the valve size, and the difficulties of anticoagulating young children are significant, with the added inconvenience of multiple blood drawings for monitoring. Other alternatives for valve replacement are also unappealing, including tissue valves, which degenerate rapidly in children, and homograft valves, which do not have the growth potential of autografts and also have a reasonably high incidence of late degeneration. However, the Ross pulmonary autograft valve replacement as described in this chapter and as extensively performed by Dr. Brown and others in many children with complex forms of low left ventricular outflow tract obstruction has proved to be a quite durable and satisfactory procedure. Dr. Brown has shown conclusively that the autograft valves can grow in young children, and the natural endothelial surface and viability of the autograft seems to be ideal for (continued)
aortic valve replacement. Thus, the favorable characteristics of the autograft valve replacement may actually permit earlier replacement of the aortic valve rather than repeated valvotomies or other procedures, which may provide only short-term palliation and potentially exacerbate ventricular dysfunction by maintaining chronic volume and pressure loads on the ventricle. The pulmonary homograft valve used to replace the right ventricular outflow tract in the Ross operation may not grow with the child; however, in most cases a much larger pulmonary homograft can be inserted than the size of the autograft valve, which in most children >3 or 4 years of age permits the use of an almost adult-sized valve. Although stenosis of the homograft valve has rarely occurred, in most cases the valves become insufficient with time, which is well-tolerated hemodynamically on the right side of the heart. When the pulmonary homograft used to replace the right ventricular outflow tract after the Ross operation becomes insufficient, it is now possible to consider using stent-mounted transcatheter valve implantation to preserve valve function and extend the life of the pulmonary homograft conduit. The use of these techniques may eliminate some of the concern about late RV outflow tract obstruction after the Ross operation.

On rare occasions, the pulmonary valve is abnormal, and some have suggested not to use bicuspid pulmonary valves for the Ross operation. However, in young children in whom other valve replacements are unappealing or a homograft replacement of the aortic valve would likely be associated with a significant risk of reoperation because of the patient’s growth, we use the bicuspid pulmonary autograft, because it may have satisfactory function over the intermediate term. However, other abnormalities of the pulmonary valve, including any pulmonary valvar insufficiency related to leaflet abnormalities such as quadricuspid valves have been associated with autograft regurgitation when used in the aortic position. Therefore, if significant pulmonary valve abnormalities are noted, even in the presence of delicate valve leaflets, we now believe that the autograft should not be used.

Dr. Brown has described nicely the Konno modification of the Ross operation for patients in whom enlargement of the left ventricular outflow tract is necessary. We have also used the technique of excising a portion of right ventricular outflow tract muscle with the autograft as a way of closing the incision in the ventricular septum; however, in patients in whom a larger septal incision is necessary, we have used a Gore-Tex patch to fill in the septal defect and have sewn the autograft to the superior margin of the patch. We have used a slightly different technique for the implantation of the pulmonary autograft than that described by Dr. Brown. While it has been well shown that implantation of the autograft in an inclusion technique inside the aortic root will have less issue with late dilation and insufficiency, the vast majority of children with aortic valve disease have an aortic annulus that is significantly smaller than the pulmonary root and therefore inclusion techniques cannot be successfully utilized. It is not uncommon to need to enlarge the aortic root slightly to accommodate the size of the pulmonary autograft. The incision in the aortic annulus as described by Dr. Brown in the Ross-Konno operation is usually all that is necessary to allow adequate size matching of the autograft and aortic outflow tract. We have tended to use a running technique for autograft implantation in young children and have found that the valve can be inverted into the left ventricular outflow tract to place a circumferential suture line in larger children or simple running suture can be used to implant the annulus in very small children. Reinforcement of the aortic annulus in these small children is not necessary or desirable due to the need to allow for growth and therefore annular reduction techniques and the use of Dacron reinforcement as described by Dr. Brown is not necessary. The need to stabilize the STJ is important; however, this must be done in such a manner as to allow for growth in very young children and therefore a pericardial strip is used if necessary rather than rigid Dacron material. The replacement of the ascending aorta with a graft will eliminate aortic root dilation up to the level of the innominate artery and may also serve the advantage of stabilizing the STJ to prevent late autograft dilation and insufficiency.

The incidence of root dilation requiring reoperation varies largely from one series to the other and Dr. Brown has perhaps the best series with freedom from this complication. The majority of patients who come to reoperation have root dilation that is sufficient to cause the onset of aortic insufficiency and in many of these patients the autograft root can be saved with valve-sparing root replacement, maintaining the benefits of a living valve, and the lack of need for anticoagulation long term. The intermediate term results for valve-sparing root replacement appear to be quite good; however, we have seen occasional patients who have had dehiscence of the valve leaflets from inside the Dacron autograft, possibly related to the distortion or abnormal coaptation of often elongated valve leaflets in these patients. This appears to have been a problem primarily in patients who have had valve-sparing root replacement for Marfan’s disease but has also been seen in patients after autograft root replacement.

When the pulmonary autograft is much larger than the native aortic root after reconstruction, the pulmonary homograft used to replace the right ventricular outflow tract is relatively large and must swing around the new aortic root, which is larger than the original. Thus, it is important to be sure that there is adequate length of the homograft used for right ventricular outflow reconstruction, and, as the suture line is brought toward the right side of the incision in the right ventricular outflow tract, that it does not become compressed by the autograft aortic root. The homograft has a tendency to be draped across the autograft root. The natural curvature of an aortic homograft may provide a better option for right ventricular outflow reconstruction than a pulmonary homograft in some cases.

Dr. Brown has also described the technique for decreasing the size of the aorta for the distal anastomosis when the ascending aorta is somewhat dilated with the autograft root replacement procedure. We have used a similar technique; however, we have found that the pulsatility of the autograft in the aortic root caused by the elasticity of the pulmonary artery can cause significant bleeding when there is a diameter discrepancy at the distal suture line, and we therefore tailor the distal (continued)
aorta, but also reinforce the suture line with a strip of Teflon felt or pericardium to decrease the pulsatility at the suture line and decrease the risk of bleeding.

The greatest long-term concern after Ross pulmonary autograft aortic root replacement is the development of progressive dilation of the autograft and AI. Although there does appear to be an incidence of progressive aortic regurgitation in these patients from dilation of the proximal autograft pulmonary artery wall and distortion of the sinuses, the incidence appears to be relatively low and the progression slow. Nevertheless, reoperations will likely be necessary in some of these patients. However, a valve replacement procedure that can be done in young children with a likely reoperation-free rate at 5 years of 80% to 90% or greater, as has been noted for the autograft, is a significant advance for the management of valvular disease in children.

With longer follow-up of the use of the Ross pulmonary autograft as a root replacement in children and young adults, there has been an increasing incidence of autograft root dilation. The sinuses and aortic wall appear to dilate, and even with annular fixation techniques that preserve valve function, significant aneurysms of the proximal aorta can develop. It is unclear at what size intervention is justified, because there is a distal suture line that potentially could prevent distal dissection as seen in Marfan syndrome; however, there has been an isolated case report of dissection of the autograft wall in association with root dilation.

Therefore, most centers expect that when root dilation progresses to 5.5 to 6.0 cm, root replacement should be performed. There is an increasing experience of use of the valve-sparing root replacement in this condition to preserve the autograft valve for as long as possible. In most cases, the autograft valve leaflets remain delicate and can coapt well when the autograft wall is replaced with a Dacron graft. There has also been increasing interest in supporting the autograft wall at the time of implantation in older children and young adults, when growth is not an issue, in the hope of preventing the complication of late aortic root dilation. The effect of a rigid prosthetic stenting of the autograft root on overall late autograft function is not known.
INTRODUCTION

Arrhythmia surgery in young patients is most commonly performed in the setting of concurrent repair of structural heart disease, and rarely performed in patients with structurally normal hearts. As the success of surgical repairs of congenital heart disease has improved survival, the late sequelae of repaired congenital heart disease include late hemodynamic/structural problems, arrhythmias, and congestive heart failure. By adulthood, the development of atrial arrhythmias in the setting of congenital heart disease is associated with a 50% increase in mortality, a twofold increase in stroke or congestive heart failure, and a tripling of the need for cardiac interventions. The incidence of reoperations for complex lesions parallels the incidence of arrhythmias and underscores the complex electromechanical interactions in congenital heart disease. In patients with congenital heart disease, arrhythmia surgery may be performed as therapy for coexisting arrhythmias, or prophylactically to reduce the risk of developing late atrial arrhythmias. Efforts to minimize arrhythmia occurrence can be expected to reduce the morbidity related to arrhythmias and hospitalizations and may alter the risk of sudden death. It has been our practice to integrate anti-arrhythmia therapies into all primary repairs as needed, and to view any reoperation for congenital heart disease as an opportunity to improve both the electrical as well as the hemodynamic status of the patient. A unique subset that we will focus on in this chapter is the patient with a prior atriovenous Fontan. These patients undergo a Fontan conversion with arrhythmia surgery.

Arrhythmia surgery in patients with congenital heart disease is challenged by the range of anatomic variants, arrhythmia types, and intramyocardial scar location. Anatomic variants include unusual atrioventricular (AV) as well as ventricle to great vessel connections, juxtaposition of the atrial appendages, anomalous pulmonary and systemic venous return among a myriad of other complex lesions. Arrhythmia types can generally be grouped into specific mechanisms, but location and ablation can be perplexing and demanding as each of the arrhythmias is ablated by different procedures indicated by the arrhythmia substrate. Scar formation is generally induced by previous reparative operations that are required to achieve a separated pulmonary and systemic circulation, but not always. Scar formation leading to intractable arrhythmias may occur owing to intracavitary hemodynamic jet lesions, atrial dilatation, myocardial tumors, and cardiomyopathy.

The purpose of this chapter is to review arrhythmia mechanisms and operative techniques for arrhythmia surgery, with attention to particular challenges associated with congenital heart disease, including resternotomy techniques for safe mediastinal reentry. The historical review is based on our previous publications in this field involving 248 patients between 1987 and 2010 from Children’s Memorial Hospital in Chicago and the Cleveland Clinic Children’s Hospital (Tables 105.1 to 105.3).

ARRHYTHMIA MECHANISMS AND ARRHYTHMIA SURGERY TECHNIQUES

A simplistic approach to the categorization of arrhythmias is summarized in Table 105.4. The most common types of arrhythmias associated with congenital heart lesions are atrial reentry tachycardia (ART), atrial fibrillation (AF), accessory connections, AV nodal reentry tachycardia (AVNRT), focal or automatic atrial tachycardia, and ventricular tachycardia (VT). Reentry is the most common mechanism for clinical arrhythmias and accounts for more than 60% of late postoperative arrhythmias. A reentrant rhythm requires a circuit, with unidirectional block and slowed conduction allowing the electrical impulse to “reenter” the previously blocked area. Reentry may occur in the atria (atrial flutter or atrial reentry), in the ventricles (postinfarction or scar-related VT), or involve all chambers (reciprocating tachycardia utilizing an accessory connection). Reentrant arrhythmias may be initiated or terminated by pacing, allowing the reproduction of the arrhythmia for elucidation of the mechanism in the catheterization laboratory or operating room. Most reentrant arrhythmias are suitable for catheter or surgical ablation, by interrupting a key component of the reentrant circuit. The majority of reentrant circuits are large, or “macro-reentrant,” such as atrial flutter. In typical atrial flutter, the electrical impulse courses up the atrial septum and down the right atrial free wall, with slowed conduction in the isthmus of tissue between the coronary sinus ostium and the tricuspid valve. In some instances, the reentrant circuit is more circumscribed, or “micro-reentrant,” and may be amenable to targeted focal ablative techniques in a discrete region. In contrast, automatic arrhythmias are local areas of increased firing and cannot be terminated by pacing or cardioversion; therapy is directed at slowing the rate of firing, or eliminating the specific focus of automaticity with ablation or resection. Examples of automatic rhythms include sinus rhythm, junctional ectopic tachycardia, and accelerated ventricular rhythms. The correct characterization of the arrhythmia circuit is essential to the success of arrhythmia surgery, as the most perfectly executed maze procedure for AF will not eliminate a focal source of atrial automaticity.

Surgical and transcatheter techniques have been highly effective in ablating these arrhythmias in pediatric and adult patients with congenital heart disease and normal anatomic hearts. Difficulty with transcatheter ablation techniques arises with complex anatomic variants, or

Complexities posed by limitations of venous access or surgical baffles or conduits. Patients with double-outlet right ventricle with subaortic conus can harbor an accessory connection in the subaortic conus between the discontinuous aortic annulus and mitral annulus, a situation that does not exist in normal hearts where the ablative techniques have been standardized. Patients with heterotaxy syndrome with either a functionally univentricular heart or two separate ventricles may have absence of the coronary sinus, presence of a left superior vena cava, separate atrial entry of the hepatic veins, and/or juxtaposition of the atrial appendages, in addition to surgical baffles limiting access to regions of the atria. Patients with congenitally corrected transposition of the great arteries (ccTGA) have a propensity to display multiple accessory connections in association with Ebstein's anomaly of the systemic tricuspid valve. In addition to these anatomic variants, repaired tetralogy patients have a high incidence of ART caused by atrial dilatation and scar formation, as well as VT in the area of the ventricular septal defect closure and right ventriculotomy. Transcatheter ablation in the older Fontan patient is hampered by both the multiplicity of arrhythmia mechanisms and circuits, location of some arrhythmia circuits in the left atrium or under surgical patches over the atrial isthmus, as well as the marked atrial hypertrophy limiting the ability to create transmural conduction block. The contemporary congenital heart surgeon should have a comprehensive understanding of all arrhythmia types and the potential methods of ablation, as well as hurdles of anatomic complexity for arrhythmia surgery if a cardiac operation or reoperation for an anatomic repair/re-repair is required in a patient with arrhythmias.

**ARRHYTHMIA-SPECIFIC SURGERY TECHNIQUES**

The basic techniques for arrhythmia surgery include dissection, linear or focal ablation (sometimes in tandem with dissection), and maze procedures. Focal or macro-reentrant tachycardias require targeted dissection or ablation of the localized arrhythmogenic focus. Accessory connections are treated with discrete ablation, or endocardial dissection along the AV annulus for multiple or complex-branching connections, as seen with Ebstein's anomaly of the tricuspid valve. Maze procedures are designed to eliminate macro-reentrant

circuits in the atria, while preserving intact AV conduction and atrial transport function, and may be performed using a combination of resection and linear ablative lesions. The right atrial maze procedure is performed for atrial reentry or atrial flutter, and both a right and left atrial maze procedure is performed for AF. The right atrial maze procedure alone is not adequate to eliminate AF, which is primarily of left atrial origin.

**MACRO-REENTRANT ATRIAL TACHYCARDIA: ATRIAL REENTRY TACHYCARDIA**

As noted previously, typical atrial flutter is a macro-reentrant circuit of the right atrium with an area of slowed conduction between the inferior vena cava (IVC), tricuspid valve, and the coronary sinus, characterized by saw-toothed flutter waves visible on electrocardiogram, and a relatively rapid atrial rate. In repaired congenital heart disease, macro-reentrant atrial tachycardia may occur in either atrium and may involve areas of slow conduction posed by electrical or surgical scar (crista terminalis, atrial septal defect patch) or anatomic orifices (inferior or superior vena cava, atrio-pulmonary anastomosis, entry of pulmonary veins or anomalies of venous return); in this setting the arrhythmia is labeled “atrial reentrant” or “intratrial reentrant” or “scar-mediated atrial reentrant” by various authors. Typical flutter waves are not usually apparent, and atrial rates are slower than typical atrial flutter, resulting in discrete P waves visible on electrocardiogram with variable AV conduction. Ablative lesions are used to interrupt the macro-reentrant circuit in the areas of slowed conduction with anatomic barriers, most commonly at the inferior right atrial isthmus, defined as the area between the coronary sinus, the tricuspid annulus, and the IVC. The ablative lesion, therefore, transforms an area of slow conduction to an area of no conduction, thereby eliminating the circuit. In normal hearts, the therapeutic lesions are noted in Figure 105.1.

Multiple areas of slow conduction may exist in patients with congenital heart disease from prior incisions, patches, or wall stress and the ablative lesions target the bridges between anatomic barriers. Identification of the relevant macro-reentrant circuits and targeting the potential areas of slowed conduction suitable for linear ablations (connecting anatomic barriers) are key to successful ablation. While the anatomic variants are many, the tenets of ablative therapy are constant, namely, that lines of block are established between two or more anatomic barriers. For right ART in the setting of congenital heart disease, the surgeon is concerned with the inferior and superior vena cavae, hepatic venous entry,
AV valve, coronary sinus, atrial appendage, and the fossa ovalis or atrial septal patch. When anatomic barriers are absent or anomalous, creative application become necessary by delivering ablative lesions using the guidelines mentioned previously. For example, since there is no tricuspid valve in tricuspid atresia, cryoablation lesions are applied as noted in Figure 105.2A. Figure 105.2B and 105.2C demonstrates the lesions that are required for single right ventricle/mitral atresia and functionally univentricular hearts with unbalanced AV canal, respectively. Figure 105.3 is a complex anatomic diagrammatic representation of the potential anomalies of systemic and pulmonary venous return, juxtaposed atrial appendages and proposed lines of block that are recommended for right- and left-sided maze procedures. The ablative lesions noted in Figure 105.3 are designed to be guidelines that are executed based on the preoperative electrophysiologic study and the type of arrhythmia that has been characterized. As an example, biatrial maze operations are performed if suture lines extend into the left atrium or if there is anomalous left superior vena caval drainage.

FOCAL OR AUTOMATIC ATRIAL TACHYCARDIA

Focal (automatic) atrial tachycardia is characterized by a localized area of electrical impulse generation, which may be caused by discrete micro-reentry or by an automatic focus. Either form of focal tachycardia inhibits the slower rate of normal sinus node firing and results in tachycardia. The electrical impulse from this ectopic focus is conducted and propagated through the atria, often with prolongation of the PR interval, resulting in stimulation of the AV node and ventricles. Surgical treatment of focal (automatic) atrial tachycardia usually requires resection and/or ablation of atrial tissue; more extensive

areas of focal tachycardia may require electrical anatomic isolation. Favorable outcomes have been achieved with cryoablation and excision of automatic foci. Automatic right atrial foci are often localized to the right atrial appendage and can be resected. Multiple ectopic foci resulting in arrhythmia recurrence stimulated surgeons to use more extensive and creative techniques such as pulmonary vein isolation, left atrial isolation, right atrial isolation, and His bundle ablation with pacemaker insertion in difficult cases.

We have successfully performed atrial appendage resection for automatic atrial tachycardia in two neonates and five older children (Fig. 105.4). One neonate underwent a concomitant Norwood procedure for hypoplastic left heart syndrome and the other, with a normal heart, was spared extracorporeal membrane oxygenation (ECMO) after the arrhythmia site (right atrial appendage) was resected and ablated in the operating room. Of the five older children, three underwent concomitant atrial (n = 2) and ventricular (n = 1) septal defect repairs with successful focal cryoablation and the other two had normal hearts with depressed ventricular function due to the arrhythmia. Atrial tachycardia can cause "idiopathic" dilated cardiomyopathy; appropriate and aggressive arrhythmia treatment may be curative, and allow ventricular function to recover. One teen-aged patient in our series presented with cardiogenic shock due to atrial tachycardia. The patient underwent emergent median sternotomy for the placement of a mechanical assist device. However, a focal right atrial tachycardia originating in the right atrial appendage was identified and resected, resulting in sinus rhythm obviating the need for the ventricular assist device. Subsequently, ventricular function recovered over a period of weeks. In the current era, automatic atrial tachycardia is usually treated by transcatheter ablation. Rare refractory cases, however, require an individualized treatment plan for accurate diagnosis and ablation.

ACCESSORY CONNECTION-MEDIATED TACHYCARDIA

Accessory connections may “manifest” on electrocardiogram during sinus rhythm resulting in the appearance of a delta wave, or Wolff-Parkinson-White (WPW) syndrome in this setting there is fusion of conduction from atria to ventricles over both the AV node and the accessory connection. More commonly accessory connections are “concealed,” and conduct only in the retrograde direction from ventricle to atrium; a delta wave is not present during sinus rhythm. The accessory connection provides the substrate for a macro-reentrant circuit including the atria, AV node, ventricular myocardium, accessory connection, and return to the atria. Thus, the existence of an accessory connection may contribute to several forms of tachycardia, most commonly orthodromic reciprocating tachycardia, but also antidromic reciprocating tachycardia, and AF with rapid antidromic conduction via a manifest accessory connection. During orthodromic reciprocating...
tachycardia, conduction proceeds normally from the right atrium through the AV node to the ventricle, and then via the accessory connection to transmit the electrical wavefront from the ventricle back to the atrium. Interruption of this macro-reentrant circuit at either the AV node (adenosine) or at the accessory connection (procainamide, ablation) interrupts the circuit and terminates tachycardia. Antidromic, as the word indicates is a circuit moving in the opposite direction and is associated with unidirectional block in the AV node, with conduction proceeding antegrade via a manifest accessory connection from atrium to the ventricle if the impulse reenters via the AV node in the retrograde direction, antidromic reciprocating tachycardia ensues. Because the manifest accessory connection may be capable of very rapid antegrade conduction (without the inherent electrical delay of the AV node), the potential exists for triggering ventricular fibrillation and is the cause of sudden death in the setting of WPW.

In the normal heart, accessory connections are most frequently left-sided, usually left laterally or posteriorly. In congenital heart disease, accessory connections may be associated with pathology of the corresponding AV valve. Thus, Ebstein's anomaly has the highest association of accessory connections related to the tricuspid valve. In the setting of ccTGA, the accessory connections are associated with the left-sided, tricuspid valve. Currently, accessory connections are optimally treated by transcatheter ablation, with acute success rates of 70% to 98% depending on accessory connection location. Excellent results have been achieved using this approach, and transcatheter ablation of manifest accessory connections is recommended prior to planned operative therapy for anatomic correction/palliation. In the setting of Ebstein's anomaly, due to the frequent association of concealed right-sided accessory connections, preoperative electrophysiology study and ablation as necessary is recommended. When an operative procedure is planned, the team must take into consideration all variables that attend the eventual repair.

The transcatheter ablation procedure can precede the anatomic repair. Alternatively, anatomic repair and the ablation procedure may be performed together in the operating room. The conditions influencing operative repair include but are not limited to right-to-left shunt, number and location of accessory connections, previously failed attempts at catheter ablation, projected cross-clamp time for the planned procedures, experience of the operating team using ablative procedures for accessory connections, and the degree of ventricular dysfunction. A staged and collaborative approach of preoperative mapping and localization of accessory connections, with transcatheter ablation as possible, and identification of anatomic considerations such as an epicardial accessory connection location or multiple accessory connections guiding operative arrhythmia surgery is optimal.

**ATRIOVENTRICULAR NODAL REENTRY TACHYCARDIA**

AV nodal reentry occurs when there is functional dissociation of conduction to the AV node between “fast” and “slow” conducting tissue in the approaches to the compact AV node, or His bundle. Normal AV nodal conduction occurs over the anterior located fast “pathway,” with a normal PR interval. Should block occur in this tissue, conduction via the slow tissue, usually located more inferiorly and posteriorly, occurs with a longer PR interval. Reentry may then occur via the fast pathway, allowing typical AV nodal reentry to sustain (antegrade “slow,” retrograde “fast” pathways). This arrhythmia is characterized by a narrow QRS with the retrograde (fast) P wave buried within the QRS; frequently appearing as an rSR’ pattern in lead V1 on electrocardiogram. Atypical forms of AV nodal reentry occur less commonly, including antegrade fast and retrograde slow circuits, as well as intermediate variants. Initial attempts at catheter ablation of AVNRT targeted the region of the fast pathway just proximal to the compact AV node and carried the risk of developing AV block. Presently, the usual catheter ablation approach targets the slow AV nodal pathway, in the region anterior to the coronary sinus ostium and carries success rates of over 95%. AVNRT occurs in association with certain forms of congenital heart disease, involving either anatomic variation of AV nodal tissue (twin AV nodes in heterotaxy syndrome), or surgical manipulation in the region of the approaches to the AV node (Mustard or Senning repairs of transposition of the great arteries). In patients with prior atrial baffle repairs, successful ablation targets atrial tissue on the pulmonary venous side of the baffle, necessitating a retrograde approach to the pulmonary venous chamber, or transvenous baffle perforation.

At the present time, AVNRT is treated by either the cryoablation or radiofrequency technique. Operatively, a linear lesion is placed from the posterior inferior rim of the coronary sinus ostium to the IVC. In the presence of a right-sided AV valve, a linear lesion from the valve to the posterior ostium of the coronary sinus is delivered. The operative approach in a beating nonworking heart using discrete cryolesions around the coronary sinus is no longer used. Results of catheter modification of the AV node slow pathway in the region of the coronary sinus ostium indicate that it is not desirable to attain prolongation of the PR interval, as previously performed. In patients with prior Mustard or Senning procedures undergoing reoperation, we have elected to perform ablation of AVNRT directly intraoperatively and avoid the retrograde catheter approach to the pulmonary venous atrium.

**ATRIAL FIBRILLATION**

AF is predominantly a left atrial arrhythmia characterized by very rapid chaotic atrial activity with variable AV conduction. On ECG, consistent P waves are replaced by rapid oscillations or fibrillatory waves that vary in amplitude, shape, and timing. AF is frequently associated with left-sided valvar pathology and carries a risk of atrial thrombosis formation and stroke, in addition to decreased cardiac output in patients dependent on atrial contributions to cardiac output, such as patients with a functionally univentricular heart. The mechanism of AF may be due to multiple micro-reentrant atrial wavelets, focal triggers from sleeves of cardiac muscular tissue often within pulmonary veins, or localized reentrant circuits with fibrillatory conduction. Sym pathetic and parasympathetic innervation from autonomic ganglia located on the epicardial surface of the posterior left atrium may contribute to perpetuation of fibrillation. In addition to a trigger, an anatomic substrate is needed for the maintenance of AF, and atrial remodeling occurs rapidly with the onset of AF. Despite characterization as multiple reentrant waves, AF does not terminate with atrial overdrive pacing.

In the setting of congenital heart disease, AF is associated with unoperated atrial septal defects in older patients, mitral valve regurgitation or stenosis, hypertrophic cardiomyopathy, and in patients at risk for recurrent atrial arrhythmias, such as atrial repairs of transposition of the great arteries, Ebstein's anomaly, or the Fontan procedure. The risk of developing AF late after closure of atrial septal defects increases with advancing age, such that as many as 60% of patients over 40 years of age at the time of intervention will develop AF. For patients undergoing surgery for ASD closure, preoperative atrial arrhythmias or age >40 years should prompt
consideration for concurrent AF surgery. Surgical intervention solely for hemodynamic problems will not eliminate AF, and arrhythmia surgery is recommended concurrently for at-risk patients undergoing structural surgery. Right atrial arrhythmia surgery is not an effective treatment for AF. The surgical treatment of AF was introduced in 1987 by Cox, Boineau, and Schuessler, and involved a “cut and sew” approach designed to prevent perpetuation of reentrant circuits, while preserving AV conduction and atrial transport function via a “maze.” There have been many subsequent modifications of the maze lesion sets in an effort to minimize the extent of surgery, including epicardial approaches and thoracotomies, or a hybrid approach; freedom from recurrent AF is improved in patients undergoing the more extensive full lesion sets. The goals of the full lesion set are to isolate the pulmonary venous atrium, and to connect the encircling pulmonary venous lesion to the mitral annulus and the base of the resected left atrial appendage, in addition to a dome lesion at the roof of the left atrium, either to the anterior mitral annulus or to the right atrial appendage. The ability to use linear or specially designed ablation catheters has largely eliminated the need for the lengthy “cut and sew” approach. Different energy sources are used, including cryoablation, radiofrequency, bipolar radiofrequency, ultrasound, and laser. In adults with unoperated atrial septal defects, atrial flutter and fibrillation occur in 14% to 22% of patients. Surgical ablation for AF prevents AF recurrence in over 90% of adult patients, often in association with mitral valve repair, atrial septal defect closure, or coronary artery bypass surgery. We have incorporated successfully the Cox–maze III procedure into repair of complex congenital heart disease, including patients with functionally univentricular hearts undergoing Fontan conversion (Fig. 105.5), atrial septal defect closure, and mitral valve repair in patients as young as 4 years of age. We have had no late recurrence of AF in our patient population undergoing the maze III lesion set in any of our patients, including patients with functional univentricular hearts undergoing Fontan conversion (Fig. 105.5), atrial septal defect closure, and mitral valve repair in patients as young as 4 years of age. We have had no late recurrence of AF in our patient population undergoing the maze III lesion set, although organized ART has recurred in up to 17% of patients, similar to the incidence reported from other centers. The addition of lesions to the mitral annulus aligned with a corresponding epicardial lesion, and dome lesions is performed in an effort to reduce the risk of late tachycardia recurrence.

**VENTRICULAR TACHYCARDIA**

VT is defined as three or more consecutive ventricular beats at rates >150 bpm in older patients, with sustained VT defined as lasting >30 seconds or requiring intervention prior to that time due to hemodynamic compromise. Among pediatric patients, the most common setting for VT is following repair of lesions requiring ventricular surgery, particularly tetralogy of Fallot and double-outlet right ventricle. Late VT is being increasingly recognized in older patients with atrial repairs for transposition of the great arteries, Fontan procedure for functionally univentricular heart, and Ebstein’s anomaly. Nonsustained VT in these patients may be a marker for declining ventricular function, and successful reoperations for residual hemodynamic problems may decrease the frequency of ventricular arrhythmias. However, patients with sustained VT prior to surgery are at increased risk for recurrences, and intervention for the arrhythmia is recommended. VT is associated with cardiac tumors, most notably fibromas, as well as rhabdomyomas, myxomas, or hemangiomas. Intractable VT of infancy is associated with histiocytoid cardiomyopathy and ion channel disorders. Patients with VT refractory to medications and transvenous catheter ablation techniques as well as patients undergoing concomitant repair of structural heart disease are considered for intraoperative ablation of VT.

As noted earlier, incessant life-threatening VT in infancy is associated with ventricular hamartomas or histiocytosis. Before the availability of intravenous amiodarone, such infants underwent surgical resection of the left ventricular endomyocardium with some success. In older patients, usually adolescents, idiopathic VT in the ostensibly normal heart typically arises from either the right ventricular outflow tract (left bundle branch block, normal to rightward QRS axis morphology) or the septal surface of the left ventricle (right bundle branch block, left axis morphology). Both forms of idiopathic VT are amenable to catheter ablation techniques, with success rates of 70% to 80%. Rarely, VT may originate from the epicardial surface of either the left or right ventricle and is amenable to epicardial arrhythmia surgery with success rates over 70%. Detailed preoperative and intraoperative mapping of the arrhythmia focus is essential to the successful performance of such procedures.
**STRUCTURAL HEART DISEASE**

Patients with postoperative tetralogy of Fallot or double-outlet right ventricle are at risk for late postoperative sustained VT, occurring in 5% to 8% of cases. Moreover, the risk of late sudden death is 2% to 6%. Risk factors for VT include older age at initial repair, residual right ventricular hypertension, right ventricular outflow tract patch or aneurysm, significant pulmonary regurgitation, prolonged QRS duration over 180 ms on resting electrocardiogram, abnormal signal-averaged electrocardiogram, and longer duration of follow-up. At least 15% of patients with repaired tetralogy of Fallot undergo reoperation for residual defects or late pulmonary valve regurgitation. Ambulatory electrocardiographic monitoring and exercise testing are excellent diagnostic tools to demonstrate sustained VT as well as significant atrial and ventricular arrhythmias. Electrophysiologic studies are indicated for patients with symptoms of palpitations, syncope or cardiac arrest, sustained wide-QRS tachycardia, or QRS prolongation > 180 ms. Sustained VT may be ablated preoperatively; should catheter ablation fail, direct endocardial resection and cryoablation may be performed intraoperatively. We and others have repaired residual hemodynamic abnormalities in the adult patient with tetralogy of Fallot concomitantly with resection and cryoablation of the tachycardia circuit. This oftentimes eliminates the need for antiarrhythmic drugs or an implanted defibrillator. Preoperative and intraoperative mapping of tachycardia will demonstrate the common sites of arrhythmia origin that are related to the ventriculotomy, outflow tract patch, and perimeter of the ventricular septal defect. Postoperative ventricular stimulation is indicated to determine efficacy. Defibrillator implantation is performed if sustained VT remains inducible. Successful surgical treatment of VT in this setting ranges from 50% to 70%. Reasons for decreased success for surgical therapy of VT following repair of congenital heart disease may be due to inadequate mapping, perhaps related to deep intramural origin with late activation of the endocardial surface, as well as the limited ability to safely resect significant amounts of ventricular myocardium.

In rare cases, patients with congenital heart disease may have sustained VT before primary surgical repair. Under these circumstances, preoperative electrophysiologic mapping can successfully localize the arrhythmia source, which may be associated with a hemodynamic jet lesion. We have successfully resected such lesions in two young patients undergoing VSD closure. Large white plaque lesions noted opposite to the VSD jet were resected and cryoablated. VT associated with dilated nonischemic cardiomyopathy may be approached surgically with a decrease in frequency of recurrences, as reported in older patients; most patients undergoing VT surgery also receive implanted defibrillators.

VT may be secondary to ion channelopathies including long QT syndrome, and catecholaminergic VT associated with disorders ofryanodine receptors or calsequestrin. Severe ventricular arrhythmia storms may present in infancy, and such patients have an increased incidence of “double hits” for gene disorders. The frequency of electrical storms can be substantially reduced by adjunctive therapy using left cervical sympathectomy. Surgical sympathetic denervation is guided by video-assisted thoracotomy (VATS) techniques, which identify the thoracic ganglion allowing partial resection. We have successfully used bedside anesthetic nerve block of the cervical ganglion prior to proceeding with surgical sympathectomy in such an infant.

**OPERATIVE TECHNIQUES SPECIFIC TO CONGENITAL HEART DISEASE**

**Techniques of Resternotomy and Cannulation**

Eighty-three percent of our patient population required resternotomy. Since our unwanted cavitary entry rate is low, we describe our techniques for resternotomy. While femoral cannulation has long been employed for emergency or prophylactic cardiopulmonary bypass in difficult cases, recent publications have offered axillary cannulation, especially for cases involving aortic ascending aneurysms or sternal adherence of cardiac chambers in which there is a high probability of myocardial injury during resternotomy. The incision and dissection of the axillary artery in preparation for arterial cannulation are shown in Figure 105.6A. The dissection is performed
in the deltopectoral groove (Fig. 105.6B). The axillary artery and the brachial plexus cords are carefully dissected; proximal and distal arterial control are easily achieved. After systemic anticoagulation (heparin), a polytetrafluoroethylene (PTFE) graft of appropriate size is anastomosed end-to-side to the axillary artery (Fig. 105.6C). An arterial cannula, usually a femoral cannula, is connected to the graft in preparation for cardiopulmonary bypass. This method allows continuous cardiopulmonary bypass without direct ascending aortic recannulation. Some surgeons prefer this technique when the aortic arch requires repair or replacement since the cannulation site is distant from the operative exposure. Furthermore, regional cerebral perfusion can be performed using this technique.

There are many options for effective and safe resternotomy. Some surgeons employ self-retaining internal mammary artery retractors that lift the sternum away from the mediastinal structures, thereby facilitating the dissection (Fig. 105.7A). The lower sternal exposure is initiated by scissors dissection where a plane can be developed (Fig. 105.7B). The heart can usually be identified by its contractile motion and the sternum by its firm osseous nature. The technical challenge is to identify the appropriate space between them. Once this is determined, the surgeon may elect to use blunt and electrocautery dissection alternately by creating fenestrated adhesive tissue bands. These can then be lysed by electrocautery all the time directly visualizing the beating heart and the extent of the dissection. A superiorly advancing “delta” dissection plane is created and resternotomy can proceed using scissors, electrocautery, and a standard sternal saw as necessary for a safe mediastinal reentry. Precautionary measures are instituted and include presternotomy defibrillation pads, preference for scissors dissection in the event that electrocautery causes premature ventricular contractions or an episode of ventricular fibrillation, and preference for scissors dissection for aortic adherence to the underside of the sternum. After safe sternotomy, standard aortobicaval cannulation techniques are performed.

**Fontan Conversion**

A unique subset of patients are those patients with a functionally univentricular heart who have had a prior atrio pulmonary Fontan procedure. These patients can develop right atrial dilatation, atrial tachycardia, and AF. This results in hemodynamic compromise and progressive heart failure symptoms. Dr. Hillel Laks reported an experience with three patients with atrio pulmonary connection who developed late arrhythmias and atrial thrombus. These three patients were treated with surgical conversion of the atrio pulmonary connection to a lateral tunnel-type Fontan. Our series at Children’s Memorial Hospital began in 1994. We have now performed 136 Fontan conversions. Our primary contribution has been the addition of arrhythmia surgery, consisting of either a right-sided

World J Pediatr Congen Heart Surg 2013;4:85-97.)

maze or biatrial maze. We have also used an extracardiac Fontan rather than the lateral tunnel type of connection. The majority of these patients had a diagnosis of either tricuspid atresia or double-inlet left ventricle.

The primary steps of the Fontan conversion procedure are as follows:

1. After placing the patient on cardiopulmonary bypass (Fig. 105.8), the IVC is transected from its entrance into the right atrium and a No. 24 mm PTFE tube graft is sutured to the IVC.

2. Cardioplegia is administered and the majority of the enlarged right atrium is excised.

3. An atrial septal defect is created for the purpose of draining the coronary sinus blood to the left atrium.

4. Right maze or right and left-sided maze are performed with cryoablation lesions as previously illustrated in Figures 105.2, 105.3, and 105.5.

5. The right atrial incision is closed and the cross-clamp is released.

6. Bidirectional superior cavopulmonary anastomosis is created.

7. PTFE tube graft is beveled and anastomosed to the undersurface of the pulmonary artery.

8. Epicardial dual chamber atrial anti-tachycardia pacemaker is placed.

The completed Fontan conversion procedure is illustrated in Figure 105.9.

From 1994 to 2011, 136 patients have undergone the Fontan conversion with arrhythmia surgery. The mean age at the time of operation was 23 years. Operative mortality was 2 of 136 (1.5%). The mean age at the original Fontan procedure was 7 years. The mean interval from original Fontan procedure to Fontan conversion was 16 years. At 10 years following Fontan conversion, 85% of patients are alive and the freedom from arrhythmia recurrence is also 85%. An analysis of the first 111 patients demonstrated the following risk factors for death or transplant: protein-losing enteropathy, CPB time >4 hours, preexisting moderate-to-severe AV valve insufficiency, and right or ambiguous ventricle.

There are anatomic variations of the Fontan operation that have proven to be a challenge for Fontan conversion and arrhythmia treatment. The following sections describe the conditions that may be encountered that will require special surgical management for an effective arrhythmia ablation procedure. Figure 105.8 shows the cannulation for Fontan conversion. Occasionally, a right atrial clot, which is associated with low cardiac output, can be found in Fontan conversion patients. The conduct of the dissection becomes complicated since oftentimes cardiopulmonary bypass will be required before the caval veins are cannulated. Figure 105.10 shows venous catheter placement away from the atrial clot, which can be identified by epicardial or transesophageal echocardiography, for temporary cardiopulmonary bypass. This maneuver avoids the possibility of clot embolization of the venous catheter resulting in ineffective venous drainage.

Takedown of Right Atrial-to-Right Ventricular Björk-Fontan Modifications

The Björk-Fontan modification either with or without a valve was designed to take advantage of a small but contractile right ventricle. The natural history of this operation, however, resulted in right atrial enlargement and atrial arrhythmias. Often times, the small right ventricle has grown

Evolving anatomic and electrophysiologic considerations associated with Fontan conversion. Semin Thorac Cardiovasc Surg Pediatr Card Surg Annu 2007;10:136-145.)
during the period of somatic growth. During surgical conversion of a Bjork–Fontan modification to a total cavopulmonary artery connection, the dilemma arises as to the management of the right ventricle.

Disconnecting the main pulmonary artery and leaving the right ventricle without an egress of blood flow has the potential for right ventricular dilatation and leftward interventricular septal deviation caused by accumulation of thebesian drainage. Therefore, the surgical considerations en route to total cavopulmonary artery connections are (1) takedown of the Bjork–Fontan anastomosis and (2) management of the right ventricle.

Patients without a bioprosthetic valve interposition graft may have a communication formed by a posterior reversed right atrial flap and an anterior prostatic patch, which forms the right atrial to right ventricular connection. Surgical takedown involves careful dissection of the right AV groove which facilitates right atrial appendage amputation, right atrial wall reduction, epicardial pacemaker lead placement, and adequate right ventricular wall patch closure. Care is taken to avoid injury to the right coronary artery (Figure 105.11A). We have preserved the right ventricular to main pulmonary artery connection allowing egress of thebesian blood flow into the pulmonary arteries. Right ventricular pressure is low under these circumstances because of decreased right ventricular preload and does not affect the nonpulsatile blood flow established by the TCPC extracardiac connection. In most cases, the pulmonary valve is competent. Figure 105.11B shows a right ventricular patch and right atrial closure in association with the extracardiac TCPC.

**RIGHT VENTRICULAR HYPERTENSION AND TRICUSPID REGURGITATION AFTER ATRIOPULMONARY FONTAN FOR PULMONARY ATRESIA AND INTACT VENTRICULAR SEPTUM**

Patients with pulmonary atresia and intact ventricular septum can present with a small right ventricle necessitating an eventual Fontan operation. In the early experience with this operation, the small tricuspid valve was intentionally made incompetent. Following atropulmonary repair, the right ventricle enlarges over time, with marked hypertrophy and suprasystemic right ventricular pressure since there is no forward flow. Consequently, significant tricuspid regurgitation occurs when the tricuspid valve is not competent. In the majority of patients with pulmonary atresia and intact ventricular septum, a fenestration is placed in the extracardiac tunnel to allow bidirectional shunting at the atrial level, thereby maintaining oxygenation during the period of transition to full extracardiac connection. This fenestration is closed once the patient is able to support their own oxygenation. Following the fenestration closure, right ventricular pressure increases, and tricuspid regurgitation may further worsen. Therefore, during the period of transition, tricuspid regurgitation may be a significant issue.

Figure 105.11B shows a right ventricular patch and right atrial closure in association with the extracardiac TCPC.
regurgitation results in marked right atrial dilatation and hypertension. If an extracardiac TCPC is performed without addressing the regurgitant tricuspid valve, increased common atrial pressure can cause compromise of the Fontan circulation. After performing the modified right-sided maze procedure, we isolated the tricuspid valve with a fenestrated (8 mm) Gore-Tex patch, which restricts blood flow into the right ventricle, and allows blood egress from the ventricle into the common atrium (Fig. 105.12). By unloading the right ventricular volume, RV pressure is significantly reduced without impacting the common atrial pressure.

**Takedown of Atrioventricular Valve Isolation Patch for Right-Sided maze Procedure**

After the initial successes with the Fontan procedure for tricuspid atresia, it was adapted to more complex anatomy such as double-inlet ventricles, criss-cross hearts, and straddling AV valves. The smaller right-sided AV valve may have been isolated using a patch or the atrial baffle. Patching of this valve accomplished separation of the circulations by establishing an atrio-pulmonary connection together with an atrial septal defect closure. The relationship of the patch to the valve annulus and the coronary sinus has important anatomic and electrophysiologic considerations. The patch may have partitioned the coronary sinus on the ventricular side to avoid complete heart block. The anatomic right atrial isthmus, therefore, is partitioned to the pulmonary venous atrium. This is problematic since in the presence of right atrial macro-reentry tachycardia, the right-sided maze cannot be safely performed because the traditional landmarks, namely the coronary sinus and the tricuspid valve, are not exposed (Fig. 105.13A). The patch over the right-sided valve therefore must be removed to allow cryoablation according to the tenets of adequate landmark identification (Fig. 105.13B). This aforementioned partitioning and restriction of access to the right atrial isthmus accounts for failure of a transcatheter ablation and will contribute to failure of right atrial maze surgery without resection of the prosthetic patch material. If the tricuspid valve is competent by bul syringe testing, one can elect to allow the valve to function normally without valvar isolation. In the setting of valve incompetency, the valve can be again isolated using Gore-Tex patch anchored to the tricuspid valve leaflets near the annulus (Fig. 105.13C).
Some surgeons revised the atrio-pulmonary connection in an effort to create a wider atrio-pulmonary anastomosis by aligning the posterior pulmonary artery directly with a revised translocated atrial outflow. Anastomosing the confluence of pulmonary arteries to the dome of the right and left atrium was performed by resecting the superior atrial septum in a subset of patients. We have named this reconstruction the “dropped atrial septum technique.” Separation of the circulation was accomplished by a synthetic septal patch that in effect dropped the atrial septum into the left atrial dome, thereby aligning the pulmonary artery with the newly formed systemic atrium (Fig. 105.14). Important arrhythmia considerations include the potential for left ART based on the suture lines that were placed in the dome of the left atrium. Successful arrhythmia surgery will require left atrial suture line resection and biatrial maze procedure. Prevention of pulmonary vein stenosis may require atrial reconstruction with a Gore-Tex patch in the dome of the left atrium.

CONCLUSION
Arrhythmia surgery requires a collaborative approach between the surgical team and electrophysiologists, with careful preoperative evaluation to correctly characterize the arrhythmia substrate. Prior knowledge of specific surgical variations, familiarity with the principles of arrhythmia mechanisms, and understanding the tenets of surgical ablation are used to design and guide the appropriate therapy. These techniques have been particularly useful for the patients requiring Fontan conversion. Evolution in mapping systems, improved energy delivery technology, and prospective clinical studies can be expected to simplify the application of arrhythmia surgery to routine surgical interventions.

SURGICAL TRANSLOCATION OF ATRIAL SEPTAL ALIGNMENT
Some surgeons revised the atrio-pulmonary connection in an effort to create a wider atrio-pulmonary anastomosis by aligning the posterior pulmonary artery directly with a revised translocated atrial outflow. Anastomosing the confluence of pulmonary arteries to the dome of the right and left atrium was performed by resecting the superior atrial septum in a subset of patients. We have named this reconstruction the “dropped atrial septum technique.” Separation of the circulation was accomplished by a synthetic septal patch that in effect dropped the atrial septum into the left atrial dome, thereby aligning the pulmonary artery with the newly formed systemic atrium (Fig.105.14). Important arrhythmia considerations include the potential for left ART based on the suture lines that were placed in the dome of the left atrium. Successful arrhythmia surgery will require left atrial suture line resection and biatrial

maze procedure. Prevention of pulmonary vein stenosis may require atrial reconstruction with a Gore-Tex patch in the dome of the left atrium.

CONCLUSION
Arrhythmia surgery requires a collaborative approach between the surgical team and electrophysiologists, with careful preoperative evaluation to correctly characterize the arrhythmia substrate. Prior knowledge of specific surgical variations, familiarity with the principles of arrhythmia mechanisms, and understanding the tenets of surgical ablation are used to design and guide the appropriate therapy. These techniques have been particularly useful for the patients requiring Fontan conversion. Evolution in mapping systems, improved energy delivery technology, and prospective clinical studies can be expected to simplify the application of arrhythmia surgery to routine surgical interventions.

taken down, a significant moiety was created which required attention lest pulmonary venous obstruc-
tion be created. (Reproduced with permission from Mavroudis C, Backer CL, Deal BJ, et al. Evolving
Fig. 105.14. Right atrial view of atropulmonary Fontan performed by moving the atrial septum posteri-
-orly, which realigned the outflow of the right atrium to conform to the more posterior main pulmonary
artery. This "dropped atrial septum" required a suture line in the left atrium, which caused scarring and
an area of slow conduction leading to atrial reentry tachycardia. In addition, when this anastomosis was
taken down, a significant moiety was created which required attention lest pulmonary venous obstruction be created. (Reproduced with permission from Mavroudis C, Backer CL, Deal BJ, et al. Evolving anatomic and electrophysiologic considerations associated with Fontan conversion. Semin Thorac Cardiovasc Surg Pediatr Card Surg Annu 2007;136-145.)

In this chapter Dr. Mavroudis and his associates have given an excellent outline of issues regarding arrhythmia surgery in patients with congenital heart disease. In the majority of cases of accessory AV pathways or AV nodal reentrant tachycardias, surgical intervention is not required, as most of these patients may be dealt with using ablation techniques in the cardiac catheterization laboratory. It is, however, imperative for surgeons to understand the anatomy related to these arrhythmias in certain cases where access is limited and surgical intervention may still be required on occasion. It should be noted that most of the ablation techniques being used today rely on earlier studies by surgeons who initially ablated these bypass tracts surgically and identified the basic anatomy and location, which could then subsequently be dealt with interventional transcatheter ablation techniques.

Dr. Mavroudis and his associates have clearly demonstrated that patients with the Fontan circulation who have inefficient venous pathways with areas of stasis and associated arrhythmias and ventricular dysfunction can be effectively treated with Fontan conversion and arrhythmia surgery with a marked improvement in exercise performance and clinical status. These results confirm the concept that the Fontan circulation should be made as hemodynamically efficient as possible, which lends support to the total cavopulmonary connection and extracardiac conduit Fontan modifications that are now the most popular techniques for Fontan completion. The single-ventricle Fontan physiology creates a situation of relatively low cardiac output, and therefore, anything that can be done to maximize the cardiac output and maintain ventricular performance should result in improved long-term outcomes.

It is unknown whether the newest modifications to the Fontan operation (such as the extracardiac conduit), which have the potential of decreasing the number of atrial suture lines, will in fact decrease the risk of late arrhythmias. The follow-up for the extracardiac conduit modification is not yet long enough on average to determine whether the incidence of late arrhythmias will be significantly decreased with this technique. There are encouraging early reports of a lower incidence of arrhythmias at 5 to 8 years of follow-up; however, because the majority of atrial arrhythmias do not occur until 10 years or later after the Fontan operation, the overall effect is still unknown. There may well be anatomic substrates for arrhythmias in the single-ventricle population that will make patients at risk for late arrhythmias regardless of the type of Fontan connection performed. In many cases, the need for atrial septectomy as a first-stage operation in association with other reconstructive procedures means that many patients will have atrial suture lines regardless

(continued)
of the type of completion Fontan. Many patients late after the Fontan operation will have relative diastolic dysfunction of the single ventricle. Diastolic dysfunction has been associated with atrial arrhythmias in normal hearts as patients age and this same phenomenon may lead to the incidence of arrhythmias, which has been seen even in patients with the extra cardiac conduit Fontan that is not associated with elevated atrial pressures. Thus, the technique of Fontan reconstruction may be less important in terms of late development of arrhythmias than the underlying substrate of the ventricular performance.

The majority of Fontan revision procedures that have been performed in most centers have converted an old-style atrio-pulmonary Fontan connection with very dilated atrial chambers and thick atrial walls to the more hemodynamic extracardiac Fontan. There will probably be an increasing number of lateral tunnel Fontan operations that develop enough dilation of the atrial pathway to require conversion in the future, although the incidence of this phenomenon is not yet clearly determined. It is likely, however, that an increasing number of patients will be referred for arrhythmia modification and conversion as the very large population of children and young adults with the Fontan circulation age. The majority of those Fontan patients who have had the procedure for hypoplastic left heart syndrome are now just entering their preteenage years. These patients may represent an increasing challenge for pediatric cardiac surgeons as they develop potential complications of Fontan physiology as they age into adulthood. Surprisingly, even after many years of follow-up, only a relatively small percentage of Fontan patients have required cardiac transplantation, as nicely demonstrated by Dr. Mavroudis and his colleagues. The primary goal with staged surgical reconstruction in single-ventricle physiology is to maintain ventricular function as much as possible to delay the need for cardiac replacement.

The increasing need for surgical arrhythmia ablation in adults with congenital heart disease has made it imperative that congenital heart surgeons learn these techniques. Our own lesser experience with ablative surgery for arrhythmias and Fontan conversion mirrors Dr. Mavroudis’ results. Despite the complexity of the operations, which are often quite prolonged and difficult, the results have been gratifying. Most patients achieve a significant improvement in exercise performance and control of arrhythmias, which dramatically improves their quality of life.

TLS
INTRODUCTION

Mechanical circulatory support (MCS) in children is used for both profound respiratory and circulatory failure. Occasionally, these conditions coexist in the same patient. Extracorporeal membrane oxygenation (ECMO) has been relatively commonly used in neonates since the initial successful use in the mid-1970s. Indications include persistent pulmonary hypertension related to meconium aspiration, sepsis, idiopathic causes, and congenital diaphragmatic hernia. As results with this population improved, the use of ECMO was expanded to a variety of causes of respiratory and circulatory failure in other infants and children.

End-stage heart failure is a growing problem in the pediatric population in patients with primary cardiomyopathies and the increasing number who are surviving with repaired or palliated congenital heart defects. These patients are conventionally managed with a combination of oral and intravenous medications. When these fail, MCS is indicated. Particularly in small patients, ECMO has been historically used for this purpose. In adults, ventricular assist devices (VADs) have become the standard of care. There are a variety of devices that are approved by the U.S. Food and Drug Administration (FDA) for both short- and long-term support of these patients. Over the past several years, improvements in technology have now made VADs available to infants and children. These devices may be indicated as a bridge to recovery of the native heart function, or, more commonly in children, as a bridge to transplant. At the current time, there are devices in clinical use or being developed that will further improve the care and outcomes of these patients. This chapter will focus on the use of ECMO and VADs in children.

RESPIRATORY AND HEART FAILURE IN PEDIATRIC PATIENTS

Profound respiratory failure may occur in infants in children due to a variety of etiologies including those mentioned above as well as other infectious or inflammatory causes. In a minority of patients, conventional medical therapy including inhaled nitric oxide and alternative ventilation strategies may be inadequate to sustain adequate gas exchange. Severe respiratory failure in the neonate may precipitate pulmonary hypertension, shock, and circulatory collapse.

In contrast to adults, heart failure is relatively uncommon in pediatric patients. As in adults, the ultimate therapy for pediatric patients with end-stage heart failure is cardiac transplantation. Worldwide, 1,500 to 2,200 children are listed for heart transplant and each year 347 to 396 are transplanted. Congenital heart disease now surpasses primary cardiomyopathy as the most common indication for heart transplant in children. Since there is a growing number of children with successfully repaired or palliated congenital heart defects, one could anticipate that the number of listed patients and their waitlist times will increase. An important subset of this population is children with a diagnosis of hypoplastic left heart syndrome or related lesions. Results of conventional staged palliative surgery for these patients are improving, leading to a larger number of children with this diagnosis surviving. A number of these patients will experience failure of the single-ventricle circulation at various stages of palliation, including after the Fontan procedure. As a result, larger numbers of these patients will be evaluated for transplant. Compared with adults, the waitlist times for children are, on average, longer. Waitlist mortality is also higher in pediatric patients compared with adults with a threefold increase in the death rate on the waitlist that is essentially unchanged over the last decade. If medical therapy for advanced heart failure fails, some children will progress to the need for MCS. In the most recent era, the percentage of children supported with a VAD at the time of transplant was 13%, which has progressively increased over time.

RATIONALE AND INDICATIONS FOR THE USE OF EXTRACORPOREAL LIFE SUPPORT

Severe respiratory failure may become manifest by inadequate gas exchange despite maximal medical therapy, or excessive and toxic ventilator support being required to maintain such gas exchange. In such cases, ECMO is indicated to sustain life and allow time for lung recovery. Most recently, ECMO has been used successfully to bridge children with end-stage lung disease to lung transplantation.

End-stage heart failure may become manifest as refractory or unmanageable symptoms on conventional medications or, in babies, by poor growth, difficulty feeding, and failure to thrive. When more advanced, function of other organs such as the kidneys may become impaired. If these conditions do not improve with intravenous inotropes, MCS is indicated. In some children, end-stage heart failure is treated in part with tracheal intubation, sedation, and mechanical ventilation. This may reduce metabolic demand and oxygen consumption sufficiently to make the heart failure symptoms more manageable. However, remaining intubated and confined to bed has many risks. In adults, the use of VADs has allowed patients to improve from a metabolic, end-organ function, and nutritional standpoint. They can be extubated, become ambulatory, and even be discharged home as they await transplant. In many cases, this therapy has allowed patients who otherwise would have died to survive to transplant, and in others it has allowed them to become better transplant candidates. These same benefits can now be realized in children.

MCS may be indicated to treat postcardiotomy failure, acute cardiomyopathy, chronic cardiomyopathy, or failed corrective or palliative surgery for congenital heart disease. The indication, as well as
the intention to use MCS as a bridge to recovery, a bridge to transplant, or permanent (destination) therapy, has implications for the type of support chosen, the technical details of implementation, and the expected results and risks. Importantly, whenever the use of ECMO or VAD support is contemplated, careful thought should go into the eventual outcome. If a reversible cause of the underlying problem is unlikely, or if the patient is not a candidate for heart or lung transplant, MCS may be contraindicated.

**EXTRACORPOREAL MEMBRANE OXYGENATION**

ECMO systems include a blood pump, an artificial lung (oxygenator), tubing, and monitoring equipment (Fig. 106.1). ECMO support is generally established by inserting relatively large-bore arterial and venous cannulae in peripheral vessels. ECMO may be venovenous (VV), in which case drainage and return of blood are both from the venous side of the circulation, or venoarterial (VA), in which case blood is withdrawn from the venous side and returned to the arterial circulation. VV ECMO is indicated for purely respiratory support and may be sufficient if cardiac function is relatively preserved and the patient is not in profound shock or on excessive inotropic or vasopressor support. In most cases, a specially designed double-lumen cannula, similar to a dialysis catheter, is used and placed through the right internal jugular vein to the right atrium (Fig. 106.2). An alternative is drainage from one cannula in the femoral vein and return via a different cannula in the internal jugular vein.

In infants and smaller children, the right common carotid artery and internal jugular vein have traditionally been used as these vessels are usually easily accessible and amenable to rapid exposure. These are typically accessed by a transverse skin incision on the right side of the neck approximately one to two fingerbreadths above the clavicle depending on the size of the child. The subcutaneous tissue and platysma are incised with the cautery. The medial border of the sternocleidomastoid muscle is mobilized. The right common carotid artery and internal jugular vein are isolated. Meticulous hemostasis is maintained since the patient will be anticoagulated. At this point, we administer 50 U/kg of intravenous heparin and allow 2 to 3 minutes for circulation. If VA ECMO is used, the carotid artery is cannulated first. Care is taken to avoid the vagus nerve, which is adjacent to the artery. A silk ligature is used to ligate the more cephalad portion of the exposed vessel. The ligature is clipped to the drape such that the vessel is placed on some traction. A loose ligature is placed around the artery proximally, and a fine vascular or bulldog clamp is used to temporarily occlude the vessel. Using a No. 11 blade, a transverse arteriotomy is made to open the artery. The appropriate-sized cannula, usually 8F or 10F for a neonate or small infant, is inserted to a depth of 2 to 3 cm and secured by tying the proximal ligature around the artery and cannula. We tie the ligature over a small piece of vessel loop to prevent damage to the vessel wall at decannulation. The more distal ligature is then tied around the cannula for security. The right internal jugular vein is cannulated in similar manner. Occasionally, a branch such as the facial vein requires ligation and division. The venous cannula, which has more side holes, is usually larger than the arterial by one or two sizes and is inserted to a greater depth such that the tip is well into the right atrium (Fig. 106.3). Both are then secured to the skin with two additional sutures each. The incision is then closed around the cannulae either with a simple running monofilament suture or with a layer of absorbable suture to reapproximate the platysma layer followed by the skin closure. Ideally, a small skin bridge
is left between the arterial and venous cannulae.

Depending on the center and clinical circumstances, when the child is weaned from ECMO support and the cannulae are removed, the vessels may remain permanently ligated or be repaired. It is unclear whether one approach is superior to the other. If the vessels are repaired, the ligatures must be removed carefully while maintaining proximal and distal control with a combination of vessel loops or fine vascular clamps. A small amount of back-bleeding is allowed to assess vessel patency and expel any debris or thrombus. The vessels are then repaired with fine, typically 7-0, monofilament sutures. Either a running or interrupted technique can be used.

In older children, there may be reluctance to ligate the carotid artery, although this has been done successfully in several centers. Other options for cannulation include the femoral, iliac, and axillary vessels. Like the cervical vessels, the femoral artery and vein are relatively superficial and amenable to reasonably rapid exposure by cutdown. Alternatively, if the child is large enough, with currently available cannulae, these vessels can be accessed percutaneously. The lower extremities are more susceptible to ischemic complications related to cannulation as collateral circulation is not as robust as in the brain. This can be treated with the placement of a more distal arterial catheter, which is connected to the arterial limb of the ECMO circuit. In small children, it may be difficult to get cannulae of adequate size to achieve full flow in the femoral vessels. In these cases, the external iliac vessels may be used. These vessels are accessed by performing an extraperitoneal dissection via an incision above the inguinal ligament. It is generally not safe to access these vessels percutaneously. If the axillary vessels are used, which is unusual, they can be accessed via an infracavicular incision. The brachial plexus is at risk of injury from this exposure. Most commonly, this incision is used for arterial access only. A vascular graft is usually sewn end-to-side to the artery and the cannula is placed in the graft rather than cannulating the artery directly. The femoral, iliac, and axillary vessels are not permanently ligated after discontinuing ECMO.

**PREPARATION FOR VENTRICULAR ASSIST DEVICE IMPLANTATION**

The placement of any VAD requires meticulous preparation. The appropriate device should be selected based on the patient size and indication as discussed above. The patient should be free from any active infection. Neurologic status should be carefully assessed prior to surgery as an acute intracranial ischemic or hemorrhagic process represents a contraindication. The presence of any intracardiac shunting should be excluded by echocardiogram. If a shunt such as a PFO is present, it should be closed at the time of VAD implantation. The patient should be rendered as metabolically stable as possible, although not infrequently conditions such as metabolic acidosis and renal insufficiency represent part of the clinical syndrome that makes MCS necessary and will improve after successful VAD placement. Any preexisting coagulopathy should be reversed to the extent possible prior to surgery.

**TEMPORARY VENTRICULAR ASSIST DEVICES**

Although ECMO can be used for cardiovascular support and has some advantages such as the potential for rapid institution (which is useful in the setting of cardiopulmonary resuscitation) almost anywhere in the hospital and its combination of
cardiac and respiratory support, these are balanced against many negative features that make it suboptimal as a durable form of circulatory support. These include the relatively unstable cannulation, which has traditionally required the patient to be fairly immobilized, nonambulatory, and generally confined to a mechanical ventilation, the relatively large artificial blood contacting surface that results in hemolysis and platelet destruction, ongoing transfusion requirements and coagulopathy, and potentially inadequate decompression of the left ventricle leading to ongoing left atrial hypertension, pulmonary edema, and in the worst cases, pulmonary hemorrhage. In addition, inadequate unloading can impair any potential recovery of the compromised ventricle. In these situations, additional steps must be taken to decompress the left side of the circulation. This can be accomplished in the cardiac catheterization lab with atrial septostomy or septoplasty, or by the surgical placement of a left atrial or ventricular vent that is connected to the venous limb of the ECMO circuit. All of these factors make ECMO suitable for short-term use, but very suboptimal for longer term use.

Better temporary support options may include centrifugal pump-based VAD systems. These systems, which employ a centrifugal blood pump, tubing, and cannulae similar to those used for cardio-pulmonary bypass (CPB), are designed for short-term use, can be customized to provide single or biventricular support, and can be adapted to fit a variety of different sized patients, and are relatively inexpensive. Temporary cannulation is employed, which is not typically stable enough to allow much patient movement. Frequently, these types of systems are placed with only temporary sternal closure in the postcardiotomy support setting, which limits the ability to mobilize the patient. Until recently, pediatric-specific pumps were not available, leading to potential problems with lower pump speeds predisposing to thrombosis and thromboembolism in this group. Recently, the Levotronix Corporation (Waltham, MA) developed a smaller version of their magnetically levitated centrifugal blood pump, the CentriMag, called the PediMag that obtained 510k clearance from the FDA in 2009 for short-term use as a pediatric blood pump (Fig. 106.4). This pump has a priming volume of only 14 ml and 1/4 inch connections, and a maximum flow of 1.5 l/min making it potentially useful as a temporary VAD for infants and small children. The PediMag has been successfully used as a bridge to transplant in an infant. Its use may increase as further experience with it is gained.

Cannulation for LVAD support is usually accomplished with direct aortic cannulation for outflow and cannulation of either the left atrium or the left ventricular (LV) apex for inflow. Apical cannulation provides more complete ventricular decompression, whereas atrial cannulation is more easily accomplished but may risk ventricular thrombus formation due to stagnant flow. RVAD support is generally accomplished by cannulation of the right atrium for inflow and the pulmonary artery for outflow. All cannulae should be secured with two concentric purse-string sutures, which are securely tied to the cannulae themselves to maximize hemostasis and immobilization. Cannulae may be selected that can be tunneled through the body wall like a chest tube to permit chest closure during the period of support. When these devices are used for postcardiotomy support with anticipated ventricular recovery, weaning at the bedside can be accomplished reasonably easily, and the temporary nature of the cannula placement facilitates device removal if sufficient recovery occurs.

**PARACORPOREAL DEVICES**

The most commonly used VADs in children today are so-called first-generation paracorporeal devices. These are displacement pumps that function much like the native ventricle with inflow and outflow valves and a pumping chamber that is pneumatically driven. These devices can be used for single or biventricular support, but employ cannulation that is stable and allows for patient extubation, mobilization, and rehabilitation. In older children, adult devices such as the Thoratec paracorporeal VAD (PVAD; Thoratec Corporation, Pleasanton, CA) have been used. Unfortunately, the blood pump and cannulae for the device are large, which leads to potential problems with thromboembolism, excessive stroke volume, low pump flow rates, and difficulty with cannula positioning. From a practical standpoint, these systems cannot be used in children under 20 kg, and even in that size range, the use of the pump is problematic.

The most important current manufacturer involved in pediatric VAD development is Berlin Heart GmbH (Berlin, Germany). In 1989, they modified an adult device in order to allow VAD placement in small children (Fig. 106.5). The Berlin Heart EXCOR Pediatric VAD is produced in a variety of sizes, with an applicable size range from 3 kg to adult size. For approximately a decade, the use of the device was confined to Western Europe. After the first usage of the device in the United States was reported in 2005, its use spread to multiple centers in North America, all under so-called compassionate use protocols. The positive experience at implanting centers led to the initiation in 2007 of a large multicenter trial, constructed to potentially permit formal FDA approval of the device. This trial has now been completed and has resulted in the recent approval of the device in the United States.

Implantation of all the paracorporeal devices is similar. For LVAD support, apical cannulation for device inflow is preferred as discussed above. Using normothermic or mildly hypothermic CPB, the pericardium is opened and the apex of the heart is identified. A skin exit site is selected for the inflow cannula in the left upper quadrant below the costal margin on a line corresponding to the location of the apex. A disc of skin slightly smaller than the diameter of

---

Fig. 106.4. A CentriMag console and pump and PediMag pump are shown. The PediMag is similar in design to the CentriMag and uses the same console but is smaller and has 1/4 inch connections.
the cannula is excised, and an extraperitoneal tunnel is created into the pericardium. Incision of the pericardium out toward the apex and sometimes partial takedown of the anterior diaphragmatic attachments facilitates this maneuver. Care must be taken to maintain hemostasis. The tunnel can be maintained by passing a chest tube or umbilical tape through it. The apex of the heart is mobilized and elevated into the field by placing sponges in the pericardium behind the heart. We prefer CO₂ insufflation of the operative field to assist with deairing of the heart. Particularly in the reoperative setting, it is important to establish hemostasis in the pericardial space prior to positioning of the apical cannula as this space will be inaccessible once the device is positioned. Depending on surgeon preference, an LV vent may or may not be used. Apical cannula placement can be accomplished with the heart beating, or with fibrillatory arrest. Once the heart is positioned, a core of apical LV muscle is removed at the intended site of cannula placement. In general, this should be at or just lateral to the apical dimple with enough of a margin between the ventriculotomy and left anterior descending coronary artery to permit suture placement. The ventricle should be inspected for thrombus, which should be removed if present. Any trabeculae that could interfere with inflow are excised. If an LV vent is not present, a cardiotomy suction catheter can be placed through the ventriculotomy. A series of 8 to 12 pledget-supported horizontal mattress sutures is then placed around the ventriculotomy. Relatively wide bites are taken through the ventricular muscle into the ventricle. If preferred, the suture may then be brought out through the epicardium near the edge of the ventriculotomy (Fig. 106.6). Once all of the sutures have been placed, they are brought out through the diaphragm and the inflow cannula. The sutures should be evenly spaced but should not have gaps between them. If the inflow cannula has a bevel, it should be positioned such that the bevel faces the septum. The cannula is placed into the LV apex until the flange is flush with the epicardium. The cannula should fit snugly into the ventriculotomy to optimize hemostasis. The sutures are tied. Depending on surgeon preference, a surgical sealant may be applied to the suture line but if used it is important to exclude this from the blood that is returned to the cardiotomy reservoir. It is our preference to then place a polytetrafluoroethylene (PTFE) membrane with a hole cut in the middle over the apical cannula such that the membrane covers the apex to prevent severe adherence to the pericardium and chest wall. We have found this helpful when explanting the device. The apical cannula is then passed through the previously created tunnel. Care must be taken to maintain its orientation and support the connection to the ventricle such that it is not disrupted. After passage through the tunnel, the apical cannula can be vented to the cardiotomy reservoir. The flange of the cannula should be flush with the diaphragm.

Attention is then turned to the placement of the outflow cannula. An exit site for this is selected which is typically more medial, often just to the right of the midline. The tunnel is created as described above. The cannula may be tunneled prior to connection to the aorta. This may be preferable in the case of the somewhat rigid Berlin Heart cannulae to avoid tension on the aortic connection with tunneling. A site for the outflow cannula placement on the aorta is selected. This is typically anterior or slightly offset rightward on the greater curve of the ascending aorta. It must be above the sinotubular junction but should also leave room distally for later aortic cannulation and transection for eventual heart transplant. The smaller Berlin Heart outflow cannulae have a tip beyond the sewing ring that is inserted into the lumen of the aorta when the sewing ring is approximated to the adventitia of the aorta. An aortotomy is made after the

**Fig. 106.5.** A 7-year-old patient with a Berlin Heart EXCOR pediatric left ventricular assist device (LVAD). The pump is connected to the heart by transcutaneous cannulae (inflow more lateral, outflow more medial) and to the system controller via a pneumatic driveline (connection just visible at far left).
application of a partial occlusion clamp to the aorta to isolate the selected site. If the aorta is difficult, cross-clamping with cardioplegic arrest can be performed, but this is avoided if possible, especially in the case of LVAD support alone as ischemia to the right ventricle is undesirable. A longitudinal incision is made in the aorta sufficient to match the size of the outflow cannula. In smaller children, it may be possible to secure the cannula with two concentric purse-string sutures, the ends of which are brought up through the sewing ring of the cannula. These are placed prior to the application of the partial clamp. The aortotomy is then made within the purse-strings after the clamp is applied and the cannula tip is introduced into the aorta as the purse-string sutures are tightened. Care must be taken to make the purse-strings large enough that the aortotomy can be made with an adequate margin of tissue around it. The sutures are secured and the cannula is deaired. In larger patients or if this technique is not selected, or in the case of a larger cannula, a series of interrupted polypropylene mattress sutures with or without pledgets is placed around the aortotomy and brought up through the sewing ring. The cannula is then lowered down to the aorta, the sutures are tied, and the cannula is deaired and clamped. Hemostasis is confirmed at the anastomosis. Some surgeons may prefer a running suture technique, but this is technically more difficult (Fig. 106.7). The Thoratec PVAD has an outflow cannula with a flexible vascular graft designed to be sewn to the aorta. In this case, the graft must be properly sized prior to anastomosis to the aorta, anticipating some lengthening when it is pressurized. A running suture is more suitable to this type of cannula.

Preparations are then made for connection of the pump. The pump should be previously primed on the back table by the perfusionists or nursing staff. The pump is connected to the cannulae after appropriate trimming, if necessary, of the cannulae to prevent kinking. Great care is taken to avoid the introduction of air during this process. Attention is then turned to deairing of the heart and pump. The Berlin Heart pump has a deairing nipple, which is accessed prior to connection of the pump when the pump is fully primed. In pumps with outflow cannulae that have vascular graft material, deairing can be facilitated with the placement of a needle in the graft. If left ventricular venting has been ongoing, it is discontinued at this time. The patient is placed in the Trendelenburg position and the lungs are ventilated. The heart is gently agitated as the heart is slowly filled. Transesophageal echocardiography is helpful in monitoring the amount of air in the heart. Once the pump has been fully deaired, the VAD is activated with single strokes from the controller or hand pump, depending on the device. The pump is observed for air. If air is not present the patient is weaned from CPB, then the VAD pumping is initiated at a conservative rate. Activating the VAD prior to weaning from CPB can lead to the entrainment of air in the heart. If LVAD support only is used, adequate support of native right ventricular function must be provided. We have found that a combination of epinephrine, milrinone, vasopressin, and inhaled nitric oxide to be useful. The pump, echocardiogram, and patient hemodynamics are observed and the VAD pumping rate is adjusted as necessary. Typically, the pump rate, positive (ejection) pressure, and negative (filling) pressure can be adjusted. The pump ejection pressure will typically need to be at least 80 to 100 mmHg higher than the patient’s systolic blood pressure. Only enough negative pressure to achieve adequate pump filling is used. Excessive pressures can contribute to hemolysis.

If biventricular support is required, another pump can be used as a right ventricular assist device (RVAD). The RVAD is typically placed with inflow from the right atrium and outflow to the main pulmonary artery. The right ventricle is more problematic to cannulate due to its geometry and highly trabeculated nature. Occasionally, if it is thought that RVAD support will only be required for a short time, a temporary centrifugal pump may be employed as described above. The use of such a pump facilitates RVAD removal and may simplify management. If longer term RVAD support is required, then a second Berlin Heart or similar pump is indicated. The outflow cannula is secured to the main pulmonary artery beyond the pulmonary valve in a manner similar to that described above for the aorta. The Berlin Heart atrial cannula is inserted through the free wall of the right atrium and secured either with purse-string sutures as described above for the aorta, or mattress pledget-supported sutures as described for LV apical cannulation or a combination of these techniques. In general, the RVAD flow should not exceed the LVAD flow. It is generally slightly lower to avoid pulmonary congestion. Importantly, if biventricular support is required, care must be taken to maintain adequate

---

skin bridges between all cannula exit sites to avoid necrosis and infection.

Bleeding may be an issue at the conclusion of these cases due to the degree of illness and preoperative coagulopathy in these patients. Aggressive early management of this coagulopathy helps to establish adequate hemostasis. Sometimes packing of the chest with temporary chest closure is useful. Adequate drainage to avoid pericardial tamponade, including a posterior pericardial drain, is useful. We have routinely tacked a PTFE membrane to the pericardial edges to prevent adhesions to the sternum and facilitate redo sternotomy.

**IMPLANTABLE DEVICES**

Further device development has led to the emergence of implantable VADs. These pumps are placed within the body and are connected to an external controller via a transcutaneous electrical driveline. The current versions are the second-generation axial flow pumps and the third-generation centrifugal pumps. Both types produce continuous rather than pulsatile flow. These devices are designed as LVADs so are generally not capable of biventricular support. Some reports of the use of these adult devices in children have appeared with mixed results. These include the VentAssist (Ventracor Limited, Chatswood, NSW, Australia), a centrifugal LVAD (which is no longer available), and the Thoratec HeartMate II, an axial flow device (Fig. 106.8). Because of the size of the implantable hardware, these devices can only be used in children with a body surface area of at least 1.2 to 1.4 m².

Most recently another adult device, the HVAD (HeartWare, Inc., Miami Lakes, FL), that has relatively recently been approved for use as a bridge to transplant in adults in the United States, has been successfully used in children. This device is an implantable centrifugal pump LVAD (Fig. 106.9). It is the smallest of the adult-implantable devices studied so far, and therefore may be more ideally suited for children, including those smaller than mentioned above. A German group has reported the successful use of this device to bridge children to transplant. It has also been used several times in the United States for this purpose, including a 10-year-old boy with dilated cardiomyopathy in our institution.

Although implantable devices are now commonly used in adults, since the pediatric market is substantially smaller and the process of developing such a device and bringing it to market is lengthy, cumbersome, and expensive, until recently there has been relatively little motivation for the development of such devices specifically for children. Several companies have now engaged in this challenge, however. An important example is Micromed Cardiovascular, Inc. (Houston, TX). This company produced the first VAD, and the only implantable device, approved for use in children in the United States. This device, the HeartAssist 5® (formerly called the DeBakeyVAD Child), received FDA approval as a humanitarian device exemption in early 2004. The approval was granted for patients between 0.7 and 1.5 m², between ages 5 and 16. The device is an axial flow pump similar to the HeartMate II and designed for LVAD usage only. After the initial U.S. implant in 2004, the device has not gained widespread acceptance predominantly because of thrombotic concerns, and very few additional reports of its usage have appeared in the literature.

Implantation of all of these LVADs is similar. The primary differences from paracorporeal device placement are that the pumps reside within the body and the electrical driveline is tunneled transcutaneously. For all but the HVAD, a preperitoneal pocket is created for the pump by dividing the anterior attachments of the left hemidiaphragm from the chest wall and dissecting posterior to the abdominal fascia. This can be done before initiating CPB. The driveline is tunneled from a preselected exit site in the right upper quadrant to this space. The electrical connection for the driveline is typically larger in diameter than the driveline itself, so we generally narrow the exit site with sutures after the driveline is passed and hemostasis is confirmed. For each device, there is an apical connector that is secured to the LV apex in much the same manner as described above for the paracorporeal VAD. The devices typically come with a coring tool that removes a round core of apical muscle. For the HVAD, the apical sewing ring is secured prior to coring. The pump is primed on the back table, and then connected to the apical attachment according to the manufacturers’ guidelines. The outflow graft is then connected to the aorta and to the pump. These outflow grafts comprise a vascular graft connected to an adapter that connects to the pump. An end-to-side anastomosis is made with a running polypropylene suture, again using a partial occlusion clamp just to the right of anterior on the proximal ascending aorta. The graft will stretch once pressurized so
it must be trimmed to the appropriate length prior to sewing the anastomosis. The proximal portion of the graft is protected with a semi-rigid outer sheath to prevent kinking. Deairing of the pump is facilitated by placing a needle in the outflow graft and then partially occluding the graft distal to the needle. The patient is weaned from CPB as described above with gradual increase of the pump speed.

**PEDIATRIC SPECIFIC ISSUES**

Despite the early stages of development of pediatric VADs, and, in fact, the failure of some to make it through the early clinical use phase successfully, it is still clear that these devices represent an improvement in support compared with ECMO. This observation is borne out in a study by Jeewa et al. in which these two forms of support were compared. Patients supported with VADs had improved waitlist mortality and hospital survival.

Perhaps the most vexing problem in the field of MCS, shared in all generations of devices, and patients of all ages and sizes, is the issue of arterial thromboembolism. This is especially true with events involving the central nervous system. Although such events may be reversible or only result in minor disability, in other circumstances the events may be devastating or even fatal. Despite multiple advances in VAD design, the problem persists to such an extent that all devices that might be used in children require intense anti-thrombotic therapy. This typically includes both anticoagulation with heparin or warfarin and anti-platelet medications. As an example, a protocol has been developed for use with the Berlin Heart and is employed by essentially all implant centers in some form. The protocol involves the introduction of unfractionated heparin within the first day after implantation, in the absence of ongoing bleeding. This is later converted to either low molecular weight heparin or a vitamin K antagonist and combined with anti-platelet medications, most commonly aspirin and dipyridamole. Despite the use of such strategies, strokes have been described in most published experienced, with rates typically in the range of 25% to 40%. Bleeding is also an issue and the transfusion requirement consequent in major bleeding is especially problematic for pretransplant VAD patients in that exposure to foreign HLA antigens increases the likelihood of the development of anti-HLA antibodies.

The most important current issue in pediatric VAD practice is the lack of an approved device with an acceptably low-risk profile and the versatility to provide durable support for the entire range of size and anatomic complexity. Although the Berlin Heart device has been used successfully in a wide range of patient sizes, there remain concerns about its risk profile and patients generally remain confined to the hospital after implantation.

Unique to pediatric VAD candidates is the issue of anatomic complexity related to congenital structural heart disease. This may be manifested in abnormalities of cardiac situs, in the case of dextrocardia or dextroversion of the cardiac apex. In other cases, the systemic ventricle may be a morphologic right ventricle, as in the case of a patient who has previously undergone an atrial switch operation for transposition of the great arteries, and this may require an alteration in VAD cannula shape or orientation (or both). Perhaps the most difficult patients are those with univentricular hearts in whom the power source for pulmonary blood flow is either the failing ventricle, or systemic venous pressure (either a superior cavopulmonary connection or total cavopulmonary connection). Conventional VAD configurations do not account for the variations in pulmonary blood flow in children with single-ventricle hearts, and consequently the experience with VAD support in these patients is very limited. A recent literature survey found only 10 single-ventricle patients implanted with VADs. Of the 10 patients reported, 6 went on to receive cardiac transplantation.

**FUTURE DIRECTIONS**

Initially, the expansion of the use of the Berlin Heart may result in slightly less favorable results as inexperienced centers learn to use the device. In the longer term, the overall outcomes should be improved, in part by reducing waiting list mortality. It may be speculated that VAD-supported patients might even become better transplant candidates with the opportunity for improved nutrition and rehabilitation. This phenomenon has been observed in adults. Furthermore, the urgency to accept a marginally suitable heart for a rapidly declining recipient may vanish, allowing optimization of patient–recipient matching.

Also on the near horizon is the initiation of the second phase of the National Heart Lung and Blood Institute (NHLBI)-sponsored trial, termed the Pumps for Kids, Infants, and Neonates (PumpKIN) Trial. For this trial, the NHLBI has awarded four contracts totaling over $23 million to begin preclinical testing of pediatric circulatory support devices. At time of this writing, a Data and Clinical Coordinating Center (DCCC) is being identified for the trial. After the DCCC is identified, it is anticipated that clinical trials of the two VAD devices in the trial will begin, possibly by 2013. The devices to be evaluated in the PumpKIN trial include two ECMO devices that will not be discussed further, and one VAD (Fig. 106.10) the Jarvik 2000 (Jarvik Heart, Inc., New York). The VAD is an implantable axial flow device, designed...
medications appear likely to provide more favorable risk–benefit profile than the traditionally used warfarin. Such agents may prove useful in MCS patients. Regardless of the specific advances in MCS that the future holds, it is clear that we are now much closer to our goal of durable mechanical support for children of all ages with a minimum of associated complications.

SUMMARY

Although pediatric MCS is an underdeveloped field, substantial progress has been made in recent years. For the first time, there is an approved VAD for pediatric patients of all ages and sizes in the United States. In the immediate future, a trial of a new implantable pediatric device will begin. With all of the activity in the field, and as more centers gain experience, VADs in pediatric patients will become more routine, expanding both their indications and applicability to increasing numbers of children with end-stage heart failure.

SUGGESTED READINGS

Mora O, Potapov EV, Redlin M, et al. First experiences with the HeartWare ventricular support.
This chapter summarizes the current state-of-the-art use of ECMO and assist device support in children with congenital heart disease. While ECMO has been the mainstay of support for both heart and lungs in children with ventricular failure or failed cardiac repair, the limitations of cannulation and the need for intense anti-coagulation with this therapy have limited its use to short-term support. It is difficult to maintain a patient on ECMO support for more than a few weeks as a bridge to cardiac transplantation. Thus, ECMO is rarely used as a sole bridge to transplantation therapy since the waiting times are now so long that it is unlikely that the patient can be supported solely with ECMO as a bridge to transplant.

Early in the use of ECMO for postoperative cardiac support and as a bridge to transplantation, the waiting times were short enough for young children such that ECMO could be used as the sole bridge; however, waiting times have continually increased for cardiac transplantation even in very small infants and children.

As noted in this chapter, there have been increasing reports of ECMO being used as a bridge to lung transplant in children. However, again the problems with this approach are that waiting times are so long for lung transplantation that ECMO is not a very effective bridge. In patients with purely respiratory issues, venovenous ECMO can be used as a bridge to transplant since it can be maintained for a longer period of time than venoarterial ECMO and patients can in fact even be ambulatory or even extubated with venovenous ECMO support for respiratory causes. Nevertheless, the relative lack of mobility and the instability of cannulation for venovenous ECMO for respiratory support continue to limit this technique and in most cases we would not consider using ECMO as a bridge to pulmonary transplantation.

Newer devices are being developed that can assist in oxygenation and ventricular support such as the Novalung Oxygenator that can be placed between the ventricle and atrium in such a way as to decompress the right ventricle in patients with severe pulmonary hypertension yet oxygenate the blood, but use the ventricle as the cardiac pump.

When ECMO is utilized it is generally preferable to repair the neck vessels at the time of decannulation. While long-term patency of the carotid artery has been demonstrated, the patency of the jugular vein is rarely accomplished long term, but repair of the vessels may at least permit recannulation if the patient deteriorates after ECMO decannulation via the same vessels. We have routinely repaired the ECMO vessels at the time of decannulation since the early 1980s and have had minimal complications of vascular disruption, hemorrhage, or pseudoaneurysm formation.

In the majority of circumstances today, ECMO is used only as a short-term bridge to cardiac recovery in patients following cardiac surgery or for resuscitation for cardiac events acutely in the postoperative period. When ECMO is used with little chance of cardiac recovery, the patient is now bridged with ECMO to implantation of a more permanent ventricular assist device such as the Excor Berlin Heart. If a patient does not recover cardiac function within 5 to 7 days of initiation of ECMO support, then bridging to more permanent support is indicated, generally as a bridge to cardiac transplantation. Some cases of recovery of ventricular function after implantation of ventricular assist devices have been observed, such that the devices can ultimately be removed after return of cardiac function. As noted by the authors of this chapter, implantation of assist devices permits patients to have better recovery of overall organ function and can result in mobilization with both pulmonary and systemic rehabilitation that can decrease the risk at the time of later cardiac transplantation.

As has been noted in the adult experience, ventricular assist devices are now commonly being used in pediatric patients as a bridge to cardiac transplantation such that at least 25% of patients...
undergoing transplants now have had a previously implanted assist device. I expect that the percentage will increase progressively as it has in the adult world such that the vast majority of patients will have assist devices as a bridge to cardiac transplant in the future as waiting times continue to lengthen.

The pediatric ventricular assist device market is somewhat limited and there have been few devices developed for our pediatric patient population. It is encouraging that device manufacturers are now looking to the pediatric market and developing newer axial-type flow devices. The PumpKIN trial that is currently being developed will help assess new devices for our patients for the future. Hopefully, these devices will become easier to implant and will have lower risks of thromboembolism and hemorrhage, which are currently the major problems with assist device use in children. As noted in the chapter, anti-coagulation is required for all of these devices and a risk of postoperative hemorrhage is significant even late after device implantation. In addition, thromboembolism is a recurring problem and the majority of patients will have some thromboembolic event with a device implanted for over 2 to 3 months. It is becoming important now for pediatric cardiac centers to have a well-established protocol for therapy of thromboembolism of patients on devices with very acute intervention and thrombolytic or thrombectomy catheter-based therapies for embolic strokes, which can improve the overall neurologic outcome of these patients.

The total artificial heart has now been developed for implantation in older children and adults and may have a particular applicability in patients after the Fontan operation. As noted by the authors, the patients with the Fontan circulation represent a particularly difficult subgroup for assist device implantation. It is unclear whether support of the right-sided circulation with pushing of blood through the lungs, or support of the left-sided circulation with pulling the blood through the lungs, is the most appropriate approach in any individual patient. Great interest is being shown now in developing assist devices for the venous side of the circulation in the Fontan situation, and implantable devices for optimizing pulmonary blood flow may appear in the near future. Until that time, the total artificial heart may be the most appropriate option as a bridge to transplant.
INTRODUCTION TO PACEMAKER THERAPY

HRS/American College of Cardiology Recommendations/Guidelines for Pacemaker Implantation

The clinical indications for pacemaker implantation in children, adolescents, and young adults with congenital heart disease (CHD) are summarized below.

Class I
1. Advanced second- or third-degree atrioventricular block (AVB) associated with symptomatic bradycardia, ventricular dysfunction, or low cardiac output.
2. Sinus node dysfunction (SND) with correlation of symptoms during age-inappropriate bradycardia.
3. Postoperative advanced second- or third-degree heart block that is not expected to resolve or that persists >7 days after cardiac surgery.
4. Congenital complete AVB with a wide ventricular escape rhythm, complex ventricular ectopy, or ventricular dysfunction.
5. Congenital complete AVB in an infant with an average rate of 55 bpm or less or a rate of 70 bpm or less in a patient with CHD.

Class IIa
1. CHD and sinus bradycardia for the prevention of recurrent episodic intra-atrial reentrant tachycardia (IART).
2. Congenital complete AVB beyond infancy with an average heart rate of <50 bpm, abrupt pauses in ventricular rate that are more than two to three times that of the sinus cycle length, or in patients with symptomatic bradycardia.
3. Sinus bradycardia in patients with complex CHD with a resting ventricular rate of <40 bpm or pauses of more than 3 seconds.
4. CHD and impaired hemodynamics due to sinus bradycardia or loss of atrioventricular (AV) synchrony.
5. Unexplained syncpe in a patient with prior congenital heart surgery complicated by transient complete heart block with residual fascicular block.

Class IIb
1. Transient postoperative complete AVB that reverts to sinus rhythm with residual fascicular block.
2. Congenital complete AVB in a patient with an acceptable rate, narrow QRS escape, and normal ventricular function.
3. Asymptomatic sinus bradycardia after biventricular repair of CHD with a resting heart rate <40 bpm or ventricular pauses of more than 3 seconds.

Class III
1. Not indicated for transient postoperative complete AVB.
2. Not indicated for asymptomatic bifascicular block after CHD surgery in the absence of prior transient AVB.
3. Not indicated for asymptomatic second-degree AVB type I.
4. Not indicated for asymptomatic sinus bradycardia with pauses <3 seconds and an average heart rate >40 bpm.

Common Clinical Indications for Pacemaker Implantation

Complete Congenital Heart Block
Complete congenital heart block (CCHB) is the most common indication for permanent pacemaker in the pediatric population in the absence of CHD. Approximately 20% to 30% of paced pediatric patients received implants for this indication. Though maternal exposure to lupus antibodies is a common etiology for CCHB, most cases are idiopathic. The importance of confirming lupus exposure is highlighted by the fact that some infants exposed to lupus antibody are also more likely to develop dilated cardiomyopathy as a result.

L-transposition, heterotaxy, and common AV valve defects are congenital lesions commonly associated with complete heart block. The most common association of CHB in the newborn is heterotaxy with left atrial isomerism. In these patients with significant fetal compromise (hydrops, poor ventricular function), outcomes remain poor. Isolated CCHB in the absence of CHD, however, carries an excellent prognosis.

Postoperative Heart Block
Before the advent of pacemakers, surgical complete heart block (SCHB) following repair of CHD carried a dismal prognosis with a 50% mortality rate. Currently, pacemaker implantation is recommended for persistent SCHB for at least 7 days, with no expected resolution. The study by Weindling et al. showed 97% recovery of AV node conduction by 10 days suggesting an extended observation period before making the decision of pacemaker implantation. Although the majority of patients with resolution of SCHB demonstrate intact AV conduction in follow-up, a small subset of patients develop recurrence of AV node disease several years after surgical intervention. As such, pacemaker implantation is a class II indication in patients with unexplained syncpe and residual bifascicular block following resolution of SCHB as these patients may be at risk for recurrence or higher grade heart block. Unfortunately, no definitive predictors of recurrence have been established in patients with normal electrocardiograms (ECGs; after resolution of immediate postoperative heart block) and these patients require close follow-up attention postoperatively.
Epicardial vs. Transvenous Considerations

Epicardial pacing systems (Fig. 107.1) are generally utilized in younger patients (<5 years or so), patients with single ventricle physiology and intracardiac shunts. In a multicenter study by Khairy and colleagues comparing transvenous versus epicardial pacing systems, the authors found a greater than twofold increase in thromboembolic events with transvenous devices in patients with significant left-to-right or right-to-left shunts. The advantage of transvenous systems is that transvenous leads tend to have lower pacing thresholds, higher lead impedances, and longer battery longevity in comparison to the epicardial leads. Of course, epicardial systems also obviate the need for a sternotomy or thoracotomy. The risks of venous occlusion and lead compromise are significantly increased in infants with transvenous pacemakers because of smaller patient and vessel lumen size. The major disadvantage of epicardial systems in young children is the higher risk of lead fracture due to mechanical stress. More importantly, maintaining long-term vessel integrity is imperative for infants requiring life-long pacing and, therefore, an epicardial system is ideal at a young age until adequate vascular growth is achieved and transvenous leads are an option.

Transvenous leads in the pediatric patient pose a unique challenge. Adhesions between the leads and endocardial or vascular tissue and patient growth can cause shear and stress tension on the lead and may compromise lead function. To circumvent this issue of growth, many implanters leave an extra loop of lead (such as right atrial loops) to minimize tension (Fig. 107.2). However, looping may create the presence of more surface lead area in the heart and promote further adhesions, thus complicating future lead extraction if needed.

Though epicardial systems are preferred in infants, the decision regarding implantation type in young children is more difficult. The risk of thrombembolism in young patients must be balanced with the risk of compromise to lead integrity. In a study of 63 children, echocardiography and venography were routinely performed to assess the risk of thrombus formation. Twenty-one percent were found to have moderate or severe thrombosis at follow-up. Patients found to have thrombosis were younger (4.5 vs. 8.2 years) and had larger lead diameter to body surface area ratio suggesting that children <5 to 6 years of age should have epicardial systems implanted. Dual chamber (two lead) systems were also found to be prothrombotic (because of two leads occupying a larger vessel diameter) and should be avoided in the younger patient population.

Epicardial systems (Fig. 107.1) are preferred in all patients with CHD and intracardiac shunting, regardless of age, because of increased risk of systemic thromboembolism. Unipolar leads (Fig. 107.1) have a single electrode with the pacemaker generator acting as the anode. Steroid-eluting leads provide lower (better) pacing thresholds and therefore preserve battery longevity. Bipolar leads (suture on) offer better sensing...
thresholds as compared with unipolar leads since they avoid far-field cardiac or skeletal muscle sensing. Ideally, bipolar leads (Fig. 107.3) should be placed on the myocardium free of scar to optimize sensing and pacing thresholds. Bipolar screw-in leads are also available for use in older patients with thicker myocardium (Fig. 107.4). In patients with multiple prior sternotomies, the left thoracotomy approach enables the surgeon to access more posterior structures such as left atrium and ventricle and avoid scar tissue (from sternotomies), thus facilitating dissection.

**Subpectoral vs. Subcutaneous Considerations**

Subpectoral devices are preferred in children as they offer the most optimal cosmetic result. However, the implant may be more technically challenging (more submuscular dissection) and need an experienced implantor. Muscular protection of the proximal lead, header, and generator improve longevity as well. Since subpectoral implants are anteriorly and posteriorly surrounded by muscular tissue, bipolar sensing and pacing are preferred to minimize muscular interference and muscular stimulation, respectively.

**Pacing in Operated Congenital Heart Disease**

The indications for pacemaker implantation in patients with and without CHD are important to distinguish. In patients with normal cardiac anatomy, bradycardia, even advanced atrioventricular heart block, can be well tolerated from a symptomatic standpoint and is not an indication alone for pacemaker implantation. However, patients with operated CHD may require closer evaluation for residual hemodynamic issues, which may influence pacemaker implantation decision-making. One such example is an adolescent with single ventricle physiology with AV valve insufficiency who has SND with bradycardia and junctional rhythm. Such a subject may be a candidate for pacing (atrial pacing) to improve his symptoms and hemodynamics. Consideration must be given to residual hemodynamic issues such as AV valve or semilunar valve insufficiency and chamber enlargement in addition to the presence of sinus or AV node dysfunction.

**Pacing for Arrhythmias**

**Intra-atrial Reentrant Tachyarrhythmias**

Pacemaker implantation is recommended for patients with CHD and bradycardia-induced IART. The purpose of pacing in these individuals is to prevent premature atrial complexes and short–long–short extrastimuli sequences, which have been implicated as tachycardia triggers. Anti-tachycardia pacing is a useful programming tool available in select devices, which has been shown to terminate atrial reentrant tachycardia in more than 50% of instances in a multicenter trial of pediatric patients with CHD. The use of anti-tachycardia pacing is limited since it is not effective in terminating atrial fibrillation and may actually induce atrial fibrillation in susceptible patients.

**Long QT Syndrome**

Life-threatening arrhythmias such as polymorphic ventricular tachycardia (VT) (Torsade de pointes, TdP) can be triggered by bradycardia or pauses in some forms of long QT syndrome (LQTS). Cardiac pacing has been employed to prevent pause-dependent TdP and has been shown to be effective in preventing ventricular arrhythmias and sudden death. Physiologic pacing has also been shown to shorten the QT interval. Pacing has also improved the clinical...
outcome in LQTS patients with 2:1 AVB at birth, long to be considered extremely high risk for sudden cardiac death (SCD).

**Biventricular Pacing in Pediatrics**

The objective of cardiac resynchronization therapy (CRT) is to coordinate right and left ventricular function in patients with clinical heart failure, particularly those with a left bundle branch block. Numerous studies in adult patients have demonstrated the benefits of CRT in those with dilated cardiomyopathy and electromechanical dyssynchrony. These controlled and randomized studies have shown an improvement in New York Heart Association (NYHA) class, exercise stress testing parameters, and mortality. Unfortunately, there are no such pediatric studies that have shown a similar benefit, but there are small series and case reports that have shown some promise of CRT in children with and without CHD. Currently, cardiac resynchronization is a class I indication in adult patients with an ejection fraction of ≤35%, QRS duration of ≥120 ms, and a NYHA class of III or IV.

The efficacy of CRT in the pediatric population, particularly those patients with CHD and right ventricular (RV) dysfunction, is not well established. As occurs in most studies in patients with CHD, the degree of heterogeneity in this population precludes large studies and conclusive statements. Moreover, traditional measures of improvement (QRS duration, tissue Doppler imaging (TDI), ventricular function) are complicated by underlying congenital cardiac lesions and establishing benefit in these patients is exceedingly difficult. In a small study, CRT was shown to increase arterial blood pressure and decrease QRS duration in the acute postoperative setting in patients with CHD. One prospective study by Jeewa et al. showed no acute benefit to CRT (cardiac index, blood pressure, TDI) in the congenital population. Long-term results in the largest retrospective study to date showed improved NYHA class and ejection fraction in 87% of patients undergoing CRT. Unfortunately, no conclusive study on CRT exists in pediatrics and most studies show conflicting results. It remains to be determined whether CRT will play a role in the management of patients with CHD, particularly those with RV dysfunction and right bundle branch block.

**Surgical Considerations**

Implantation of pediatric pacemakers is best performed by a team (cardiologists, surgeons, and anesthesiologists) skilled in the management of children. Particular attention for anatomical considerations is often the key in patients with CHD as anatomical variations often dictate the surgical approach. Ideally, general anesthesia should be performed by a pediatric cardiac anesthesiologist with special attention to effects of anesthesia on the hemodynamics of the cardiac lesion.

Careful screening for patients deemed pacemaker dependent (defined as an unreliable underlying escape rhythm) is a crucial part of surgical preparation. Anesthesia commonly suppresses conduction and may exacerbate brady arrhythmias. Pacemaker-dependent patients undergoing generator changes must also have an appropriate mechanism for maintaining hemodynamic stability. Isuprel administration or a temporary transvenous pacing lead via the femoral vein are useful adjuncts in preparation for pacemaker implantation in patients with unreliable escape rhythms.

Patients with CHD frequently have variations in venous anatomy, thereby complicating the transvenous approach. As such, venography of the subclavian, innominate, and superior vena cava can document patency and provide a “road map” for venopuncture.

Clear elucidation of intracardiac anatomy and the presence or absence of shunts is also imperative. The presence of an unrecognized patent foramen ovale may lead to inadvertent placement of the ventricular lead in the left ventricle (Fig. 107.5). This could be avoided by careful fluoroscopic imaging of the leads using different angles to confirm anterior lead placement. On the other hand, the ventricular lead placement in a patient with transposition of the great arteries (in the pulmonary ventricle-anatomically left ventricle) will be posterior fluoroscopically compared with a patient with normal segmental anatomy (Fig. 107.6). Demonstration of patent systemic venous return in patients with atrial switch operations (Mustard, Senning) is imperative as occlusion prevents transvenous access to endocardial tissue. Narrowing, stenosis, or interatrial leaks of the atrial baffle needs to be recognized by angiography and addressed (surgically, by stent or atrial septal defect device placement) before transvenous leads are placed (Figs. 107.6 and 107.7). Cardiac angiography in this patient population is also indicated to assess for baffle leaks that are a risk for paradoxical emboli and stroke. Baffle leaks need to be closed (either by device closure or surgical approach) before transvenous leads are inserted. The use of transvenous approach for atrial and ventricular pacing has been described in patients with single ventricle physiology and Fontan palliation. However, this poses technical challenge of finding viable atrial tissue capable of capture (in Fontan baffle with prosthetic material) and also obviates the need for chronic anticoagulation and its associated complications.

**LEAD EXTRACTION**

Summarized below are the indications for lead extraction as it pertains to the pediatric patient:

**Class I**

1. Sepsis related to device infection.
2. Life-threatening arrhythmia or immediate physical threat related to retained lead fragments.
3. Clinically significant thromboembolic event caused by lead fragment.
4. Lead that interferes with subsequent implantation.

![Fig. 107.5. X-rays in an AP (A) and lateral (B) view showing inadvertent placement of transvenous ventricular lead (arrows) across a patent foramen ovale into the left ventricle.](image-url)

Several tools have been devised to facilitate lead extraction. In the past, direct traction was the only available method. Not surprisingly, direct traction often led to complete lead fracture with retained fragments requiring surgical removal. The advent of locking stylets allows for traction to be placed on the distal lead tip, increasing the likelihood of complete extraction. Telescoping sheaths and laser sheaths provide counterpressure and countertraction, both disrupting fibrous tissue adhesion to vascular structures thus facilitating lead removal.

Life-threatening complications of lead extraction include myocardial avulsion, vascular tear, pneumothorax, pulmonary embolism, arteriovenous fistula, and death. Minor complications are pericardial effusion, hematoma, venous thrombosis, and arrhythmia. Recent reported complication rates are between 0.4% and 1.0% with lead extraction success rates of >95%. The most important factors predicting extraction failure are increased implant duration, physician inexperience, younger patient age, and ventricular versus atrial leads. The risk of failed extraction, based on this database, doubles for every 3 years of implant duration. Operators who have performed fewer than 20 extractions had lower success rates. As described earlier, the pediatric population is more likely to develop calcified fibrous matrices lending to lower success rates in younger patients. Because of the increased risks, such complicated procedures should be limited to experienced operators with all available resources including surgical operating room backup for emergency surgical intervention in the event of any of the above-mentioned life-threatening complications.

### Pacemaker Follow-up Challenges

The objective of pacemaker follow-up is to optimize device function, prolong battery longevity, and identify possible lead/generator issues. At implant, threshold margins (both pacing and sensing) are programmed with 2 to 3X safety margin. This is because myocardial edema and scarring may transiently affect threshold values in a fresh lead implant. Lead maturation occurs over the course of 6 weeks to 3 months at which time thresholds remain stable (chronic thresholds) and reprogramming to optimize battery longevity is indicated.

Pacemaker status evaluation can be performed in a variety of settings. Conventionally, device checks are performed in the office by an electrophysiologist or a cardiologist with pacemaker programming.

### Class II

1. Localized pocket infection.
2. Pocket site that causes significant discomfort.
3. Lead that poses potential threat due to lead design or failure.
4. Nonfunctional lead in a pediatric patient.

### Class III

1. Risk of removal outweighs benefit.
2. Lead that can be reused at time of generator change.

The most common class I indication for lead extraction is pocket/device infection (Fig. 107.8). Successful treatment of pacemaker-related infection requires complete removal of all prosthetic (pacemaker and lead) material. In a study from the Cleveland Clinic of 123 patients undergoing hardware removal for infection, four patients experienced recurrence of infection and all four patients had retained device remnants, both transvenous and epicardial. Complete extraction was achieved in 118 patients, all of whom had no infection recurrence. Lead malfunction in the pediatric population is the most common indication for lead extraction. Lead insulation disruption and inner pacing or sensing coil fracture (Fig. 107.9) are common causes of lead malfunction, particularly in pediatrics as trauma and patient growth can compromise lead integrity. Traditionally, epicardial leads are abandoned (after new lead/s placement) without the need for extraction.

Thrombus formation around the lead is the major impediment to extraction. Fibrous tissue then forms over the lead in the course of days to months. Typical sites of fibrous accumulation (on the lead) include the venous entry site, the anastomosis of the superior vena cava and innominate vein, and the distal lead tip. In younger patients with older leads, calcification may further strengthen the fibrous matrix, thereby complicating extraction.

Several tools have been devised to facilitate lead extraction. In the past, direct traction was the only available method. Not surprisingly, direct traction often led to complete lead fracture with retained fragments requiring surgical removal. The advent of locking stylets allows for traction to be placed on the distal lead tip, increasing the likelihood of complete extraction. Telescoping sheaths and laser sheaths provide counterpressure and countertraction, both disrupting fibrous tissue adhesion to vascular structures thus facilitating lead removal.

Life-threatening complications of lead extraction include myocardial avulsion, vascular tear, pneumothorax, pulmonary embolism, arteriovenous fistula, and death. Minor complications are pericardial effusion, hematoma, venous thrombosis, and arrhythmia. Recent reported complication rates are between 0.4% and 1.0% with lead extraction success rates of >95%. The most important factors predicting extraction failure are increased implant duration, physician inexperience, younger patient age, and ventricular versus atrial leads. The risk of failed extraction, based on this database, doubles for every 3 years of implant duration. Operators who have performed fewer than 20 extractions had lower success rates. As described earlier, the pediatric population is more likely to develop calcified fibrous matrices lending to lower success rates in younger patients. Because of the increased risks, such complicated procedures should be limited to experienced operators with all available resources including surgical operating room backup for emergency surgical intervention in the event of any of the above-mentioned life-threatening complications.

### Pacemaker Follow-up Challenges

The objective of pacemaker follow-up is to optimize device function, prolong battery longevity, and identify possible lead/generator issues. At implant, threshold margins (both pacing and sensing) are programmed with 2 to 3X safety margin. This is because myocardial edema and scaring may transiently affect threshold values in a fresh lead implant. Lead maturation occurs over the course of 6 weeks to 3 months at which time thresholds remain stable (chronic thresholds) and reprogramming to optimize battery longevity is indicated.

Pacemaker status evaluation can be performed in a variety of settings. Conventionally, device checks are performed in the office by an electrophysiologist or a cardiologist with pacemaker programming.
expertise. With the advent of remote monitoring, transtelephonic checks can provide information regarding sensing/pacing thresholds, stored electrograms in the device for arrhythmia troubleshooting, and battery longevity. However, formal device interrogations by a technician or an electrophysiologist are required on a yearly basis, and more often for those patients with CHD or ongoing pacemaker issues.

Generator Replacement

The commonest indication for generator replacement is battery depletion. Several factors influence battery longevity in pacemakers. Current drain for pacing is dependent on pacing rate, percent pacing, programmed voltage, programmed pulse width, and lead impedance. Ohm’s law \( V = IR \) (where \( V \) = voltage, \( I \) = current, \( R \) = resistance) dictates that the current is inversely proportional to impedance at any given voltage. Therefore, leads with higher impedances (such as transvenous bipolar leads) tend have lower current drain (for a similar voltage) and longer battery longevity. Moreover, contemporary pacemakers have several features obligating current including sensing measurements, rate response sensors, and algorithm implementation.

Most devices are equipped with an algorithm that will estimate battery life. Devices that reach elective replacement indicator (ERI) will typically revert to an industry-d dictated mode that is recognizable to the clinician. For example, Medtronic devices will pace VVI at 65 bpm if ERI is reached. Depending on variables mentioned, generators will have only months of battery life at ERI and generator replacement planning during that time frame is required. Patients with CHD who are reliant on AV synchrony will become quite symptomatic in an asynchronous pacing mode (e.g., VVI). As such, many clinicians will opt to replace the generator just prior to ERI in such selected patients. Of course, a thorough investigation of lead competence should be performed prior to generator change in all patients.

Fig. 107.8. Pictures showing pacemaker pocket infection (A) and device extrusion (arrows) (B).

Fig. 107.9. X-rays in AP and lateral views showing epicardial (A and B) and transvenous pacing lead fracture (circles) (C and D).
Pacemaker Recalls/Device Malfunction

Pacemaker malfunction is rare, occurring in approximately 0.4% of all implanted pacemakers translating into 1.3 malfunctions per 1,000 person-years. Unfortunately, device and lead recalls carry an enormous financial and psychological burden. Regular monitoring of lead and device performance by various device companies and subsequent FDA reporting has paved the way for physicians to closely monitor some of the “recalled” leads and devices. As technology continues to improve, device malfunctions will hopefully be limited to nonclinically significant events.

Improvement in magnetic resonance imaging (MRI) and pacemaker device technologies has seen the introduction of “MRI safe” pacemakers in the last couple of years. However, all risks of MRI exposure have not been completely understood and the use of MRI in patients with pacemakers or implantable cardioverter defibrillators (ICDs) should be carefully considered after discussing the risks and benefits of the diagnostic testing with the patient and treating physician.

Special Challenging Situations

Older Fontan

Bradyarrhythmias and tachyarrhythmias cause significant morbidity in patients with Fontan physiology. Incidence of SND and atrial flutter increases with time after the Fontan operation. Loss of AV synchrony in Fontan patients can lead to significant hemodynamic compromise. As such, 6% to 10% of patients with Fontan physiology require pacing 5 years postoperatively.

Venous anatomy in Fontan patients precludes direct access to atrial tissue limiting the ability to implant transvenous devices, particularly in patients with an extracardiac conduit. Though reports of transvenous implantation in patients with lateral tunnel Fontans have been reported, the risk of thromboembolism mandates coumadin therapy. For these reasons, surgical placement of epicardial pacing leads is the preferred option. Adhesions and scarring can prolong dissection times and limit the amount of viable tissue to obtain adequate pacing and sensing thresholds. Extensive dissection has been theorized to increase the duration and longevity of postoperative pleural effusions (and thus prolonging hospital stay) though a comparison of Fontan versus non-Fontan patients has shown no difference in length of chest tube drainage, particularly since the advent of the Fontan fenestration.

Difficult Vascular Access

Patients with complex CHD, multiple cardiac catheterizations, or a history of venous thrombosis who are being considered for transvenous pacemaker placement should undergo vascular studies as part of the pre-implant evaluation. Ultrasonography and/or venography are crucial in demonstrating feasibility of access, certainly prior to pocket formation. In patients with occlusion of the left innominate vein, right-sided access is possible and safe. Sometimes, right-sided access is preferred in patients who are left-handed as well. If vascular access precludes transvenous placement, the epicardial approach is indicated.

Newborn with Congenital Heart Block

Permanent pacing in patients with congenital CHB is quite common with 53% to 63% of patients requiring pacemaker implantation, 33% within the first 9 days of life. Among patients paced, the mortality rate in the first year of life is 17%, mostly related to dilated cardiomyopathy. Fetal hydrops is associated with a particularly poor outcome with a mortality exceeding 80%. Though anecdotal, no clinical trials have proven the efficacy of these measures.

The surgical approach in this patient population is often determined by limitations in patient size and myocardial access. Atrial tissue in a neonate tends to be friable and single chamber pacing with ventricular leads is often preferred as the initial permanent pacing system. Also, the atrial rates in newborns are significantly faster (120 to 160 bpm) and AV synchronous pacing at faster rates may be detrimental to achieving optimal cardiac output. As mentioned, asynchronous pacing may be poorly tolerated depending on baseline hemodynamics and may not be appropriate for all patients, particularly those with significant CHD.

Premature Infants with/without Congenital Heart Disease

Prematurity, low birth weight, low ventricular rate (<55 beats/min), significant structural heart disease, evidence for ventricular dysfunction or associated cardiomyopathy and presence of hydrops fetalis all predict poor outcome in neonates with complete heart block. Antenatal treatment has been pursued in these high-risk patients and consists of (1) inotropic medications to increase fetal heart rate, (2) plasmapheresis and steroids to counteract an inflammatory component, (3) digoxin and/or lasix to treat ventricular dysfunction, and (4) fetal pacing. Unfortunately, no clinical trials are available to demonstrate the efficacy of these methods. In fetuses that are profoundly affected with evidence of hydrops, early delivery and pacing have been performed.

In the premature infant, technical challenges in combination with relative hemodynamic instability complicate permanent pacemaker implantation. Reports of pacemaker implantation in premature infants >2 kg exist. However, the importance of early stabilization in these patients may trump the need for permanent pacing. One approach is to place temporary pacing wires immediately after birth for stabilization, thus circumventing the possibility of low cardiac output and acidosis in the neonatal period. This approach also allows for achieving adequate growth, thus facilitating permanent epicardial pacing at a later date.

The premature patient with significant CHD continues to portend a dismal outcome with nearly uniform mortality. Unfortunately, no approach has been shown to demonstrate a more favorable result in this patient group. Certainly, fetal counseling about possible poor outcome is imperative for the family with an in utero diagnosis.

INTRODUCTION TO ICD THERAPY

HRS/American College of Cardiology Recommendations/Guidelines for ICD Implantation

The clinical indications for ICD implantation in children, adolescents, and young adults with CHD are summarized below.

Class I

1. Survivors of cardiac arrest (CA) after exclusion of reversible causes.
2. Symptomatic sustained VT in association with CHD.

Class IIa

1. Recurrent syncope of undetermined origin in the presence of ventricular dysfunction or ventricular arrhythmias at electrophysiology study (EPS).

Class IIb

1. Recurrent syncope associated with complex CHD and advanced ventricular dysfunction with no other identifiable cause.

Class III

1. Not indicated in patients with a life-expectancy of <1 year.
2. Not indicated in patients with incessant VT of VF.
3. Not indicated in patients with significant psychiatric illness that may be aggravated by a device.
4. Not indicated in patients with syncope of undetermined cause with no inducible VT and no structural heart disease.

The indications for ICD implantation in young patients is mostly based on adult data and has evolved substantially in the last 15 years. Unfortunately, pediatric patients experience a high rate of mortality compared with adults following resuscitation after a sudden CA. Fewer than 1% of all ICDs are implanted in the pediatric patient, thereby limiting our ability to assess the efficacy in this vulnerable population. Generally, the risk of sudden death is likely smaller in a pediatric patient than in an adult with the same disease process. As such, guidelines based on adult literature may not be extrapolated to the pediatric patient.

Appropriate patient selection is imperative. One must balance cumulative lifetime risk of a presenting condition with the cumulative lifetime risk of having an ICD before making the decision. Typical indications for ICDs in the pediatric patient include CHD with significant arrhythmias and risk of sudden death, cardiomyopathies, and inherited arrhythmia syndromes. Antiarrhythmic therapy is variably effective with significant toxicity in some. Patient compliance, particularly in the teenage population, offers yet another obstacle to medical management. Though the frequency of device implantation has increased in recent years, technological advances have not translated into freedom from inappropriate shocks and device/lead malfunction. Therefore, the decision to implant a device must accompany a candid conversation of risks and benefits with the patient and family. As will be discussed, the specific clinical situation and diagnosis are the crux of the decision-making process.

Common ICD Clinical Situations

Primary prevention therapy is intended to prevent SCD in patients susceptible based on risk factors. Secondary prevention therapy is intended to prevent SCD in patients with a previous aborted cardiac event.

Long QT Syndrome

LQTS is a cardiac channelopathy associated with syncope and SCD as a result of ventricular arrhythmias, particularly TdP. The management of LQTS is aimed at preventing significant arrhythmia and SCD. Current therapy consists of beta-blockers, ventricular pacing (in some situations) (as discussed in the previous section) and left cardiac sympathetic denervation. ICD therapy is recommended for patients with recurrent syncope despite medical therapy, sustained or nonsustained ventricular arrhythmias indicating a risk of sudden death or an aborted SCD event. Current guidelines state that primary prevention ICD therapy may be considered in patients with a strong family history of SCD, though this is controversial. In a study by Kimbrough et al., sudden death in the family does not increase the risk of lethal events in other family members. Certainly, in these scenarios, emotional considerations complicate the conversation and decision-making process.

Genotype considerations have received a great deal of attention in the literature and offer critical insight into the decision-making process. Though not formally part of the HRS/AHA guidelines for device implantation, these associations cannot be ignored as the risk of SCD is not the same among different genotype classifications. Fortunately, the most common genotype (LQT1) confers the least risk of SCD. In a study evaluating 187 LQT1 patients treated with beta-blockers, the incidence of CA was 1.1%. In this same study, the incidence of CA among 120 LQT2 patients was 6.6%, none of which experienced sudden death. Therefore, approximately 99% and 93% of patients with LQT1 and LQT2, respectively, are free from significant cardiac events on beta-blocker therapy. These results contrast with that of 28 treated LQT3 patients of which 14% experienced CA in the same study. In these higher risk LQT3 patients, beta-blockers clearly do not offer the same protection against SCD and the threshold to implant an ICD should be presumably lower.

Arrhythmogenic Right Ventricular Cardiomyopathy

Arrhythmogenic RV cardiomyopathy/dysplasia (ARVC/D) is characterized by fibrofatty replacement of ventricular myocardium leading to ventricular arrhythmias. In younger patients, SCD may be the presenting symptom. As such, ICD implantation has become an emerging treatment modality for ARVC. Historically, the decision to implant an ICD was largely driven by merely meeting diagnostic criteria. In a study by Corrado et al., nearly 50% of patients with an ICD required appropriate ICD intervention despite antiarrhythmic drug therapy over a mean follow-up period of 3.3 years. Fatal arrhythmias (ventricular fibrillation) were experienced by 24% of patients. This study concluded that a history of either CA or VT with hemodynamic compromise, younger age, and LV involvement are all independent risk factors for fatal arrhythmias. Induction of VT during an EPS was thought to be of limited value in this study though a more recent study states that a positive EPS is a strong predictor of lethality.

According to the AHA/HRS guidelines, patients with prior CA, syncope due to VT, extensive RV disease, LV involvement or presentation with polymorphic VT and apical RV aneurysm are at higher risk of SCD. The guidelines also state that the decision to implant an ICD should ultimately be based on “experience, judgment and available data” until more information becomes available.

Brugada Syndrome

The Brugada syndrome has the characteristic ECG findings of right precordial ST elevation and is associated with a high incidence of sudden death. Typically, events occur during sleep or with fevers and are caused by a primary cardiac, sodium channelopathy. Like other channelopathies, therapy is aimed at preventing SCD. Unfortunately, ICDs are the only intervention shown to prevent SCD; therefore, risk stratification serves an important role. Much like LQTS, a family history of sudden death does not predict a higher risk for events in other family members. Patients with a spontaneous Brugada-type pattern and a history of syncope are at a sixfold increase risk of SCD.

As with ARVC, the role of EPS in risk stratification remains controversial. With a low positive predictive value of 23%, but a high negative predictive value over 3 years of 93%, some argue its utility in identifying low-risk patients. Supraventricular tachycardia exists in 20% of Brugada patients and the role of EPS is mainly to eliminate the causes of supraventricular tachycardia (atrial fibrillation, AVNRT, WPW) prior to ICD placement as SVT will increase the likelihood of an inappropriate shock. Though gene testing can identify approximately 50% of Brugada patients, specific mutations in the SCN5A gene have not been useful in identifying patients at risk for SCD.

Based on a consensus statement, ICD implantation is recommended for patients with a Brugada pattern on ECG (whether spontaneous or induced) who present with an aborted sudden cardiac event. ICD is also recommended for patients with symptoms such as syncope, seizure, or nocturnal agonal respiration after exclusion of noncardiac causes. Management of asymptomatic patients with positive ECG findings and a family history of Brugada

Chapter 107: Introduction and Overview of Pacemaker/ICD Therapy in Children 1175
is controversial. Some studies have shown that the use of EPS may be helpful in risk stratification. Asymptomatic patients with a negative family history and an induced ECG pattern should be followed closely.

**Catecholaminergic Polymorphic Ventricular Tachycardia**
Catecholaminergic polymorphic VT (CPVT) is characterized by ventricular arrhythmias in the setting of physical or emotional stress. Patients with CPVT have normal resting ECGs, unlike patients with LQTS. Symptoms typically develop in childhood during exertional activities. The ryanodine receptor (RyR2) is responsible for approximately half of all the autosomal dominant cases of CPVT. The autosomal recessive type is associated with mutations in the calsequestrin gene (CASQ2). Beta-blocker therapy is the accepted mainstay of therapy and has been shown to reduce SCD. A minority of the patients continue to have VT and/or syncope on adequate beta-blocker treatment and are candidates for ICD therapy. Fortunately, CPVT is a rare disease and as such, risk stratification does not currently exist.

**Epicardial vs. Transvenous Considerations**
Compared with standard pacemaker leads, ICD coils tend to be thicker thus increasing the risk for vascular damage and thrombus formation, particularly in smaller children. Also, in order to provide adequate therapy charge, ICD generators are much larger than the standard pacemaker generator. Therefore, the age limitations for ICDs tend to be more conservative than that of pacemakers. As with pacemakers, infraclavicular implantation (whether subcutaneous (SQ) or subpectoral) is possible in the older patient (usually >7 years of age) undergoing transvenous placement. In the younger child, abdominal implantation is preferred with an epicardial lead system. Intracardiac shunts are a contraindication to transvenous lead implantation.

The technical challenges in ICD implantation are not only the result of lead and device size but also due largely to limitations in establishing an appropriate shocking vector. Several configurations have been explored with the goal of providing an adequate shocking threshold while limiting invasiveness and procedural complication. Conventionally, epicardial patches have been employed in the past for pediatric patients. Unfortunately, this technique requires a thoracotomy or sternotomy and restrictive pericarditis (secondary to the patch) is a known complication of epicardial patch implantation. As such, alternative defibrillator configurations have been developed, particularly the SQ array. Other configurations employ transvenous leads placed on the epicardium (Fig. 107.10) with an active can and/or a SQ array. Though no major differences in configuration type are described in the literature, establishing an adequate shocking vector continues to be challenging.

SQ sensing and defibrillation leads are being developed, though their use in pediatric patients is likely not imminent. These devices do not require intracardiac or intravascular hardware. Unfortunately, “leadless” ICDs (or SQ ICDs) do not allow for pacing. More importantly, sensing would be compromised, which could increase the risk of inappropriate shocks, particularly during sinus tachycardia or supraventricular tachycardia that are very common in the pediatric population. However, this technology appears to have promise for the pediatric population.

**ICDs in Patients with and without Congenital Heart Disease**
Due to the heterogeneity of CHD in the pediatric patient, there is a lack of large pediatric studies that do not require intracardiac or intravascular hardware. Unfortunately, “leadless” ICDs (or SQ ICDs) do not allow for pacing. More importantly, sensing would be compromised, which could increase the risk of inappropriate shocks, particularly during sinus tachycardia or supraventricular tachycardia that are very common in the pediatric population. However, this technology appears to have promise for the pediatric population.

**Fig. 107.10.** Epicardial ICD placement in a patient with Fontan surgical correction. The arrows in panel (A) show an anteroposterior depiction of the epicardial electrode placement around the heart and panel (B) shows a lateral depiction of the same with an abdominal generator.

**D-Transposition of the Great Arteries**
Complete transposition of the great arteries with atrial switch operation is among the highest risk congenital lesions for SCD. The incidence of SCD in this patient population is more than three times that of TOF and is the most common cause of late mortality. Also unlike tetralogy, D-TGA atrial switch patients are at a higher risk for atrial tachyarrrhythmias. In a multicenter study by Khairy and colleagues, SVT was found to coexist or precede VT during intracardiac ICD tracings prior to defibrillation. Therefore, rapidly conducting atrial tachycardia, and VT, are both proposed mechanisms for SCD in this high-risk patient population. A positive ventricular stimulation study was
not predictive of appropriate ICD shocks in this study suggesting that EPS for risk stratification has a low yield. Additionally, secondary prevention ICD implantation for RV dysfunction, nonsustained VT, and syncope are not currently supported in the literature.

Early reports of the arterial switch operation are promising though much remains to be seen regarding the risk of SCD in this group. Long-term results are emerging and are equally promising thus far. In a study by Tobler and colleagues, no arrhythmia deaths were reported and one patient had VT out of 65 patients followed over 20 years. As this population reaches adulthood, risk stratification for ICD implantation will be elucidated.

**Hypertrophic Cardiomyopathy**

Known risk factors for SCD in hypertrophic cardiomyopathy (HCM) are as follows: (1) previous CA, (2) sustained VT, (3) nonsustained VT, (4) family history of SCD, (5) syncope, (6) septal thickness >30 mm, and (7) abnormal blood pressure response to exercise. In these high-risk patients, primary prevention ICD interventions were common and frequently restored sinus rhythm. It is worth mentioning that severity of disease and symptoms such as chest pain, dyspnea, and exercise intolerance do not correlate with SCD risk and should not be used as justification for ICD implantation.

**Left Ventricular Noncompaction**

Left ventricular noncompaction is a congenital disease caused by abnormal embryogenesis of the endocardium and epicardium. Complex ventricular arrhythmias occur in approximately 40% of pediatric patients with LV noncompaction and sudden death is the most common etiology for mortality. Though data do not currently exist to risk stratify these patients, primary prevention ICD implantation has been performed and is a "reasonable clinical strategy" according to guidelines.

**Technical Considerations**

Similar to pacemaker implantation, meticulous attention to anatomical detail is essential to successful ICD implantation. Systemic venous anomalies are important to elucidate as part of procedural preparation. In the case of a persistent left superior vena cava (LSVC) draining to the coronary sinus (with an absent right SVC), positioning the lead toward the tricuspid valve from the coronary sinus may require use of long sheath or atrial looping to direct the lead toward the ventricle. Venous occlusion, particularly in patients with prior leads and CHD, is also important to consider. In patients with suspected occlusion, venography to ensure vein patency prior to pocket creation is recommended.

**Left Ventricular Noncompaction**

Examples of atrial (A) and ventricular lead (B) dislodgement seen on X-ray—AP views.

**Long-Term Complications**

Acute complications of device implantation are similar to that of pacemakers and include infection, bleeding, lead placement issues including dislodgement (Fig. 107.11), and vascular damage. In a study from the pediatric ICD registry of 443 patients, 64 acute (<30 days) complications occurred in 55 patients, the most common of which were lead dislodgement and inability to defibrillate at an acceptable defibrillation threshold testing (DFT). Chronic complications in this study included conductor/insulator breach and changes in electrical properties and occurred in 116 patients.

Issues related to growth, development, and trauma are unique among the pediatric population. ICD malfunctions related to these issues can be quite debilitating and potentially fatal. Inappropriate shocks have become the most burdensome complication of ICD implantation in pediatrics and, unfortunately, occurs much more commonly than in the adult population. Of 409 patients with ICDs, 87 (21%) received an inappropriate shock with a mean of six shocks per patient compared with appropriate shocks in 105 patients (26%). Common etiologies for inappropriate shocks in the study group included lead failure, inability to distinguish sinus tachycardia or SVT, and/or oversensing of T wave. Clinical interventions such as ablation of SVT substrates, adjusted sensing to eliminate T wave oversensing, and initiating anti-arrhythmic medications can reduce
the rate of inappropriate shocks after the etiology for the event is established. Behavioral disorders, anxiety, device dependence, and social withdrawal have been reported in patients with ICDs. Appropriate counseling before and after device implantation with the assistance of psychiatric professionals is warranted in some cases.

Fortunately, the mortality rates in pediatric patients with ICDs are much lower than adults. With a mean follow-up of 7.5 years, arrhythmia-related mortality occurred in only 1% of patients in the pediatric ICD registry. Moreover, the high rate of inappropriate shocks justifies implantation in selected at-risk patients as described in previous sections.

Defibrillation Threshold Testing

The objective of DFT is to determine the lowest amount of energy required to convert VF into sinus rhythm as a surrogate for establishing device reliability and margin of safety. DFT was once an obligatory component of ICD implantation and considered standard of care in the early implant years. Recently, this practice has come into question as adult data from the SCD-HeFT (SCD in heart failure trial) has shown no significant benefit in terms of survival in a select group of patients receiving ICD therapy as primary prevention for SCD. In this study, shock outputs were programmed at 30 Joules regardless of DFT values. No differences were found in success of first shock regardless of DFT results. The authors are quick to note that these results should not be extrapolated to other patient groups, particularly those that are higher risk for SCD. The safety and clinical utility of DFT are also debated. Viskin and colleagues thoroughly describe the shortcomings of DFT. Specifically, DFT employs induction and detection of VF, which may not be the clinically relevant arrhythmia in the ambulatory setting. Furthermore, there is no guarantee that external defibrillation as a “bail out” for ICD refractory VF will be successful and death has been reported as a result.

Though the low-risk adult population may not benefit from DFT, most pediatric electrophysiologists perform DFT at implant. Contraindications to DFT are important to recognize. The pediatric relevant contraindications are as follows: (1) intracardiac thrombus, (2) severe aortic stenosis, (3) inadequate sedation, and (4) hemodynamic instability. In those high-risk patients, particularly patients with HCM, restrictive cardiomyopathy or severe dilated cardiomyopathy, surgical support, and ECMO backup are crucial in preventing catastrophic outcomes during DFT.

Routine, follow-up DFT has also been employed in the past but not proven to be useful. With the concerns mentioned in device longevity (such as increasing charge times) in the pediatric population, changes in DFT over time may be clinically significant and require attention. In the largest pediatric study assessing utility of follow-up DFT, the authors concluded that routine testing is not clinically useful though should be considered if clinical changes occur. Currently, no guidelines regarding DFT in pediatrics exist.

ICD Follow-up, Recalls, and Device Malfunction

ICD Follow-up

Due to the high rate of device complications in children, routine follow-up serves the purpose of optimizing device function and ensuring patient safety. Most centers perform outpatient device interrogation every 6 months. These visits are focused on assessing patient symptoms (palpitations, dizziness, syncope, device discharges) and evaluating lead parameters, battery longevity, and battery life (charge time). Depending on the device parameters, intracardiac electrograms may be available to review for high rate episodes. If sinus tachycardia is noted close to the defibrillation zone, adjustments should be made accordingly to avoid inappropriate shocks. All device discharges are also available for interrogation allowing the clinician to determine the rhythm inciting the discharge event.

Frequently, lead fractures can be identified prior to inappropriate shocks highlighting the utility of routine interrogations. A sudden change in lead impedance, accompanied by “lead noise,” should prompt further investigation and possible lead extraction and replacement. Low battery life or long charge times suggest the need for generator replacement.

Advanced transtelephonic systems are available in most current devices allowing remote assessment of device parameters. The reports provide pacing and voltage impedance, arrhythmia detection and therapy logs, pacing and sensing thresholds, and programmable alerts (e.g., lead noise). Most clinicians perform remote monitoring approximately every 3 months, or sooner depending on device status.

Device Recalls and Device Malfunction

The implications of device and lead malfunction are severe, particularly in our patient population. The decision to explant an ICD system must be carefully discussed. Factors affecting this decision include presumed risk of an adverse event related to the malfunction and the presumed risk of ICD revision. Certainly, patients that are at high risk for SCD with a high probability of clinically significant consequences from device malfunction should undergo revision.

In a study performed by members of the Pediatric and Congenital Electrophysiology Society, 58 of 233 (25%) ICD patients were identified as having device advisory or recalls in a 5-year period. Thirteen of these patients underwent explantation with a mean time from implant of 3.1 years. None of these patients were found to have defective devices upon investigation by the manufacturer, which highlights the importance of risk assessment in these scenarios.

From the initial commercial availability in 2004 to the lead recall in 2007, 268,000 Sprint Fidelis leads were implanted in patients worldwide. Manufacturer concerns regarding high lead fracture rate were publicized and clinicians were left with a difficult decision, particularly the pediatric electrophysiologist as younger patients had a much higher incidence of lead failure. The failure rate for this lead was 2.8% per year, unlike other leads with a failure rate of approximately 0.43% per year. Though deaths were not reported as a result of Fidelis lead failure, inappropriate shocks were extremely common. As mentioned, inappropriate shocks have a pervasive psychological impact.

Special Challenges in ICD Implants

Difficult Vascular Access

Ultrasoundography and/or venography are crucial in demonstrating the feasibility of access in those patients considered to be at high risk for venous occlusion. Patients with complex CHD, multiple cardiac catheterizations, or a history of venous thrombosis who are being considered for ICD placement should undergo vascular studies prior to pocket formation. As with pacemaker patients, the epicardial approach is preferred if vascular access precludes transvenous placement.

High Defibrillation Threshold Testings

DFT is influenced by many factors including electrolyte balance, sympathetic tone, and antiarrhythmic drugs. A 10-Joule safety
margin has been widely accepted as standard practice. High DFTs occur in 5% to 6% of patients and are associated with LV dilation and medication use (see below). Presumably, these patients are not adequately protected and are at higher risk of SCD. Several management options are available and all aim to provide the highest discharge output through the most efficient shocking vector.

Prior to exchanging or adding hardware, reversible causes of high DFTs should be investigated. For instance, air is a poor electrical conductor and pneumothoraces must be excluded as a culprit. Medications particularly mexiletine, carvedilol, sildenafil, and amiodarone have all been shown to increase DFT. Perhaps the least invasive approach to circumvent a high DFT situation is to replace the generator with a higher output device. Higher output devices tend to be larger and may not be an option in a smaller patient. An SQ array can be introduced to enhance the shocking vector as well. Some have advocated using additional coils (e.g., SVC coil). Addition of sotalol has been shown to lower DFTs and is a reasonable option in selected patients with a normal baseline Q75 interval.

**Single Ventricle Patients**

Risk assessment in patients with single ventricle physiology is yet to be clearly defined. Khairy et al. evaluated 261 Fontan patients of which 76 died with a substantial portion experiencing SC (7 patients, 9.2%). Due to small numbers, no predictors of SCV were proposed in this study. Heart failure from severe ventricular dysfunction predicts a high rate of mortality and is likely not ameliorated by ICD therapy. Typically, patients with severe cardiac dysfunction are better served by cardiac transplantation. Certainly, the risk of anesthesia and surgical ICD placement must be considered and discussed with the family after other interventions are thoroughly evaluated.

**SUGGESTED READINGS**

Blatt JA, Poole JE, Johnson GW, et al. No benefit from defibrillation threshold testing in the SCD-HeFT (Sudden Cardiac Death in Heart Failure Trial). J Am Coll Cardiol 2008;52:551-556.

The authors have nicely summarized the indications for pacemaker and resynchronization and ICD therapy in children. A particularly difficult group of patients are those with heterotaxy syndrome with hydrops and complete heart block with fetal compromise. It is interesting that despite aggressive pacemaker implantation at birth, these patients do not seem to tolerate pacing well with poor cardiac output and a high mortality rate despite what would appear to be good AV sequential pacing or reestablishment of AV synchrony with a higher ventricular rate. In some cases, the patients may be best served by ventricular pacing without atrial synchronization. The mechanism by which the increased heart rates do not result in improvement in clinical outcome and cardiac output in these patients has not been well elucidated, and they continue to be an extraordinarily high-risk population with poor results.

Postoperative complete AV block is often transient as noted in the chapter. It is preferable to wait 7 to 10 days after initial cardiac surgery with complete AV block prior to committing the patient to a permanently implanted pacemaker system. The significant majority of patients will return to normal sinus rhythm in this timeframe. However, as noted, since AV block can reoccur even after the recurrence of sinus rhythm in some patients, the patient who has a poor escape rate and relatively dense AV block who then recovers sinus node function late at 7 to 10 days after initial surgery may be best served in some cases by placement of a back up VVI generator to protect them from possible late recurrence of lack of AV conduction.

An additional issue with pacemaker implantation in postoperative complete heart block is the fact that although pacemakers are generally implanted after 7 to 10 days of lack of sinus rhythm, after placement of a pacing system some patients will revert back to sinus rhythm over the next several months to years. Thus, it is imperative to follow these patients and consider whether or not they continue to need active pacing systems over time. In some cases, if sinus rhythm can be demonstrated and is stable on Holter monitoring or long-term follow up through the pacing device, it may be possible to explant the device with an assurance that sinus rhythm will be maintained.

As noted by the authors, the relative efficacy of resynchronization pacing therapy in children with congenital heart disease is not well established. There are isolated reports of significant improvement in exercise performance after resynchronization therapy in some patients, including those with single ventricle physiology. Large series, however, have not been accumulated and therefore it is difficult to know when to recommend this type of therapy in the pediatric patient population. In addition, the variations in venous anatomy and ventricular morphology make transvenous implantation of resynchronization leads more difficult in these patients and epicardial leads may be necessary. Deciding on location for epicardial placement of pacing leads can be difficult and previous surgery can make exposure quite challenging.

The indications for placement of ICD devices in the pediatric population are well summarized by the chapter. It is important to emphasize as the authors have done in this chapter that ICD placement carries a significant morbidity due to the psychological impact of inappropriate counter shocks not to mention the psychological issues of the potential for counter shocking at any time. It would seem appropriate that very stringent indications be followed for placement of these devices in the pediatric population due to the high incidence of complications, the relatively short durability of the leads and pacing systems, and the relatively large sizes of the devices which have cosmetic implications in small children.
Birth of conjoined twins (twins whose bodies are connected at some level) is indeed very rare and estimated by various authors as 1 in 50,000 to 100,000 births. A majority (40% to 60%) are stillborn and 35% do not or cannot survive after birth. They are associated with a high incidence of maternal polyhydramnios, prematurity, and low birth weight. They are always the same sex and approximately 70% are female. Isomerism is common: twins are born with two right sides, two left sides, in mirror images of normal anatomy, or a mixture of the two with shared organs.

**HISTORY**

There are numerous historical accounts of the existence of conjoined twins. The earliest recorded history was found in ceramics of ancient Peru in 300 AD.

History then records two Arabian brothers who were joined with one leg to the others head. They were separated with a sword in 750 AD.

The most famous report described “Siamese Twins” which gave a new popular synonym that is often substituted for “Conjoined Twins.” These were the historical twins named Eng and Chang who were born in Siam in 1811 (now Thailand but really they were Chinese) sharing a common liver and joined at the abdominal area. King Rama ordered them to death because he believed that they represented a sign of an evil omen. Later, this decree was withdrawn. Interestingly, they joined the circus, settled in Wilkes County, NC. In January 1874, Eng woke up to find Chang dead; thus, both died at the age of 63. The social element of this subject of marriage to two separate sisters, a “bed for four,” and after a severe argument between the sisters the creation of two separate “homesteads,” created a fascinating account. Conjoined twins are not limited to any racial or ethnic group.

Also famous were the Biddenden Maids born together in 1100 and who died together in 1134.

There appeared to be an epidemic of conjoined twinning in South Africa and in Sweden; this cluster of births has, however, been disputed.

There are also published accounts of conjoined twins occurring in cattle, rabbits, cats, hamsters, pigs, rats, and mouse.

**MECHANISM OF CONJOINED TWINS**

There are two theories of the mechanism of conjoined twinning (which are incompletely understood and are contradictory). One theory is called “fission” in which there is an incomplete and asymmetrical partial splitting of a single embryonic fertilized egg. The second theory is called “fusion” in which the fertilized egg was destined to become completely separate twins but then stem cells search for like stem cells on the other twin (due to their close proximity) then fuse together. One author states that the “fission” theory is more widely acceptable; however, now the “fusion” theory is stated to look most probable. If the splitting or rejoining of the fertilized egg occurs after 12 days with either theory, the result will be a conjoined twin.

**ETIOLOGY OF CONJOINED TWINS**

Conjoined twins are monozygotic (one egg) and are monoaminotic and monochorionic. The one amnion is the inner layer that holds the embryo and later the fetus within the amniotic fluid. The chorion is the inner membrane that contains the embryo and part of the placenta. It is known that twinning may tend to be prevalent in some families.

While the etiology of either fission or fusion may be disputed, various teratogenic agents may influence the incidence of conjoined twins. These may include:

(a) The use of gonadotropins, which are fertility drugs for women and hormonal imbalance in men.

(b) Experimental studies in animals demonstrate that general and local anesthetics, acetaldehyde (a metabolite of ethanol), and some tranquilizers may induce conjoined twinning.

(c) Another cause has been shown to be lack of calcium and magnesium salts.

(d) Seven cases (two published) have been reported in which conjoined twinning occurred with the use of clomiphene for induction of ovulation.

(e) Maternal exposure to valproic acid has been reported when used as an anticonvulsant or with the use of valerian, a common mood-stabilizing agent.

(f) Fungistatic agents as griseofulvin (used as a fungicide) also has been associated with conjoined twins. Agent Orange and other herbicides. There has been a marked increase in conjoined twins in Vietnam due to Agent Orange and other herbicides.

**CLASSIFICATION OF CONJOINED TWINS**

A general nomenclature has been established for all types of conjoined twins. Twins are classified according to the common area of the body onto which their bodies are joined and the ending “pagus” from the ancient Greek language is added which means “fixed.”

Spencer provides a classification of eight different types of conjoined twins: parapagus (26%), thoracopagus (25%), omphalopagus (17%), cephalopagus (11%), ischiopagus (9%), pygopagus (6%), craniopagus (5%), and rachipagus (2%). However, this classification is difficult to follow for the cardiothoracic surgeon because thoracopagus and omphalopagus often coexist. Several alternative classifications are more useful for cardiothoracic surgeons. In one classification, the types in alphabetical order are described as anterior (front), posterior (back), lateral (side), and ventral (area of abdomen).

This classification specifies the types of twins, which either have two hearts, one
shared heart, and a possible involvement of the heart in these infants. When indicated there is involvement of the heart in most cases and possible involvement in some cases.

I. Ventral union (referring to the front of the body, faces, four ears, and two bodies)

(a) Cephalopagus: Twins joined at the upper part of the body with one head. They are joined by one face with two bodies. There is one face with four ears. These types are extremely rare and do not survive (Fig. 108.1).

(b) Cephalothoracopagus (cephalothoracopagus syncephalus, cephalothoracopagus craniothoracopagus): Joined at head and thorax. There are two faces, one brain, one head, usually share one heart and fused gastrointestinal tracts (Fig. 108.2).

(c) Thoracopagus: Joined at upper thorax to umbilicus. Shared heart in 90% and 75% have a joined heart which cannot be separated, four arms, four legs, and two pelvises (Fig. 108.3).

(d) Omphalopagus: Joined in the area of the umbilicus, sometimes thorax, however, not affecting the heart. Two pelvises, four arms, and four legs (Fig. 108.4).

(e) Thoraco-omphalopagus: A combination of thoracopagus and omphalopagus. Joined at upper thorax to the umbilicus and usually share a heart. Ninety percent have a common pericardium and 75% have a shared heart. They have four arms and legs. Xipho-omphalopagus look similar but their hearts are normal (Fig. 108.5).

(f) Xiphopagus (a subset of omphalopagus): Joined at the xiphoid from lower sternum (gladiolus) to the umbilicus (Fig. 108.6).

(g) Ischiopagus: Twins joined at the level of the umbilicus end to end with the spine. There are four arms with various combinations of legs. Of the above types, there may be only two legs present (ischiopagus dipus), three legs present (ischiopagus tripus), or four legs present (ischiopagus tetrapus/quadrupus).

(h) Omphalo-ischiopagus: A combination of omphalopagus and ischiopagus are similar to ischiopagus twins facing each other. There can be cases of thoraco-omphalo-ischiopagus and xipho-omphalo-ischiopagus twins who are joined facing each other but are joined at the chest.

II. Lateral union (referring to twins joined side by side with shared umbilicus, abdomen, and pelvis. These rarely involve the heart.

(a) Parapagus: Twins joined at the pelvis with one symphysis pubis and one or two sacrums (Fig. 108.7).

(b) Dithoracic parapagus: Twins joined at the abdomen and pelvis but not the thorax (Fig. 108.8).

(c) Di cephalic parapagus (diecephalus): Twins joined at the abdomen, pelvis, and thorax. All of the above may have two arms (dibrachius), three arms (tribrachius), and four arms (tetrabrachius).

III. Dorsal union (referring to twins joined at the dorsal aspect (at the back). In these twins, there is no involvement of the thorax and abdomen.

(a) Cranioptagous: Twins joined at the skull except for the face.

(b) Pygopagus (pyopagus or illeopagus): Twins joined at the sacrococcygeal, perineal, and occasionally the sacrum.

(c) Rachipagus: Twins fused dorsally above the sacrum and the lumbar spine. This type is very rare. The above classification constitutes one of many and excludes many other rare types. Two of these types are:

- Parasitic twins (asymmetrical, unequal) in which if one dies or
receives inadequate nutrition while in the uterus then one embryo maintains dominant development at the expense of the other.

A cardiac twin is an incomplete twin without a heart that grows separately and receives nourishment from its normal twin.

A second simpler classification listing the frequency of conjoined patterns is as follows:

1. Thoraco-omphalopagus (twins joined at the chest, abdomen, or both)—74%.
2. Throracopagus or xiphopagus (joined at the chest)—40%.
3. Omphalopagus (joined at the abdomen)—34%.
4. Pyopagus (joined at the buttocks)—18%.
5. Ischiopagus (joined at the ischium)—6%.
6. Craniopagus (joined at the head)—2%.

CARDIAC INVOLVEMENT IN CONJOINED TWINS

For the purpose of this chapter, while other types of twins are possible, our concern is twins with involvement of the cardiovascular structures. These twins are all joined primarily in the thoracic area. There may be either a single heart or partial duplications of cardiac and vascular elements. There can also be two hearts with extensive sharing of the vascular elements. The sternum is either partially or totally absent in all cases, the pericardium in 90% and the hearts fused in 75%.

The other organs that can be involved include the unusual saddle-shaped liver, a joined common duct (while the gall bladders and hepatic ducts might be separate), and hepatic veins either separate or shared. There can be persistent left superior vena cavae, which drain into separate atria. Also obviously, there is a great variation of gastrointestinal tracts. Obviously, those
with two hearts, each with one heart in a thoracic cavity, have a better chance of survival.

One of the most difficult tasks is to present a classification of the morphology and anatomical arrangement of the heart or hearts in these twins. A simple general classification has been presented by Ambar:

2. Group B: Separate hearts, common pericardium.
3. Group C: Fused atia, separate ventricles.
4. Group D: Atrial and ventricular fusion.

With the above cardiac abnormalities, one must consider the other associated various organ systems, with either multiple or incomplete formation of the liver, intestines, and urinary systems.

The most common atrial malformations include a single atrium with atrial septal defects. The most common ventricular malformations are a single ventricle and large ventricular defects. Combined pulmonary arteries and aorta have not been reported. Of the others, any combinations of basic defects have been described: D-transposition, interrupted aortic arch, pulmonary stenosis and atresia.

Successful separation of thoracopagus twins in cases of conjoined heart is difficult. There has been only a single report of successful separation of a conjoined heart and in this instance it was conjoined atria. In a series of 13 surgeries on conjoined twins in The Children’s Hospital of Philadelphia, PA none of the patients with complex fused hearts survived even after sacrificing one of the twins. Cases of thoracopagus conjoined twins with normal separate hearts, common pericardium, anomalous systemic venous drainage, fused atria, and atrial septal defects have been successfully separated.

DIAGNOSTIC PROCEDURES IN CONJOIN TED TWINS

There are two phases of diagnosing the presence of conjoined twins: early in the prenatal period and then following delivery. Evaluation of the extent of pathological patterns of both the cardiovascular system and other involved organs that can potentially affect the question of infant separation and survival of both twins is necessary. For the fetuses, prenatal ultrasound has been used as early as 1960 and with more modern techniques, the use of transvaginal ultrasound may give the diagnosis as early as 7 to 14 weeks into the pregnancy.

Prenatal magnetic resonance imaging has better established the intricate shared multiple organs of the fetus. Magnetic resonance imaging has the advantage of being capable in twins to determine the systems of blood flow and the production of three-dimensional and multislice imaging, which can clarify the venous and atrial anatomy.

Early imagery allows proper counseling with regard to prognosis, management, and if indicated, termination of pregnancy. One interesting case diagnosed with a fetal echocardiogram was the condition never reported prior to the year 2000 of a single heart in conjoined twins diagnosed by the pumping of blood though the cord from the one infants single heart to create circulation in the noncardiac infant. The delivery of the two and the cutting of the cord would cause both infants to die. Surgery was performed by a caesarian section. Separation of the infants caused immediate death of the infant without the heart. At separation, the heart did not fit into the chest and protruded in a similar manner to an ectopia cordis. A rib cage was created from the chest wall from the twins tissues. The second infant was alive at 14 months at the time of this report.

ANESTHETIC MANAGEMENT OF CONJOIN TED TWINS

Perioperative management includes monitoring, airway and fluid management, ventilator support, and anesthetic medications. There are usually two teams of anesthesiologists. There are obviously difficulties in the positioning of the twins; body alignment is of utmost importance because of the ability to intubate because of the various anatomic positions and single or multiple airways, and only the use of airway masks if intubation is impossible. The management of the potential dead twin upon separation is too variable to explain. In a rare case in which one twin had a rudimentary heart and there was severe cardiac dysfunction in the possible normal twin, a method of intubation (an EXIT procedure [ex utero intrapartum treatment]) is performed immediately after the extraction of the fetus from the womb and separation of the dead twin. Prior to cutting of the umbilical cord, the surviving twin is either intubated or tracheostomy is performed.

In many of the twins, there is also marked difference in the twin’s circulatory systems, which present with different arterial blood pressures and atrial oxygen saturations.

SURGICAL SEPARATION

The surgical separation of conjoined twins is a delicate and risky procedure, requiring extreme precision and care. Decision to separate twins is a serious one. In 1689, Konig performed the first recorded separation of twins joined at the umbilicus with a ligature. There have been approximately 250 successful operations in which either one or both twins have survived. Of 47 pairs of surgically separated thoracopagus (omphagotoracopagus) twins with completely separate hearts only 42 survived (70%), and in 5 patients with only atrial connections, only 1 patient survived. In nine patients with both atrial and ventricular connections, there were no survivals. The site of the anatomical pericardial and/or cardiac conjoined areas is the most important consideration of a successful outcome.

Once separation is successfully achieved, tight closure of the pericardium and large abdominal and thoracic defects should be avoided. Silastic sheeting or the author’s preference of a thin polytetrafluoroethylene (PTFE) membrane should be used. Skin coverage of the separated areas is necessary. Skin flaps, as in ectopia cordis, can be used. In one case, the chest wall of the nonsurviving twin was used. Other surgeons have used a resin called “Cranioplastic” (commonly used by neurosurgeons, to create a “resin plate”). In other cases, siliconized rubber sheets, acrylic materials, and another resin mesh made of polypropylene mesh have been utilized. In the authors surgical management of ectopia cordis, a Gore-Tex® material (PTFE by Gore) was used to stabilize the chest, which was then covered by skin. This can be accomplished by raising skin flaps or use of the expired twins’ redundant skin, or use of tissue expanders if separation can be delayed for a few months.

ADDITIONAL CONSIDERATIONS FOR CONJOIN TED TWINS

Surgical separation of conjoined twins that results in the death of one of the twins raises complex legal, moral, ethical, religious, and financial issues.

Conjoined twins raise the ethical issue of “Is it justified to sacrifice one life to save another.” Ethical issues arise for each of the twins in which the following apply:

(a) There is a law of conduct, namely, “Thou shall not kill.”
(b) Natural law demands us not to harm anyone’s health, liberty, or possessions.
(c) The medical staff understands that life is sacred where every life is equally valuable. The problem lies in analyzing each of the twin’s different anatomies and chances of survival.
CONGENITAL WALL DEFECTS (ECTOPIA CORDIS)

Ectopia cordis is classified within the broad spectrum of congenital chest wall deformities, which include (1) pectus excavatum; (2) pectus carinatum; (3) Poland’s syndrome; (4) sternal cleft defects that include ectopia cordis; and (5) other miscellaneous conditions. Thus, reviewing ectopia cordis is necessary to understand sternal cleft defects and separate ectopia cordis from the other isolated sternal cleft anomalies. The embryological failure of the fusion of the sternal bars within this category create a complete or partial separation of the sternum.

The three categories of chest wall defects include:

- **Isolated sternal clefts**: These occur within the upper sternum and there is normal skin coverage; the heart is within the sternum; the pericardium is intact; the diaphragm is normal; and omphalocoeles do not occur. These patients seldom have intrinsic congenital heart disease.

- **Ectopia cordis**: The various forms of ectopia cordis are often associated with other midline defects, which include intrinsic cardiac defects, complete or partial absence of pericardium, omphalocele, and ventral diaphragmatic hernia.

DEFINITION OF ECTOPIA CORDIS

Dr. Anderson emphasizes that the term ectopia, which is derived from the Greek word “ektos,” classically means “away from a place” which could mean the displacement of the heart somewhere within the thorax, but this classical term is now commonly used to refer to the heart either partially or completely outside of the thorax.

Descriptions of ectopia cordis also vary from a complete absence of the sternum to a completely intact sternum in which the heart is located in the cervical area or dropped below the diaphragm.

The term ectopia cordis was first used and independently reported in 1706 by Haller and Martínez. Numerous cases were subsequently reported. Each of these cases had various descriptions of the ectopic heart. In Barardo, references to cases beginning with Martínez in 1706 to 1884 are listed with many giving to the location and position of the heart. Ravitch described a more extensive history of early cases.

The number of these cases increased to the point that many initial classifications were either discarded or added on to. These changes in classification occurred as an attempt to include all forms of ectopia cordis. Even today there is disagreement concerning the multiple classifications.

INCIDENCE

The incidence reported by Abbott in 1936 was 0.8% of all cardiac malformations, which is about 0.004% to 0.005% of the entire population.

However, in 1988, this very rare effect was reported to occur with an estimated prevalence of 0.079/10,000 births (5.5 to 7.9 million live births) and may occur more frequently in females.

The most recent statistics quoted in 1995 and 1996 are 5.5 to 7.9 per 1 million live births.

In evaluating this figure, one must account for cases remaining unreported. One must also account for the varying definitions of ectopia cordis and for incidence figures that include varying numbers of partial ectopia cordis. The purpose of this article is to discuss the *true* or *thoracic* ectopia cordis and its surgical correction.

Helen Tausig stated “little wonder that such a severe anomaly, which must completely alter the forces of stress and strain, is associated with some gross and bizarre cardiac anomaly. It is interesting, however, that this entity is not so rare among the lower animals, especially birds and it has also been described in cattle.

APPLICATION AND USE OF A PROCRUSTEAN CLASSIFICATION

The general classification of the anatomical types has now been well established.

The problem lies in the definition of true “ectopia cordis.” Anderson describes “Ectopia Cordis” as a “Procrustean” term. Procrustes was a mythological Greek God who offered hospitality to passing strangers, who were invited in for a pleasant meal and a night’s rest in his very special bed. Unknown to the guest was that he has to fit exactly into the bed, stretching him on the rack if he was too short for the bed and chopping off his legs if he was too long.

The difficulty is that many definitions include sternal clefts, Pentalogy of Cantrell, and other lower midline sternal defects in the general classifications of “ectopia cordis” in addition to the much more rare and difficult group with true exteriorization of the heart.

Garson writes: “About two hundred cases of Ectopia Cordis have now been reported, though many have had only a part of the heart exposed, and others have been simply cases of bifid sternum, the heart remaining within the thorax, albeit just beneath the skin. The latter cases should not be considered as a Ectopia Cordis.” Morales and his associates in 2000 reported four successful cases, including one of ectopia cordis and three of Cantrell’s Pentalogy. The first case described as a “thoracic ectopia cordis” is shown in the figure provided as a partial form of this entity with a small amount of ventricle and diverticulum exposed. The other three were described as “Cantrell’s Pentalogy,” in which the definition includes “the extrathoracic heart is covered by body wall, having a covering of either membrane or skin, therefore adding to the confusing description of ectopia cordis.”

In a 1996 article on ectopia cordis (in which all patients were listed as “Ectopia Cordis”), the authors state that of the 15 patients reported, there were only 5 survivors. They explain that Shamberger in 1990 presented these same patients; however, he did not discuss the details of the clinical course, cardiovascular anatomy, hemodynamics, and cardiac operations of these 15 patients in this earlier report.

However, in reviewing this earlier report, which was cited by the previous authors, Shamberger states, “We have reviewed our experience with sternal defects. Sixteen patients with sternal defects were identified. Of the five patients with thoracic ectopia cordis with a completely naked heart, all were fatal. Of the eight with a form of thoracoabdominal ectopia cordis with a covered heart, five of these patients survived. The three patients with a cleft sternum all survived.

A more complete description of “ectopia cordis” should allow the subgroup analysis of sternal defects including:

1. **Anatomical position of the heart.**
2. **Partial or complete forms of the ectopic heart.**
3. **The heart covered or uncovered by pericardium and/or skin.**
4. **The time of intervention (minutes, hours, days) after the infants birth.**
5. **Associated intracardiac or vascular anomalies.**
(6) Achieved surgical result (exterior or interior placement of the heart within the chest wall).
(7) Time of stages of repair.
(8) Subsequent surgical interventions.
(9) Current status of the patient.

PREFACE ON THE HISTORICAL ASPECT OF ECTOPIA CORDIS

Descriptive History of Ectopia Cordis

The earliest recorded report of a child with ectopia cordis was that of Neil Stensen in 1671. The name “Stensen” was translated by many as “Nicholas Steno” (1638 to 1686).

Stensen was a famous Danish physician and anatomist who first described an “embryo monster” in an abbreviated translation by Willius. Stensen and he observed the following anatomy: “the sternum was split and the heart, liver, with most of the intestine and right kidney have passed through the split in the sternum and thus were uncovered.” The anatomy of the heart clearly described what was to be a form of “Tetralogy of Fallot.”

EMBRYOLOGY IN THE DEVELOPMENT OF THE HEART AND CHEST WALL

When the embryo reaches its third week of life, it can no longer rely on nutrient and gas exchanges by diffusion. The cardiovascular system begins its formation within the developing embryo and the primary germ layers of ectoderm, mesoderm, and endoderm begin to form. The cellular sponge-like layer of mesoderm splits into splanchnic (visceral) and somatic (parietal) sheets (Fig. 108.9) (cross section of heart). The coelum divides into spaces for the heart and lungs. The heart, which is forming at the same time as the surrounding sternal element, originates from the visceral (splanchnic) layer including the diaphragm, pericardium, and epicardium. This early formation of the heart originates in a very cephalad position within the cervical region but reaches its position by flexing ventrally at about 2 to 3 weeks of development. The sternum arises from the parietal (somatic) layer as a pair of mesenchymal bars at about 6 weeks of gestation (Fig. 108.10). These paired mesenchymal bars, which have no connection with the lateral forming ribs, become fused at about 9 or 10 weeks of age. Above these two bars (cranially), another mass of mesoderm tissue in the midline, the future (primordial) manubrium, also called the pre sternum, is separated by other mesenchymal tissue on each side that eventually becomes the articulating junctions between the manubrium and the clavicle (The red arrow in this figure demonstrates the exterioization of the heart). As the sternal bars fuse together, they separate into three sternobranchial segments: the manubrium, the body, and the xiphoid. Ossification occurs later. Concurrently, the muscle formation of the diaphragm and pericardial cavity occurs by closure of the transverse septum (Fig. 108.11).

Conditions in which failure of the two sternal islands to come together without the failure of the heart to be properly placed are known as a sternal fissure, bifid sternum, sternal cleft, or sternal “fusion defects.” These usually occur without other intrinsic cardiac anomalies.
The conditions in which the heart is externally placed have been classified as the "cervical type." These occur when the heart becomes trapped above the sternal closure.

In true ectopia cordis, the failure appears to be secondary to the presence of the heart inserted primarily into this abnormal position. The other forms that will be discussed are the cervical, cervicothoracic, thoracic, thoracoabdominal, and abdominal types (Fig. 108.12).

It is extremely useful in these classifications to describe the outward (external) displacement of the heart as partial or total.

The Pentalogy of Cantrell is a thoracoabdominal type of ectopia within the classifications of the ectopic heart. Cantrell in 1958 described the syndrome, which consists of a malpositioned heart extruding partially or totally from the thorax with (1) defect in the midline supraumbilical abdominal wall (omphalocele); (2) defect in the lower sternum (sternal cleft, bifid sternum); (3) anterior diaphragmatic deficiency (diaphragmatic hernia); (4) defect of pericardium (communication with peritoneal cavity); and (5) intracardiac defects (most common are tetralogy of Fallot, diverticulum of the left ventricle, and ventricular septal defect). Many other cardiac defects have been reported.

These five conditions may not always be present in the complete form, thus should disqualify it as a true ectopia cordis. The heart may also have no intracardiac defects.

**PATHOGENESIS OF ECTOPIA CORDIS**

The etiology of ectopia cordis in which there is disruption of the midline fusion is unknown. Various theories have been proposed:

(A) Changes within the sequence of the gestational process of the formation of the heart and thorax include the following:

1. Premature rupture of the fetal membrane that surrounds all other membranes.
2. Premature rupture of the membrane that enlarges and lies next to the umbilicus.
3. Abnormal formation of the coelum.

(B) Ventral body wall defects—an abnormal closing of the ventral body wall over various organs:

1. Upon the heart—ectopia cordis.
2. Upon the abdominal wall—gastrochisis in which the infant’s intestines extrude from the body through a defect on one side of the umbilical cord.

(C) Genetic karyotype abnormalities include trisomy 18 (Edwards syndrome), Turner’s syndrome, testicular disorders, craniofacial disorders, and others.

(D) Teratogenic agents include the following:

1. Studies on chick embryos demonstrated that administration of hydrocortisone will cause a high incidence of ectopia cordis. Hydrocortisone injected into chicks on the fourth embryonic day caused a 84.8% incidence of ectopia cordis.
2. Antitumor agents such as platinum thiamine blue.
4. Aminopropionitriles that are used for the removal of scar tissue and also as antirheumatic agents used in veterinary medicine.

(E) Environmental factors include the following:

1. Gas emissions reported in South Asia from three-wheel autorickshaws in which compressed natural gas caused production of CO₂, CO, NO, and other nonmethane volatile organic compounds. Chick embryos treated with these gases produced four different types of ectopia cordis.
2. Genetic karyotypes—genetic testing of the patient and parents for chromosomal variations to determine the possible causative factors should be encouraged.
3. Some suggest that other environmental factors such as general air pollution, smoking, alcohol, and drugs could react with genetic patterns.

**CLASSIFICATION**

The most complete classification, given in 1962, includes five types, which are discussed in the following sections.
Cervical (Ectopia Cordis Cervicalis)

This extremely rare lesion occurs when in the unfolding process, the heart, which initiates in the cervical area, fails to descend from the embryologic submandibular region, and the sternal bars come together leaving the heart behind. Two infants have been described to live only hours after being born. Van Praagh in 1983 dismissed this lesion as occurring only in stillborn.

Cervicothoracic (Ectopia Cordis Cervicothoracalis)

The heart is partially in the neck, with an upper sternal cleft defect. This form is extremely rare; however, Leca reported 18 cases of this type, some of whom had intact sternum.

Thoracic (Ectopia Cordis)

This may be described as the heart protruding from the defective sternum partially or completely. Although the heart completely exposed can be considered true thoracic ectopia cordis, it is difficult to know the exact incidence of this defect. It has been described as occurring in 36%, 58%, and 62% of reported cases.

Thoracoabdominal (Ectopia Cordis Thoracoabdominalis, Ectopia Cordis Ventralis, L'ectopia-Abdominale, Cantrell's Pentalogy, Cantrell's Pentad)

Cywes in 1967 believed this type not to be a true ectopia cordis. The first successful repair of “a thoracoabdominal type” was by Wieting in 1912.

It has been described as varying from an open “incomplete expression” to a severe expression in which the complete form may include at least four of the five defects described by Cantrell. In many cases, only a small portion of the heart is not covered by skin, and even Cantrell stated that the heart appears to be extrathoracic. Even though the heart appears to be extrathoracic, it is truly adjacent to other thoracic elements. One can question whether the presence of an omphalocele places the ectopic heart within the classification of thoracoabdominal rather than thoracic. Hornberger, in 1996, reported 13 cases of ectopia cordis, of which four were described as the thoracic type. Yet, three of the four had an omphalocele. We would classify these three as an “incomplete” expression of the thoracoabdominal type.

Abdominal (Ectopia Abdominalis)

In this form, the heart lies totally within the abdomen with a diaphragmatic defect. In 1809, Cullerier reported a case in which the heart was displaced along with its pericardium into the abdomen through an anterior diaphragmatic displacement into the cavity of an absent left kidney. This defect relates to the incomplete formation of the transverse septum. Although from 11% to 13% of ectopia cordis cases are reported as abdominal thoracic ectopia cordis, Van Praagh insists that the heart was not within the abdominal cavity but displaced downward in communication with the thorax and recommends that this form be deleted from the classification of ectopia cordis.

The diagnosis, if not made by fetal echocardiography, is extremely evident on inspection of the infant at birth. It is essential to determine any intracardiac defects of the infant by sterile careful epicardial ultrasound if not previously detected by prenatal ultrasound. Cardiac catheterization is not necessary for surgical correction. Correction or palliation of any major intracardiac defects is imperative prior to enclosing the heart in the body cavity or skin. Genetic karyotyping maybe performed by chorionic villus sampling for abnormal chromosomal complements; however, this has not always correlated with the diagnosis of ectopia cordis. Finally, prior to surgery, chest and abdominal radiographs should be performed to judge the volume of these cavities. Once the diagnosis of ectopia cordis has been confirmed prenatally, it is recommended if possible that a cesarean section delivery be performed.

SURGICAL CORRECTION

Successful correction must include the following:

1. Prenatal diagnosis and delivery by cesarean section.
2. Immediate coverage of the heart with the patient’s own skin.
3. Palliation and/or repair of any congenital defects at presentation.
4. Placement of the heart within the thoracic cavity.
5. Delayed repair of the thoracic cage defect.

Prenatal Diagnosis and Delivery by Cesarean Section

Vaginal delivery might prolong compression of the heart or rupture of the atrial diverticulum or omphalocele and can cause damage to the herniated abdominal viscera, if present.

Immediate Coverage of the Naked Heart with the Patient’s Own Skin

As previously stated, some partial forms are adequately covered with skin. In these patients, there is adequate time to attend to the remaining factors listed below. If not, then the heart should be covered with sterile dressing after applying Betadine or other antibacterial agents to the skin.

If mobilization of the skin is not possible, rotational flaps have been used with split-thickness grafts in the absent lateral portion. Hochberg, in 1993, used Gore-Tex temporarily with tissue expanders bilaterally to stretch the tissue and then within 48 hours raised bilateral myocutaneous flaps. Seven months later, the Gore-Tex was removed (we would recommend it to be left in). The native tissue was reapproximated in the midline and skin grafts applied to the lateral chest and abdominal walls. Tissue expanders were also used in 1978 to stretch the skin prior to covering this defect. Other alloplastic materials, such as methyl methacrylate, and Marlex composite struts were used in the sternal defect and then covered with bilateral muscle flaps. Silastic membranes have also been used.

Repair of Intracardiac Defects

Only a few cases of complete intracardiac repair have been reported in the literature. These were in cases of partial ectopia cordis. A double-outlet right ventricle was repaired with a Dacron patch and the child’s heart returned to the thorax. However, the child died of sepsis on the 12th postoperative day.

Hornberger in 1996 reported four infants with intracardiac defects. Two thoracoabdominal types of these had severe-to-moderate pulmonary hypoplasia. Both infants died within 48 hours. A third infant with a thoracic ectopia cordis and a tetralogy of Fallot had several attempts to return the heart into the left pleural space and cover the heart with a skin flap and the large omphalocele with a silastic membrane and Teflon mesh, but died within 48 hours. The fourth infant with thoracoabdominal ectopia cordis had a double-outlet right ventricle, ventricular septal defect, and pulmonary atresia and received a Blalock-Taussig shunt. The omphalocele and skin defect were repaired. This infant died at 5 weeks of life with candidal sepsis and pericarditis.

This author’s second case of total thoracic ectopia cordis presented days after
delivery at another hospital. This child had a double-outlet right ventricle and pulmonary atresia. A single-stage repair was performed and the heart was successfully returned into the thoracic area. One month later, the child died of overwhelming sepsis. Litwin in 1998 operated on a similar child who died of sepsis several months later. Repair of intracardiac defects has been mentioned in the repair of thoracoabdominal ectopia cordis, but few of these were described in detail.

**Placing the Heart within the Thoracic Cavity**

There have been numerous methods described for enlarging the thoracic cavity to admit the heart. Division and dropping of the anterior diaphragm to attach it inferiorly to the lower part of the defect has been done to create a larger space. The author has done this successfully in three cases. Incision of the costal cartilages and division of some of the lower ribs were done in all three of the author's cases. This maneuver will not cause anterior bulging but rather lateral expansion of the chest wall.

Aytac in 1975 reported performing a left lower lobectomy to increase the intra-thoracic space. When the heart became brachycardic, he then performed a left pneumonectomy. The patient lived 20 hours after surgery but then the heart arrested. At autopsy the heart showed a hypoplastic left ventricle, transposition, and anomalous coronary arteries. Also suggested to provide more space was resection of the left lobe of the liver and lengthening of the inferior vena cava to put the heart back into the chest, but no successes were reported.

**Repairing and Closure of the Thoracic Cage Defect (Delayed)**

These maneuvers are usually performed in cases either with staged repair of the ectopic defect or in cases where the protrusion of the heart is not pronounced. A partial ectopia cordis was repaired and reported by Sabiston in 1957, where the costal cartilages were divided in an oblique manner and allowed to slide to the midline and stabilize the anterior thoracic wall.

Nine months after the initial repair of an ectopic heart by the use of large skin graft flaps, Dobell reported the use of autogenous bone segments from alternating ribs to repair the sternum. With the authors' three cases of total ectopia cordis in which the heart was successfully brought into the thoracic cage without difficulty, a flask-shaped piece of Gore-Tex was sewn to the edges of the widely open sternum. This was followed by skin closure above the Gore-Tex. The second case did not survive due to the tissue swelling from a severe infection, caused by the delay of repair from the time of the infant's birth.

Finally, if it is not possible to create an enclosure of the heart within the chest cavity, it is advised that the skin be mobilized to cover the heart that is extruding from the chest wall and to use an artificial device or a curved external shield fashioned to protect the heart immediately below the skin. It is, however, important to understand that even in the author's single-stage repair with the chest appearing normal, a protective vest should be used to protect the heart until full growth is achieved. At that time, the use of ribs taken alternatively from both sides of the chest can be inserted to protect the heart.

**THORACIC ECTOPIA CORDIS**

If described well, this category represents the true form of “ectopia cordis.” Again the reader is cautioned to read the description of the anatomy with the understanding of partial or total protrusion of the heart. Morello, in a literature review, reported 239 cases of ectopia cordis, and states that most of these cases were of the abdominal and thoracoabdominal types, in which the majority of these cases were “Cantrell’s syndrome.” Morello then states that only 91 infants had true ectopia cordis but did not distinguish whether these “true” thoracic cases were partial or total ectopia cases.

Many of these were reported as stillborn, whereas others were premature and many survived only a few hours. Only one of the children with major intracardiac defects survived. However, this child was classified as a true ectopia cordis and grouped with three others as thoracic types of ectopia cordis. Three of the four children had an omphalocele, which the authors would have classified as thoracoabdominal cases. It is assumed that there are a number of cases of ectopia cordis that have not been reported in the referred literature.

**THORACOABDOMINAL ECTOPIA CORDIS WITH THE INCLUSION OF CANTRELL’S SYNDROME**

This condition can be divided into complete and incomplete forms. Partial exposure of the heart and technical advances as previously described render this type more easily repaired and survival more frequent than in true ectopia cordis. Shamberger lists eight methods of repair of thoracoabdominal ectopia cordis in 27 patients. All these patients were repaired with variations similar to the repairs described for true ectopia cordis. Some required secondary epithelialization of the omphalocele or repair of the abdominal wall defect.

EDITOR’S COMMENTS

Very few textbooks of congenital heart surgery include chapters on ectopia cordis and conjoined twins. Both of these defects are complex and rarely have successful surgical outcome. As noted by Dr. Amato, the classification of ectopia cordis is quite confusing in the literature. I believe that the majority of what has been classified as ectopia cordis actually involves chest wall defects and abdominal defects, which could largely be considered variations of sternal cleft and omphalocele. Pentalogy of Cantrell is usually a distal sternal cleft, which has associated cardiac anomalies and ventricular diverticulae and is usually associated with a superior omphalocele. These defects can generally be repaired with early placement of more rigid covering over the heart and then eventual closure of the sternum or creation of an anterior sternal plate with rib grafts or extensions. These defects have a relatively higher success rate with complete repair and are quite different from true ectopia cordis, which I consider to be a heart that is exposed anterior to the sternum and without a skin covering. These defects have a very high risk for surgical repair primarily because of sepsis and the difficulty in relocating the heart truly into the mediastinal space. Most of these defects should have initial repair immediately to try to prevent infection with relocation as best as possible with diaphragm repositioning with some type of skin coverage and cardiac protection.

Sternal clefts are often considered in the category of ectopia cordis, but these defects are generally easily repaired and do not have the same implication for morbidity and mortality as true ectopia cordis. The incidence of these conditions is extremely low and, therefore, few surgeons have extensive experience with operative repair. Nevertheless, with the techniques described in this chapter some successes can be expected, especially in the more minor defects. It is important to coordinate repair of lower sternal and abdominal defects with general pediatric surgeons so that the attempt to reposition the abdominal contents in the abdomen does not cause additional compression of the diaphragm, which can limit the amount of room in the chest for relocation of the heart. It may be necessary to relocate the heart initially with a silo for the abdominal organs and then gradual closure of the abdominal defect to allow the heart to reposition. Care must be taken when repositioning the heart in the chest to avoid compression of other structures. We have seen an instance where right ventricular outflow tract obstruction has developed from abnormal positioning of the heart in the mediastinum and also limitation of flow through a left superior vena cava to the coronary sinus in another patient.

Conjoined twins are an extremely difficult subgroup of patients to deal with. The vast majority of thoracopagus conjoined twins have hearts that cannot be separated without demise of one or the other twin and often the twin that might be most likely to survive from an abdominal organ standpoint has the most limited cardiac structure. Very rare cases of separation of twins joined at the heart have been reported and most have been unsuccessful. We have seen situations where hearts are joined by a small bridge of tissue at the atrium, which has permitted separation even though the patients had a common pericardium. In this situation, both hearts were separate but there was a bridge of tissue at the base of the atrium connecting the two. Interestingly, the patients had both identical heart rates due to the tissue, which acted as a bypass tract from one atrium to the other. When medications were given to one twin, the other twin’s heart rate responded in a similar manner. As soon as the twins were separated surgically, the heart rates became independent.

In the majority of cases of separation of conjoined twins at the thorax and abdomen, chest reconstruction and respiratory insufficiency are the primary cause of morbidity and mortality. These patients often require tissue expanders prior to separation to allow skin coverage of the chest but the lack of significant portions of the rib cage and sternum make respiratory function inefficient. Creation of more rigid thoracic shells may be necessary in some cases to allow for adequate ventilation and many patients will require tracheotomy and long-term ventilation during extensive chest wall reconstruction.

operative principles for, 679–680
operative techniques for, 680–683, 681f–684f
pathology of, 677
pathophysiology of, 677
postoperative care for, 683–684
pulmonary thromboendarterectomy for, 679
reperfusion response management and, 684
surgical complications of, 683–684
Chyle, composition of, 276f
Cone resection, with electrocautery, 83f
Congenital heart disease
anatomy of, 688–698
aortic arch obstructions and, 753–754
aortopulmonary shunts for, 764–771
atrial arrhythmias in, 643
atrial septectomy for, 775, 776f
balloon angioplasty and, 753–756
balloon valvuloplasty for, 749–750, 751f
Blalock-Taussig shunt for, 756f, 764–769, 765f–768f
branch pulmonary artery stenosis and, 754–755, 755f
chamber/valve/vessel abnormalities and, 692–698
classification of, 688–698
accuracy in, 689
aims/principles of, 688–689
atrioventricular alignments and, 692, 692f–693f
cardiac segment and, 689–692
intersegmental alignments and, 689, 692–698, 692f–697f
organization of, 688
precision in, 689
quantification, 689
segmental approach to, 689
segmental notation and, 690–692
ventricular loop and, 689–690, 690f
ventriculoarterial alignments and, 689, 692
visceral arterial situs and, 690, 691f
conduits/shunts, 756, 756f
device closures and, 757–758
echocardiographic evaluation of, 700–714
embolizations and, 756–757
endoventricular stenting and, 753–756
imaging children with, 702–706
abdomen view of, 702
atria/ventricles, 687–688
atrioventricular connection, 705–706
situs and, 702–705
venous connections and, 712
intraoperative transesophageal echocardiography/postoperative imaging and, 713–714
miscellaneous palliative procedures for, 775
modified Blalock–Taussig shunts for, 756f, 765–769, 767f–768f, 767f
palliative operations for, 764–776
Potts shunt for, 770–771, 771f–772f, 771f
pulmonary artery band for, 759f, 771–775, 773f
pulmonic valve stenosis/atresia and, 749–750
retrievals and, 758–759
septostomy procedures for, 748
syntax for diagnosis, 698
systemic pulmonary veins and, 755–756
transcatheter therapy for, 746–760
hemodynamic assessment and, 746–760
Waterston/Cooley shunt for, 769–770, 769f–770f, 769f
Congenital wall defects
ectopia cordis, 1186
isolated sternal clefts, 1186
Congenitally corrected transposition of great arteries (ccTGA), 708, 709f, 954–960, 1077–1078
anatomic repair for, 957–960
anatomy of, 954
background on, 954
classical repair of, 955
diagnosis for, 954–955
embryology of, 954
palliative operations, 955
subpulmonary obstruction repair for, 956–957
surgical results of, 959–960
surgical treatment for, 955–957, 956f–957f
ventricular septal defects closure for, 955–956
Congenital mitral valves, pediatric mitral valve repair and, 1112–1113
Conjoined twins

positioning/approach for, 810f
reduction of, 811f
Intercostal arteries, reimplantation of,
581–582
Intercostal muscle (ICM) harvesting of, 61f
Intercostal space (ICS), 112
Internal shunt system for chylothorax, 279f
in position, 280f
Interposition graft, aortic coarctation and,
854
Interrupted aortic arch, 861–870
anatomy of, 861
with aortic valve hypoplasia/atriesia,
864–865
classification of, 862f
clinical presentation of, 861–862
diagnosis of, 861–862
early/late mortality with, 869t
neonatal cardiovascular conditions with,
862f
operative management of, 862–864
postoperative management for, 867
repair of aortopulmonary window, 842–843
with single ventricle, 866–867
special circumstances of, 864–867
survival for, 867–868
with TGA, 866
with truncus arteriosus, 865, 866f
repair of, 915–917
Intervertebral foramen, first thoracic nerve root from, 322f
Intracardiac defects, closure procedures for, 756
Intramural hematomas, retrograde extensions of, acute Type B aortic dissections, 572
Intraoperative cerebral monitoring, neurologic injury prevention and, 394
Intraoperative transesophageal echocardiography/postoperative imaging, congenital heart disease and,
713–714
Intrathoracic lymphatics anatomy of, 304
drainage of, 304–307
Intonphoresis, 328
IPF. See Idiopathic pulmonary fibrosis
Ischemic mitral regurgitation (IMR), 431–439
Carpentier–McCarthy–Adams IMR etiologic ring for, 433f, 436
Carpentier’s functional classification of, 432f
late outcomes for, 438
mild/moderate, 434
mitral valve exposure and, 435
mitral valve repair and, 435–436
myocardial protection and, 443–435
operative mortality for, 437–438
peroperative considerations for, 434
residual, 437
severe, 434
surgical approaches to, 434
surgical indications, 434
type II clinical presentation of, 438
diagnosis of, 438
medical/surgical treatment for, 438
pathophysiology of, 438
surgical results for, 438
undersized remodeling ring annuloplasty for, 435–436
Ischemic mitral valve repair, 431–439
Ischiopagus, 1183, 1184f
Isolated aneurysms, 590
Isolated aortopulmonary window, 842–843
Isolated atrial fibrillation, minimally invasive epicardial ablation and, 648
Isolated left superior caval veins, 781–782
IVC. See Inferior caval vein
Jackson esophagogastroplasty, 6f
Jejunal interposition, 215–216
long-segment, 215
long-segment reconstruction and, 215–216
Juxtaductal coarctation, 850f
J-Wire, 487
K
Ketorolac, 338
Left anterior oblique view
Left anterior oblique view (LAO), 706f, 711f–713f, 749f
Left atrial anastomosis, lung transplantation and, 237f
Left atrioventricular valve competence, AVSDs and, 898–901
Left atrium, left superior caval veins drainage into, 782
Left inferior pulmonary vein, view of, 65f
Left internal mammary artery grafting, coronary artery anomalies and, CABG for, 1058
Left internal mammary artery (LIMA), 375, 403f, 494, 498f, 500f, 515, 1058
Left lower lobe sleeve, 56–59
Left main bronchus, left main pulmonary artery and, 55f
Left main pulmonary artery, left main bronchus and, 55f
Left pulmonary artery anomalous development of, 802f
Left pulmonary vein, view of, 58f
Left pulmonary artery, right superior caval veins to, 782–784, 784f
Left pulmonary hilum, view of, 54f
Left-sided pneumonectomy, surgical procedure for, 64–65
Left-sided pulmonary resections, 53–59
Left-sided resections, 73–75
Left subclavian-to-left coronary artery anastomosis, coronary artery anomalies and, CABG for, 1058
Left superior caval veins anatomy of, 780
drainage to left atrium, 782
occlusion of, 780
Left superior pulmonary vein, view of, 65f
Left thoracoabdominal approach, to esophagectomy, 179
Left thoracotomy, 199, 771f, 772, 773f, 851f–854f
esophageal mobilization in, 163, 193f
Left-to-right shunt lesion, hemodynamic assessment, of patients, 747
Left upper lobe resection, 53–58
Left upper lobe sleeve resection, 73–75
view of, 75f
Left ventricular assist devices (LVADs), 532, 1057
preoperative evaluation for, 533–534
Left ventricular end-systolic volume index (LVESVI), 527
Left ventricular function, in normal hearts, 371f
Leaflet advancement technique, for mitral valve repair, 409–410, 409f–410f
Leaflet advancement technique, valvular repair, 328
Left anterior oblique view (LAO), 706f, 711f–713f, 749f
Left atrial anastomosis, lung transplantation and, 237f
Left atrioventricular valve competence, AVSDs and, 898–901
Left atrium, left superior caval veins drainage into, 782
Left inferior pulmonary vein, view of, 65f
Left internal mammary artery grafting, coronary artery anomalies and, CABG for, 1058
Left internal mammary artery (LIMA), 375, 403f, 494, 498f, 500f, 515, 1058
Left lower lobe sleeve, 56–59
Left main bronchus, left main pulmonary artery and, 55f
Left main pulmonary artery, left main bronchus and, 55f
Left pulmonary artery anomalous development of, 802f
Left pulmonary vein, view of, 58f
Left pulmonary artery, right superior caval veins to, 782–784, 784f
Left pulmonary hilum, view of, 54f
Left-sided pneumonectomy, surgical procedure for, 64–65
Left-sided pulmonary resections, 53–59
Left-sided resections, 73–75
Left subclavian-to-left coronary artery anastomosis, coronary artery anomalies and, CABG for, 1058
Left superior caval veins anatomy of, 780
drainage to left atrium, 782
occlusion of, 780
Left superior pulmonary vein, view of, 65f
Left thoracoabdominal approach, to esophagectomy, 179
Left thoracotomy, 199, 771f, 772, 773f, 851f–854f
esophageal mobilization in, 163, 193f
Left-to-right shunt lesion, hemodynamic assessment, of patients, 747
Left upper lobe resection, 53–58
Left upper lobe sleeve resection, 73–75
view of, 75f
Left ventricular assist devices (LVADs), 532, 1057
preoperative evaluation for, 533–534
Left ventricular end-systolic volume index (LVESVI), 527
Left ventricular function, in normal hearts, 371f

diagnostic considerations of, 575–576
hemodynamic instability control, during aortic cross-clamping, 578–579
incision/operative exposure in, 577–578
operation completion for, 582
spinal cord preservation and, 579–580
Thoracoabdominal incision, 38, 38f, 174, 600
anastomotic complications of, 97–98
postoperative management of, 96–97
Tracheal resection
anastomotic complications of, 97–98
hemorrhage and, 93f
postoperative management for, 96–97
Tracheobronchial angle, exposure of, 57f
Tracheobronchial tree, 2, 4f
Transapical ventriculotomy, 661, 661f
Transatrial closure, of VSDs, 833f
Transaxillary approach, dorsal sympathetic chain, stellate ganglion and, 320
Transcatheter aortic valve replacement, 385, 479–491
Transcatheter aortic valve replacement (TAVR)
annulus sizing criteria, 481f
current transcatheter heart valve technology, 481–482
Frailty Index, 480, 480f
pathophysiology, 479
patient selection and screening, 479–480
preoperative evaluation, 480–481
risk stratification, 479–480
surgical technique
anesthesia, 482
heart valve team approach, 482
preparations, 482–483
transfemoral approach
balloon aortic valvuloplasty, 484–485, 487
clinical outcomes, 487–489
closure, 487
PARTNER Trial Cohort A clinical outcomes, 488f
representative transesophageal images, 469f
transapical and vascular access, 486–487
transapical approach, 486
valve deployment, 485, 487
valve positioning and deployment., 468f
vascular access, 483–484
vascular access site closure, 485–486
Transcatheter heart valve (THV) replacement, 479
Transcatheter therapy
for congenital heart disease, 748–760
hemodynamic assessment and, for congenital heart disease, 746–760
Transcervical thymectomy (TCT), 134–138
Transclavicular approach, 323–325
Transcranial Doppler (TCD), 394, 584, 802
Transdiaphragmatic fenestration, diaphragmatic surface and, 118f
Transhiatal esophagectomy, 157–171
cervical phase of, 160–161
introduction to, 157
operative technique for, 157–168
postoperative care for, 169–170
postoperative complications for, 169–170
preoperative assessment for, 156, 169
preparation for, 157–158
results of, 168–170
Transplant for congenitally corrected
transposition of great arteries
pediatric heart transplantation and,
1074–1082
Transposition of great arteries (TGA), 710, 861, 866
anatomy of, 937–938
arterial repair and, 940–944
atrial repair, 940
background on, 937
clinical features of, 939
management of, 939
operative intervention of, 940
palliative operations of, 940
pathophysiology of, 938
Rastelli operation on, 944, 946–947
surgical correction for, 940–944
surgical repair history, 939–940
surgical repair results, 930–936
Transsthoracic esophageal resection/
reconstruction principles of, 173–176
surgical technique for, 173
Transsthoracic Nissen fundoplication, 351
Transsthoracic partial fundoplication,
153–154
Transsthoracic repair, 352–353
Transsthoracic total fundoplication,
152–153
Transventricular closure, of conoventricular
defect, 834f
Tricuspid atresia, single ventricle and,
708–709
Tricuspid regurgitation evaluation/operative
intervention of, 940
Tricuspid valve replacem ent, pediatric,
450–451
Truncal valve repair/replacement, truncus
arteriosus with, 917–918
Truncus arteriosus, 711
alternative repair, 914–915
background on, 910
diagnosis of, 911
interrupted aortic arch with, 915–917
pathophysiology of, 910–911
postoperative care for, 919, 921
surgical technique for, 911–919
truncal valve repair/replacement with,
900–902
van Praagh classification, 894t
Tube graft placement, 581
Tumor(s). See also specific cancers; specific
neoplasms; specific tumors
cardiac, 664–669
diaphragm, 272
on paravertebral fascia, 321
primary, 43
subclavian artery dissection from, 322
Tunnel repair, of DORV, with subaortic
ventricular septal defect, 925–926
“Two-staged” approach, 515, 516f
Type II paraesophageal hernias, 341
Type III paraesophageal hernias, 341
Type IV paraesophageal hernias, 341
U
Ultrasound frequencies, ultrasound physics/
aplications and, 700
Ultrasound physics/applications
Doppler principle and, 700–701
modified Bernoulli theorem and, 701
principles of, 700–701
ultrasound frequencies and, 700
Undersized remodeling ring annuloplasty, for
type IIIb, ischemic mitral regurgitation, 435–436
Unidirectional cavopulmonary shunts,
1008–1009, 1008f, 1009f
V
VA database. See Veterans Affairs database
VADs. See Ventricular assist devices
Valvular aortic stenosis
in neonate/infant, 871–875, 872f
in older child, 872–873
Valve regurgitation, pediatric aortic valve
repair and, 1119–1120
Valvular tags, pediatric mitral valve repair
and, 1105
Van Praagh classification, for truncus
arteriosus, 711–712
Vascular connections, closure procedures for,
756–758
Vascular rings
classification of, 797–810, 803f
complete, 797–804
anatomy of, 797
embryonic development of, 799–800
requiring median sternotomy, 803
requiring right thoracotomy, 803
VATS. See Video-assisted thoracic surgery
Velocity mapping, with cardiac magnetic
resonance imaging, 703f, 721f
Venae cavae, 693–694
Venous connections
cardiac magnetic resonance imaging and,
preoperative/postoperative, 732–733, 732f
Venous embryology, schematic of, 781f
Venous sinus valves, anomalies of,
785–786
Ventricular assist devices (VADs), 532–540,
1157–1165
background on, 532–533
patient selection for, 533–534
postoperative care for 540
potential complications for, 539–540
preoperative evaluation for, 533–534
surgical procedure for, 535–538
Ventricular septal defects (VSDs),
829–836
aortic coarctation and, 857
cardiac/noncardiac pathologic conditions
associated with, 831
characteristics of, 830
classification of, 829–830
clinical presentation of, 544
closure, for ccTGA, 955–956
common incisions for, 832f
infundibular septum and, 710f
myocardial infarction complications,
544–548
natural history of, 544
operative technique for, 545–548
operative timing of, 544–545
pathogenesis of, 544
patient characteristics of, 830
pulmonary vascular resistance and,
830–831
surgical results for, 947–953
survival of, 548
transatrial closure of, 833
view of, 840f
Ventricular septum, 694–698, 697f,
707–708
Ventricular tachycardia (VT), 66
Ventriculoarterial alignments, 694f
Ventricular body resection
of superior sulcus tumor, 322
for superior sulcus tumor resection, 321f, 322, 322f
Veterans Affairs (VA) databases, 380
Viacor’s PTMA coronary sinus device, 441.

repair
Vicodin. See Hydrocodone
Vicryl suture, 104, 170f
Video-assisted thoracic surgery (VATS), 108, 110, 111
Video-assisted thoracoscopic pulmonary
resections, 108–114
contraindications for, 108, 110
indications for, 108, 112
morbidity/mortality after, 110
outcomes of, 110
wedge resection with, 109–110
Vigorous achalasia, 199, 202f
Vocal cord dysfunction, pneumonectomy
and, 65–66
Volume-rendered object (VRT), 717
VRT. See Volume-rendered object
VSDs. See Ventricular septal defects
VT. See Ventricular tachycardia

Index
W
Warm blood cardioplegia
for myocardial protection, 370
solution contents, 373f
Waterston anastomosis
construction of, 770f
preparation of, 769f
takedown of, with cardiopulmonary
bypass/PTFE patch, 770f

Wedge resection
of apical blebs, 121f
using linear stapler, 82f
with VATS, 82

X
Xiphoid process, 337
Xiphopagus, 1183, 1184f

Z
Zenker’s diverticulum, 222–226,
223f, 224f
barium esophagram of, 223f
clinical presentation of, 222
diagnosis of, 222
diagnostic surgical technique for,
223–224
preoperative management of, 223
surgical results for, 225–226
